Finally, as NIH considers new approaches for assessing and incentivizing scientific impact, it is essential that evaluation frameworks reflect the full breadth of contributions that advance biomedical research and improve human health. The considerations outlined above underscore the need for a balanced, flexible, and context-sensitive approach to impact assessment that recognizes the diverse pathways through which research generates scientific, clinical, economic, and societal value. Washington State University (WSU) further emphasizes that expert peer review should remain a central component of any assessment framework and should be integrated with both quantitative and qualitative indicators. Reviewers should possess the scientific expertise and contextual understanding necessary to evaluate the significance of research contributions, including their methodologies, hypotheses, and intended outcomes. This is particularly important for interdisciplinary, foundational, community-engaged, and emerging areas of research, where conventional metrics may not adequately capture scientific significance, long-term influence, or future potential. No single metric can fully reflect the value of scientific contributions, and excessive reliance on any one measure risks creating unintended incentives, narrowing research priorities, and overlooking important dimensions of research excellence.

Accordingly, WSU recommends that NIH adopt a comprehensive, multi-indicator framework for assessing scientific impact that recognizes contributions across multiple dimensions, including rigor and reproducibility, data and software sharing, mentorship and workforce development, collaboration and team science, entrepreneurship and translation, foundational scientific exploration, and broader public impact. Metrics should inform, rather than replace, expert judgment and should recognize the many ways biomedical research advances knowledge and benefits society. Evaluation systems should remain adaptable to differences in discipline, institution type, career stage, and research context, while avoiding overly prescriptive measures that may discourage innovative, high-risk, exploratory, or community-focused research. NIH should also carefully monitor implementation to identify and mitigate unintended consequences, including increased administrative burden, incentives that favor easily measurable activities over meaningful scientific contributions, disadvantages for certain disciplines or institution types, and disincentives for high-risk or long-term research. A balanced framework that integrates multiple forms of evidence, relies on existing data sources whenever possible, and incorporates ongoing evaluation and refinement would provide a more comprehensive and fair assessment of scientific impact, encourage diverse pathways to success, and better align researcher incentives with NIH's mission to advance rigorous, collaborative, transparent, innovative, and publicly beneficial biomedical research.

Thank you for the opportunity to provide these comments. Washington State University appreciates NIH's leadership in developing a more comprehensive approach to measuring and rewarding scientific impact and looks forward to continued engagement on these important issues.

Sincerely,

Kim Christen, PhD
Vice President for Research
Washington State University

Response to NIH Request for Information on Measuring and Rewarding Scientific Impact
NIH Notice Number: NOT-OD-26-087
Date: August 18, 2026
Email: govrelations@broadinstitute.org

I. Rigor and Reproducibility

Rigorous methodologies and open data sharing are foundational parts of the Broad Institute's mission. We welcome the NIH Director's focus on prioritizing agency-wide reproducibility and elevating scientific standards across federally funded research. The recommendations below outline how NIH can build on these established practices by leveraging shared computational infrastructure, encouraging secondary data analysis, and establishing clear frameworks for causal inference.

a. **Embed research integrity into lab culture**: Encourage standardized onboarding materials and clearly documented expectations for data management and intra-laboratory reproducibility.
    i. Maintain standardized onboarding documentation that outlines laboratory norms, expectations, and procedures for intra-laboratory reproducibility.
    ii. Implement standard operating procedures (SOPs) for routine lab-level data checks, error logging, and protocol verification before publishing.
b. **Promote digital data tools and internal quality checks:** Support the adoption of digital tools, standardized review practices, and internal quality checks to strengthen scientific rigor:
    i. **ELN adoption & review SOPs**: Encourage the use of Electronic Lab Notebooks (ELNs) that incorporate NIH Data Management and Sharing (DMS) guidelines and support documented data management and intra-lab reproducibility practices. Ask institutions to report on the use of ELNs and the maintenance of standard operating procedures (SOPs) for reviewing data and handling identified issues.
    ii. **Data sharing in shared computational infrastructure**: Encourage researchers to share detailed methods, protocols, and supporting data to maximize the reach and impact of research findings. Robust data sharing facilitates the reuse of research outputs, improves reproducibility, accelerates new insights, and allows other investigators to build seamlessly on prior discoveries. To fully support this, investing in shared computational infrastructure for storing and sharing/analyzing data can ease technical barriers and ensure these research assets can be fully leveraged across the scientific community.
c. **Establish multi-track mechanisms to validate high-Impact research:** Without systematic validation, researchers risk investing time and federal resources into building on results that are incomplete or unrepeatable. To ensure foundational science is robust

before the field expands on it, the NIH should support validation through two complementary tracks:

i. **Computational validation (secondary analysis)**: Provide dedicated funding for computational scientists to re-evaluate high-impact, publicly deposited datasets using alternative statistical pipelines, novel algorithms, or cross-study cohorts to verify analytical robustness.

ii. **Laboratory validation (experimental replication)**

1. Direct replication: Establish dedicated funding mechanisms for independent labs to repeat and report on high-impact, foundational experiments conducted elsewhere.
2. Foster author collaboration and SOPs: Pair replicating labs with original study authors to troubleshoot methodological nuances, cross-train, and encourage the publication of open-access, standardized operating procedures (SOPs) for the broader scientific community.

II. Data, Software, and Model Sharing

At the Broad Institute, the open sharing of data, software, and predictive models is fundamental to accelerating discovery and enabling peer validation. One of the most efficient and scalable paths to reproducibility is ensuring primary research outputs are AI-ready, standardized, and sustainably funded. Recognizing these assets as core scientific outputs across NIH funding and institutional evaluation will ensure the broader community can seamlessly access, evaluate, and build upon prior discoveries. To build a sustainable ecosystem for data reuse, NIH should focus on the following strategies:

a. **Grant review recognition**: Encourage grant applications to include a summary of the investigator's history of sharing data, software, and resources, if available, and consider this information as part of grant review. This commitment should be evaluated as a positive indicator of scientific impact during peer review.

b. **Sustainable funding models**: Establish direct-cost mechanisms and allowable budget lines for long-term data curation, software maintenance, and storage. Supporting these needs through shared computational infrastructure prevents "data graveyards," relieves individual labs of long-term hosting burdens, and helps ensure data generated with NIH support remains readily available for research.

c. **Academic promotion criteria**: Encourage research institutions to formally recognize the development, maintenance, and sharing of open-source datasets, models, and tools as primary criteria for tenure, promotion, and career advancement.

d. **Evaluate impact of shared resources:** Evaluate the reach and value of shared resources using field-appropriate indicators (such as downstream preprints, clinical trial applications, code forks, and access requests) rather than raw download counts. A specialized tool or dataset in a niche field may have transformative scientific value that raw download numbers may fail to reflect.

III. Training and Mentorship

Mentorship is an important component of scientific impact, so building high-performing training environments are practices embedded in Broad's operational model. We encourage NIH to evaluate mentorship through a comprehensive set of indicators - measuring success by trainee growth, long-term career advancement, transition to scientific independence, and real-world workforce retention rather than grant volume alone. Potential indicators to assess and quantify the impact of mentorship include:

a. **Mentorship training**: Encourage the completion of formal mentorship training programs, such as those offered through the Center for the Improvement of Mentored Experiences in Research (CIMER), as an indicator of effective mentorship.
b. **Trainee-to-PI transition**: Evaluate how effectively training environments support early-career researchers as they navigate the transition into independent research roles and scientific leadership.
c. **Trainee recruitment**: Track whether mentorship environments attract new trainees and support them in successfully completing their training with the PI.
d. **Trainee feedback**: Incorporate anonymous or confidential feedback and exit surveys to assess the quality of mentorship and to truly capture the trainee's experience.

IV. Collaboration

At the Broad Institute, complex biomedical breakthroughs are driven by team-based science, shared platform infrastructure, and interdisciplinary hubs designed to accelerate scientific impact everywhere, not just at Broad. Evaluation frameworks should look beyond raw publication or collaboration counts to capture real functional impact, middle-author leadership, platform engineering, and cross-disciplinary contributions. The approaches below recognize the diverse expertise, leadership, and contributions that enable successful team-based science.

a. **Clear classification of collaboration**: Establish standardized federal definitions for "collaborator" and "active collaborator" to better assess contributions.
b. **Collaborative research engagement:** Evaluate the depth, functional role, and strategic impact of a scientist's contributions within a team, rather than the raw number of collaborative projects.
c. **Funding contributions**: Recognize individuals who are named collaborators on successful funding applications, including sub-awards and collaborative grants.
d. **Collaborator feedback mechanisms**: Incorporate qualitative and quantitative feedback from collaborators and co-investigators regarding an individual's contributions. This feedback could be included in grant progress reports, publication processes, or promotion reviews.

V. Entrepreneurship and Translation

Moving biomedical discoveries from "bench to bedside" requires coordination across research, biomanufacturing, industry partnerships, and clinical organizations. To capture the true breadth of these efforts, evaluation frameworks must recognize high-risk, high-reward research,

especially within regional innovation hubs where proximity to expertise, advanced infrastructure, and commercial partners accelerates biomedical progress. We encourage NIH to consider the following indicators when assessing translational impact across funded institutions:

a. **Startup creation:** Track the formation, growth, and trajectory of spin-off companies created to advance discoveries, evaluated by their technology pipelines and commercial viability.
b. **Industry R&D partnerships**: Acknowledge robust collaborations with pharmaceutical and biotech partners that are focused on developing therapies, diagnostic tools, and biological insights.
c. **External & private sector investment:** Evaluate evidence of meaningful sponsored research funding, co-development capital, and private investments secured from industry partners to advance bench-to-bedside projects.
d. **IP deployment & licensing:** Consider active technology licenses issued to external/commercial parties to transition lab discoveries and inventions into market pipelines and clinics.
e. **Clinical pipeline progression**: Monitor the number of patents filed that successfully lead to licensing agreements, Investigational New Drug (IND) applications, or clinical product launches.

VI. Foundational Scientific Exploration

At the Broad Institute, we believe paradigm-shifting breakthroughs require bold exploration and an inherent tolerance for risk. Transformative science is rarely linear; it takes time, involves unexpected turns, and carries a real possibility of failure. To sustain true foundational discovery, evaluation frameworks must accommodate non-linear progress, account for delayed impact, and treat informative failures as valuable contributions to scientific knowledge.
We encourage NIH to support and incentivize high-risk, high-reward research through the following approaches:

a. **Value learning from failure:** Encourage researchers to share well-documented negative results and preprints from high-risk projects. Publishing these insights saves time and resources across the scientific community, preventing duplicate work and advancing progress overall. Program officers and reviewers should view informative failures as valuable scientific outputs rather than signs of an unproductive lab.
b. **Create flexible funding mechanisms**: Develop short-term seed grants (e.g. 2-3 years) to test high-risk research questions, paired with a streamlined peer-review process to convert promising early results into multi-year funding.
c. **Recognize long-term, delayed impact**: Adopt metrics to recognize publications and discoveries that take years to demonstrate their full impact, reinforcing the value of supporting paradigm-shifting research that may not show immediate impact.
d. **Empower scientific program leadership:** Expand the role of scientifically knowledgeable NIH program officers to identify and champion high-risk opportunities. Program officers and managers with deep expertise in their fields can help guide strategic investments and recognize promising research directions.

1. Rigor and Reproducibility: The pure mission of "rigor and reproducibility" leads to designing machines or researching on drugs that target "receptors." In practice, rigor and reproducibility represent purifying or synthesizing chemicals. This approach is disregarding the rising problem: Accumulating nomenclature/catalog based on search-subjective or profitable origin to finish end-related (offer), and alternatively speaking, "force" acronym data. These are evident in multi-conditionality jumbled "pathway and signaling" maps.

2. Data, Software, and Model Sharing: It's not enough to send finished products and call them "sharing." Understanding and communicating natural basics in comprehending these "tools" should be a priority.

3. Training and Mentorship: Training and mentorship need to be diversified and improved by addressing real world problems. Concentrating under old and identical mentality of thought does not nurture growth and independence. It creates stagnation. To advance training, even the mentors (directly or indirectly experienced adults) need to recognize their limitations and seek ways to improve beyond technical and/or work outputs.

4. Collaboration: More people working together does not necessarily represent collaboration. It may simply equal working under the same roof. If collaboration merely increases the same output, perhaps it should be called manufacturing. In order words, is collaboration leading to independently noticeable improvements or merely increasing socializing networks?

5. Entrepreneurship and Translation: Before rushing to entrepreneurship and translation, holistic and basics problems need to carefully addressed.

6. Foundational Scientific Exploration: Addressing real world research challenges is not "high-risk," but a necessity for improvement. High-risk implies skydiving or reckless betting for profits. The outcomes are predictable.

7. Public Impact: It's not enough to present publications results. These are endless and subjective. Leadership and research efforts need to focus on endeavors that improve natural and relational comprehension on all deficiencies.

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: Reproducibility is a cornerstone of the scientific process. However, the scientific community has become increasingly aware that some published scientific findings cannot be reproduced. We agree that steps should be taken to address this issue. One way to measure reproducibility and impact is tracking the frequency with which publications are supported or contradicted by subsequent research, using citation statements classified as supporting, contrasting, or merely mentioning prior work. Unlike traditional citation counts, such measures can provide insight into whether findings are being independently validated by the research community. Journal- or researcher-level indicators based on evidence of replication, support, and reproducibility could complement existing metrics and help incentivize more robust and reliable science. Another potential indicator of scientific quality that is more robust than traditional citation counts is tracking where research is published. Major indexing and archiving services, such as Web of Science, Scopus, the Directory of Open Access Journals and PubMed Central, require journals to meet established standards related to editorial quality, transparency, ethics, technical rigor, and accessibility. Incentives for researchers are needed to address reproducibility concerns. Replication studies are frequently overlooked because researchers rarely receive dedicated financial support to undertake research whose primary purpose is replication. Instead, the scientific community maintains scientific rigor through the peer review process, which ensures the quality and reliability of scholarly publications. However, robust peer review is time consuming work, done in addition to other research and service duties, disincentivizing the effort needed to thoroughly review articles prior to publication. ASM suggests the following indicators of rigor and reproducibility: • Incorporate independent, external measures of research reliability and reproducibility into NIH's measures of scientific impact, such as the Scite Index. • Track how often individual researchers publish in journals indexed by major indexing and archiving services with established standards. ASM suggests the following incentives to promote rigor and reproducibility: • Create funding streams for replication studies that supplement and do not supplant existing funding streams for original research. • Recognize and reward researchers' participation in the peer review process by measuring peer review as part of the researcher's overall scientific impact.

2. Data, Software, and Model Sharing: Data, Software, and Model Sharing Scientific advancement occurs through continual expansion of knowledge, which requires access to accurate and complete data for confirmation of findings and building on previously published knowledge. While sharing data, datasets, and software continues to improve, some data or code lack the necessary information and metadata to

make them readily usable by other researchers when they are shared. Measuring the quality of the shared data or software, in addition to the frequency of use, and rewarding groups that consistently publish usable, high-quality data and software can begin to change the open-access scientific data and software landscape. ASM suggests the following indicator to promote data, software and model sharing: • Implementation of a sharing index that measures how often researchers' data and software is used and cited, when it is shared and the completeness and FAIR (Findable, Accessible, Interoperable, Reusable) compliance of their data. ASM supports that agencies provide funding incentives to promote data, software and model sharing for labs that produce and share high-quality, well-annotated public data and datasets that become community resources.

3. Training and Mentorship: Mentorship of trainees is a cornerstone of the scientific enterprise yet is often not evaluated in grant applications and traditional measures of scientific impact and scientific training. ASM suggests agencies provide funding for training of mentors in leadership, mentoring, and managing people.

4. Collaboration: N/A

5. Entrepreneurship and Translation: Although moving basic science discoveries into clinical and field settings is a key goal of translational research, the translation of science extends beyond the development and commercialization of a finished product. Metrics of translational impact should therefore capture the full range of pathways through which research informs practice, policy, technology, and future innovation. Even if the translation fails, capturing the attempt to translate, provided the science was rigorous, can provide indicators of researchers looking to move their science beyond the lab and into practice. This, paired with ongoing funding for programs like the Small Business Innovation Research and Small Business Technology Transfer (SBIR/STTR) programs can help to encourage researchers to dedicate more of their efforts to exploring translation of their findings for the public good. ASM suggests the following indicator to measure entrepreneurship and translation: • Track activities related to the commercialization of research, such as the issuance of patents, investigational new drug applications and validated biomarkers, and manuscript reads that may be linked to commercial interest but not result in citations linked to research interest. • ASM suggests the following incentive to promote entrepreneurship and translation: • Continue robust funding for SBIR/STTR programs and other programs to promote entrepreneurship among researchers, such as the iCorps program.

Re: Request for Information (RFI) on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Dear Dr. Jorgensen,

Thank you for the opportunity to respond to the Request for Information (RFI) on Measuring and Rewarding Scientific Impact. ASM is one of the oldest and largest life science societies with over 38,000 members in the U.S. and around the world who are dedicated to conducting robust, rigorous research.

ASM appreciates NIH's interest in promoting scientific rigor and developing alternative measures for scientific success, beyond traditional measures like publication and citation counts. ASM integrates scientific rigor and reproducibility across our programs and our portfolio of 17 peer reviewed journals. Please see below for ASM's comments on rigor and reproducibility, data, software and model sharing, training and mentorship as well as entrepreneurship and translation categories described in the RFI.

Rigor and Reproducibility

Reproducibility is a cornerstone of the scientific process. However, the scientific community has become increasingly aware that some published scientific findings cannot be reproduced. We agree that steps should be taken to address this issue.

One way to measure reproducibility and impact is tracking the frequency with which publications are supported or contradicted by subsequent research, using citation statements classified as supporting, contrasting, or merely mentioning prior work. Unlike traditional citation counts, such measures can provide insight into whether findings are being independently validated by the research community. Journal- or researcher-level

1752 N St. NW
Washington, DC 20036
asm.org

indicators based on evidence of replication, support, and reproducibility could complement existing metrics and help incentivize more robust and reliable science.

Another potential indicator of scientific quality that is more robust than traditional citation counts is tracking where research is published. Major indexing and archiving services, such as Web of Science, Scopus, the Directory of Open Access Journals and PubMed Central, require journals to meet established standards related to editorial quality, transparency, ethics, technical rigor, and accessibility.

Incentives for researchers are needed to address reproducibility concerns. Replication studies are frequently overlooked because researchers rarely receive dedicated financial support to undertake research whose primary purpose is replication. Instead, the scientific community maintains scientific rigor through the peer review process, which ensures the quality and reliability of scholarly publications. However, robust peer review is time consuming work, done in addition to other research and service duties, disincentivizing the efort needed to thoroughly review articles prior to publication.

ASM suggests the following indicators of rigor and reproducibility:

- Incorporate independent, external measures of research reliability and reproducibility into NIH's measures of scientific impact, such as the Scite Index.
- Track how often individual researchers publish in journals indexed by major indexing and archiving services with established standards.

ASM suggests the following incentives to promote rigor and reproducibility:

- Create funding streams for replication studies that supplement and do not supplant existing funding streams for original research.
- Recognize and reward researchers' participation in the peer review process by measuring peer review as part of the researcher's overall scientific impact.

Data, Software, and Model Sharing

Scientific advancement occurs through continual expansion of knowledge, which requires access to accurate and complete data for confirmation of findings and building on previously published knowledge. While sharing data, datasets, and software continues to improve, some data or code lack the necessary information and metadata to make them

1752 N St. NW
Washington, DC 20036
asm.org

readily usable by other researchers when they are shared. Measuring the quality of the shared data or software, in addition to the frequency of use, and rewarding groups that consistently publish usable, high-quality data and software can begin to change the open-access scientific data and software landscape.

ASM suggests the following indicator to promote data, software and model sharing:

- Implementation of a sharing index that measures how often researchers' data and software is used and cited, when it is shared and the completeness and FAIR (Findable, Accessible, Interoperable, Reusable) compliance of their data.

ASM supports that agencies provide funding incentives to promote data, software and model sharing for labs that produce and share high-quality, well-annotated public data and datasets that become community resources.

Training and Mentorship

Mentorship of trainees is a cornerstone of the scientific enterprise yet is often not evaluated in grant applications and traditional measures of scientific impact and scientific training. ASM suggests agencies provide funding for training of mentors in leadership, mentoring, and managing people.

Entrepreneurship and Translation

Although moving basic science discoveries into clinical and field settings is a key goal of translational research, the translation of science extends beyond the development and commercialization of a finished product. Metrics of translational impact should therefore capture the full range of pathways through which research informs practice, policy, technology, and future innovation. Even if the translation fails, capturing the attempt to translate, provided the science was rigorous, can provide indicators of researchers looking to move their science beyond the lab and into practice. This, paired with ongoing funding for programs like the Small Business Innovation Research and Small Business Technology Transfer (SBIR/STTR) programs can help to encourage researchers to dedicate more of their eforts to exploring translation of their findings for the public good.

ASM
Microbes Make Our World

1752 N St. NW
Washington, DC 20036

Re: NOT-OD-26-087, Request for Information on Measuring and Rewarding Scientific Impact

Dear Director Jorgenson:

On behalf of the physician and medical student members of the American Medical Association (AMA), I appreciate the opportunity to respond to the National Institutes of Health (NIH) Request for Information (RFI) on Measuring and Rewarding Scientific Impact (NOT-OD-26-087). The AMA commends NIH's efforts to strengthen the biomedical research enterprise in ways that promote rigorous and reproducible science, accelerate transformative discovery, and ultimately improve patient care and public health. We offer the following recommendations to help advance those shared goals.

1. Fund the Research Questions Patients and Physicians Most Need Answered

Despite major advances in biomedical science, physicians encounter questions every day for which little evidence exists to guide clinical decision making. These gaps persist in part because of misaligned incentives in the research enterprise. Commercial sponsors tend to invest in research with clear commercial applications, while academic funding and promotion structures may place greater value on grant success and publication than on a study's potential to improve health outcomes in the real world.

NIH should ensure that taxpayer dollars fund the research questions with the greatest potential to improve public health, health outcomes, and the value of health care. Physicians, who routinely confront evidence gaps in clinical practice, are well positioned to help identify what those questions are. NIH should thus establish a recurring process through which physicians help identify high-priority research questions and should fund studies designed to answer them. Other countries have demonstrated that this approach is workable: in the United Kingdom, the James Lind Alliance convenes clinicians and patients to rank the most important unanswered questions in a given clinical area, and research funders use those rankings to guide investment. A research portfolio aligned with the questions physicians most need answered would also give NIH a direct, defensible measure of the real-world impact this RFI seeks—evidence generated in response to demonstrated clinical need.

2. Promote Comparative Effectiveness Research and Cost-Effectiveness Analysis

Clinical research in the United States generates substantial evidence about whether individual interventions are efficacious but far less comparative effectiveness research (CER) evaluating the relative

benefits and harms of available treatments or cost-effectiveness analysis (CEA) relating a treatment's cost to the health benefit it provides. This leaves important gaps in the evidence base physicians use to guide treatment decisions and policymakers use to shape value-based pricing policies.

To address these evidence gaps, NIH should increase funding for CER and CEA and strengthen its standards for comparator selection. When an established standard of care exists, the agency should require investigators to compare new treatments against an appropriate active comparator rather than placebo alone; when an active comparator is not feasible, investigators should justify the alternative as methodologically appropriate for the study objective, population, and treatment effect being estimated. NIH should also prioritize post-approval CER when treatments enter clinical use without adequate evidence comparing their benefits and harms with existing care.

3. Strengthen Methodological Standards for NIH-Supported Research

NIH should direct research dollars toward studies designed to generate reliable, clinically useful evidence. The agency can accomplish this by translating its peer review framework into explicit methodological requirements for research. In the following recommendations, we discuss four areas in which stronger standards could substantially improve the reliability and clinical value of study findings: endpoint selection, duration of follow-up, external validity, and prespecification of design and analysis. To apply these standards effectively, NIH should ensure that peer review includes experts in biostatistics and trial methodology and, when appropriate, physicians with expertise in the clinical area under study.

Require the use of clinically meaningful endpoints. NIH should require studies to use endpoints that are clinically meaningful and appropriate to the question under investigation. Clinical trials frequently rely on surrogate or intermediate endpoints that are weakly connected to patient outcomes and distort estimates of treatment benefit. A 2024 JAMA analysis found that most surrogate markers used to support Food and Drug Administration approvals in non-oncologic chronic diseases lacked high-strength evidence linking them to clinical outcomes, and a separate meta-epidemiological study found that surrogate primary outcomes can overestimate treatment efficacy by more than 40 percent. Although surrogates are necessary in select circumstances, NIH should require investigators to select primary endpoints that directly measure outcomes relevant to the clinical question; justify any use of surrogate, composite, or intermediate endpoints with evidence linking them to the patient-important outcomes they are intended to predict; and ensure that conclusions are commensurate with the outcomes measured.

Require sufficient duration of follow-up. Clinical trials of treatments intended for prolonged use often end before long-term effects are adequately assessed. As a result, they may detect early treatment effects without establishing whether benefits persist, harms emerge with continued use, or long-term clinical outcomes improve. To resolve these uncertainties, NIH should require investigators to demonstrate that planned follow-up is sufficient to answer the study question and capture benefits and harms over the relevant time horizon. Where extended follow-up within the original trial is impractical, NIH should support extension studies or linkage to registry and claims data to capture long-term outcomes.

Strengthen external validity. Research can only improve patient care when its findings are generalizable to the patients and settings in which an intervention will be used. Yet many trials today enroll populations that are systematically healthier and less medically complex than patients encountered in routine practice and are conducted in settings that bear little resemblance to those in which most care is delivered. These choices undermine external validity, contributing to the efficacy-effectiveness gap and expending taxpayer dollars on research with limited capacity to improve patient outcomes. To help address this gap, NIH should require applicants to identify the populations and settings a study is intended to represent and to explain how their proposed eligibility criteria and site selection support that generalizability.

Investigators who restrict enrollment should provide sufficient scientific justification and should confine their conclusions to the populations their evidence supports.

Require prespecification of key design and analytic decisions. Clinical trials are required to adhere to detailed protocols, yet published results frequently diverge from what those protocols specify. Analyses have found that roughly one third of trials change, add, or omit a primary outcome before publication, and that statistically significant outcomes appear in the published literature several times more often than nonsignificant ones. Studies that alter outcomes or analyses after results are known can produce false or exaggerated conclusions—distortions that then carry through to systematic reviews, clinical guidelines, and treatment decisions. To prevent these distortions from entering the literature, NIH should require investigators to prespecify outcomes, statistical methods, and planned subgroup analyses before data analysis begins and to finalize protocols and statistical analysis plans before unblinded outcome data become available.

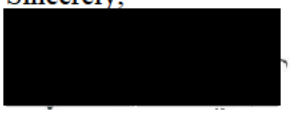
4. Strengthen and Enforce Results-Reporting and Data-Sharing Requirements

Despite NIH policies requiring clinical trial results reporting and data sharing, substantial compliance gaps remain. A 2022 Department of Health and Human Services Office of Inspector General audit found that 51 percent of the 72 NIH-funded clinical trials reviewed failed to report results on time, including 35 percent that had not submitted results at all, and that NIH continued to fund new research by responsible parties with outstanding reporting obligations. These failures limit researchers' ability to reproduce, reanalyze, and build upon federally funded work, reducing its reach and impact.

NIH should strengthen enforcement by making compliance with applicable reporting and data-sharing requirements a condition of continued and future funding. Before issuing a new or continuation award, the agency should verify that existing obligations have been satisfied and, when material noncompliance persists, should consider withholding funding, imposing award conditions, or suspending an award.

Beyond strengthening compliance with data-sharing requirements, NIH should ensure that shared data are readily accessible and usable. The agency should establish minimum usability requirements specifying that data must include sufficient metadata, documentation, and analytic materials to support interpretation and reproduction; use common data elements and interoperable formats where standards exist; and be deposited in established repositories when available. To further facilitate reuse, NIH should link each award in NIH RePORTER to its resulting publications, datasets, protocols, statistical analysis plans, and ClinicalTrials.gov records, creating a single record of the research products generated by each award.

5. Protect Scientific Independence and Federal Research Investments



NIH should adopt policies that protect objective, expert-driven decision-making throughout the research award lifecycle, from initial review through continuation, renewal, and termination. These policies should prohibit political officials from selecting reviewers, influencing peer review deliberations, or directing changes to reviewers' scores, and should establish clear standards governing when agency leadership may depart from peer review recommendations. Furthermore, because terminating ongoing research can disrupt scientific progress and waste resources already invested, NIH should provide public notice and an opportunity for comment before terminating a research program for reasons unrelated to noncompliance with award terms or research misconduct and should publish an assessment of the potential consequences for scientific progress, public health, federal investments, and, where applicable, participant safety. These protections should extend to the stability of research funding. NIH should ensure the timely obligation and distribution of available funds, avoid administrative delays or restrictions that impede their use, and preserve annual incremental funding for multiyear grants rather than charging their full value

against a single fiscal year's appropriation. Such an approach would maintain continuity for ongoing studies while leaving resources available for new grants and clinical trials.

Conclusion

The AMA appreciates NIH's commitment to producing rigorous, impactful research that advances biomedical discovery and improves health outcomes. We welcome the opportunity to support the agency in these efforts. Please contact me directly at 312-464-5288 or John.Whyte@ama-assn.org if you have questions or need further information.

Sincerely,

John Whyte, MD, MPH

Re: Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Dear Director Bhattacharya,

On behalf of Yale University, I appreciate the opportunity to share our feedback for the Request for Information (RFI) on Measuring and Rewarding Scientific Impact (NOT-OD-26-087).

Summary

Yale encourages NIH to modernize its understanding of scientific impact without replacing expert judgment or narrowing the range of science it supports. The appropriate framework is plural, stage-specific, and grounded in evidence. It should recognize rigorous learning, foundational discovery, training (in ethics, rigor, and reproducibility), mentorship, team contributions, responsible sharing, translation, implementation, and public benefit. Across these domains, NIH should identify a limited set of qualitative and quantitative measures; specify whether each applies to projects, investigators, programs, or portfolios; and validate each measure before implementation. Measures should inform expert judgment rather than become formulaic scores and should be revised or discontinued when they add burden, distort incentives, or fail to improve decisions. NIH should be cognizant of the resources of any new systems or processes that it requires during the application, review, funding, and reporting stages to reduce administrative burden.

Yale supports NIH's effort to recognize the defining features of rigorous, collaborative, and mission-driven science. Any new approach should preserve and strengthen the core features that have made NIH successful: sustained bipartisan Congressional investment; a vast extramural network; investigator-initiated science selected through independent expert peer review; expert scientific judgment in the review and conduct of research; high-risk, groundbreaking foundational discovery (such as deciphering how genes encode proteins and developing CRISPR gene editing); and the research workforce and infrastructure that enable innovation and impact.

Scientific impact should be assessed according to the stage of discovery. For each stage, NIH should define relevant indicators prospectively and evaluate results retrospectively over an appropriate time horizon:

- Basic science and methodological research should be assessed by the knowledge, mechanisms, methods, tools, datasets, and capabilities it creates.
- Translational research should be assessed by validation and progression toward practical application.
- Clinical research should be assessed by the quality and relevance of the evidence it produces.
- Implementation research should be assessed by adoption, reach, access, reliability, affordability, sustainability, and population- and individual-level health outcomes.

Retrospective assessments are critical to better understand impacts that may not have been foreseen, which may guide future portfolio assessments. Moreover, projects should not be judged solely by outcomes expected only at a later stage (i.e., development of a new therapeutic intervention). Portfolio priorities may consider disease

burden, unmet need, preventability, potential reach, and scientific opportunity, but these factors should not become formulaic scores for individual proposals. Impact assessments may also consider workforce development, education and training opportunities, and collaborative engagement fostered by projects.

During development, NIH should specify each measure's intended purpose, unit of analysis, and timing of use, distinguishing among projects, investigators, programs, and portfolios. Before implementation, NIH should establish each measure's validity, reliability, feasibility, and incremental value beyond expert review of scientific impact and merit. NIH should also compare new measures with existing quantitative indicators, such as publication count and journal impact factors. Validated measures should first be used retrospectively at the program or portfolio level to evaluate prior investments and inform strategic planning, not to affect individual awards or investigators' future funding. Only after demonstrating value at the relevant level should a measure be considered prospectively in individual award decisions, with advance notice and interpretation through expert review rather than as a formulaic threshold. Validation should include research-intensive universities, smaller institutions, health systems, community organizations, and small businesses, with attention to differences in infrastructure and administrative capacity. NIH should not conflate access to institutional resources with scientific impact and should fund any capacity required to meet new expectations. NIH should discontinue measures that do not improve decisions or that produce excessive burden or unintended incentives.

NIH should match incentives to the barrier being addressed: dedicated awards, supplements, and allowable costs for activities requiring resources; and contribution statements or biosketch recognition for work not captured by conventional outputs. These approaches should precede changes to priority scores or funding criteria, which carry greater risk of distorting behavior and should be considered only after the underlying measures have been validated.

Measures of scientific impact should be distinguished from measures of NIH's operational performance, but both are necessary for efficient, reciprocal accountability. Investigators should report progress they can reasonably influence. Separately, NIH should report review and award timelines, administrative burden, policy stability, and portfolio-level results. New requirements should use existing information whenever possible and should protect research participants, privacy, security, intellectual property, program stability, and scientific independence.

Rigor and Reproducibility

NIH should preserve field-specific expert review and its existing emphasis on sound study design, transparent methods, careful interpretation, and conclusions proportionate to the evidence. Rigor should be defined by whether the design, conduct, analysis, and interpretation are appropriate to the scientific question. This assessment is distinct from determining whether that question is a funding priority. Expected rigor should be assessed prospectively through expert review; reproducibility should be evaluated after completion through transparent reporting, appropriate sharing of data and code, and targeted replication when warranted. Rigor does not require every study to use the same design or every finding to undergo independent replication. The appropriate standard depends on the question, maturity of the evidence, feasibility, and consequences of error.

NIH funding and policies make this possible at scale by supporting not only individual projects but also the shared infrastructure and institutional stewardship on which rigorous research depends. Yale supports NIH's increased attention to replication and reproducibility. Yale's capabilities are targeted rather than centralized. The DISSC (Data-Intensive Social Science Center) Open and Reproducible Research program provides consultation and infrastructure for transparent and reproducible social science; the YODA (Yale University Open Data Access) Project supports responsible clinical-research data sharing; and Yale co-founded medRxiv to enable timely, transparent dissemination of health-science research. Research cores, methodological consultation, and the Yale Center for Clinical Investigation (YCCI) provide broader support for rigorous study design, conduct, analysis, and dissemination. These capabilities serve distinct purposes: DISSC supports computational reproducibility; YODA enables data access and reuse; medRxiv advances transparent dissemination; and research cores and consultation primarily support rigor. None substitutes for dedicated support for independent replication, which requires separate funding and infrastructure.

NIH should assess whether a project's design, conduct, analysis, interpretation, and claims are appropriate to the question and evidence. Relevant indicators may include preregistration and statistical analysis plans when appropriate; transparent reporting of deviations, limitations, negative findings, and credible null results; and adherence to established reporting standards. NIH should not impose a single federal definition of causal research or a universal hierarchy of study designs. Investigators should identify the question being answered, state material assumptions and limitations, and calibrate causal claims to the evidence. Qualitative and exploratory research should be evaluated using field-appropriate standards for methodological fit, transparency, reflexivity, interpretive rigor, and learning value, rather than criteria designed primarily for confirmatory or causal studies.

NIH should integrate and streamline existing reporting requirements to produce a structured, publicly available final scientific report for research awards, proportionate to the award's scale and purpose, while minimizing incremental burden and avoiding a separate reporting process. Reporting fields should reflect the stage of research: knowledge and capabilities for foundational work; validation and progression for translational work; evidence for clinical research; and adoption, reach, access, and outcomes for implementation research. Across stages, reports should link research products and describe the availability of protocols, methods, materials, data, and analytic code; important deviations; null or negative findings; and material limitations. Appropriate exceptions should protect participants, privacy, security, and intellectual property. Machine-readable reports would support reuse and allow the scientific community to develop and validate better measures of impact.

Replication is generally a subsequent scientific activity, often conducted by an independent group, rather than an attribute that every original proposal can demonstrate prospectively. NIH should identify replication priorities at the portfolio level based on scientific importance, uncertainty, downstream reliance, feasibility, and the consequences of an incorrect result. Dedicated awards should support independent replication, while supplements may support validation or methodological work when independence is not essential. These projects should be evaluated for rigor and informativeness rather than conventional novelty.

Replication, null findings, reusable methods, and research-quality infrastructure often receive less recognition than novel positive findings. They also require dedicated time, expertise, and funding. Unfunded documentation or replication mandates could reduce rather than improve scientific productivity. Structured public reporting should consolidate or replace existing requirements, not become an additional reporting layer.

NIH should fund the infrastructure required for rigor, reproducibility, and replication; incorporate relevant activities into allowable budgets; pilot structured reporting before broad implementation; prepopulate it with information already available through existing systems; limit fields to information with demonstrated value; and measure and mitigate investigator and institutional time and cost.

Data, Software, and Model Sharing

Responsible sharing increases the value of federal research by enabling validation, reuse, collaboration, and new discovery. NIH has advanced this objective by making responsible data management and sharing an explicit component of federally supported research, encouraging institutions to build the infrastructure and expertise needed for implementation. Yale supports this work through research-data services, Yale Dataverse, institutional access to Dryad, statistical consultation, secure computing, and clinical-research informatics. These resources help investigators manage, document, preserve, and share research products while meeting ethical and legal obligations.

NIH should recognize data, software, and models as scientific contributions when they are well documented, usable, maintained for an appropriate period, and made accessible under terms consistent with consent, privacy, security, and intellectual-property obligations.

Potential indicators include:

- Use of persistent identifiers, versioning, metadata, data dictionaries, and appropriate documentation.
- Clear access conditions and reasonable time from a valid request to access.
- For software, availability of documentation, testing, dependencies, and reproducible computing environments.
- For scientific models, documentation of provenance, intended use, validation, limitations, version changes, and human oversight.
- Evidence of meaningful reuse or extension, which may need to be interpreted qualitatively rather than through download counts alone.

NIH should fund, either intramurally or with extramural partners, the development of repositories, secure computing, curation, storage, maintenance and personnel required for responsible sharing. Congress should support this infrastructure through dedicated appropriations that supplement, rather than compete with, funding for investigator-initiated research. Controlled-access, federated, or privacy-preserving approaches should receive appropriate recognition when unrestricted sharing would be unethical or unlawful.

NIH should also establish proportionate guidance for generative AI. Disclosure should be required when AI materially influences scientific design, data generation, analysis, results, reproducibility, or interpretation.

Sharing can be limited by participant consent, privacy requirements, cybersecurity risk, licensing terms, intellectual property, inconsistent data standards, and the continuing cost of maintaining research products. Metrics that reward volume or unrestricted openness could encourage poorly documented releases or inappropriate disclosure.

NIH should develop AI and sharing policies with scientific, technical, ethical, security, and patient input. Requirements should be harmonized across institutes and should take effect only when compliant infrastructure and funding are available.

Training and Mentorship

NIH training and career-development programs are essential to the stability and renewal of the biomedical research workforce. Individual fellowships, institutional training awards, career-development awards, protected research time, and sustained mentorship should remain central.

NIH investment in training awards and research infrastructure provides a foundation that institutions can extend through complementary programs tailored to workforce needs across career stages and fields of inquiry. Training in clinical trials, within and outside of the health care system, are important for future scientific rigor and reliability.

For example, Yale's Combined PhD Programs in the Biological and Biomedical Sciences Program coordinates PhD training across nearly all bioscience disciplines and includes numerous specialized NIH-funded training programs, complemented by NIH-supported research in affiliated laboratories. Together with YCCI's training programs, the Office of Physician-Scientist and Scientist Development, and the Yale Physician-Scientist Development Awards, these programs demonstrate a lifecycle approach spanning foundational, clinical, translational, and community-based research. YCCI reports that its programs trained 227 individuals from 2006 to 2025, with a long-standing track record for graduates subsequently receiving substantial independent research support. These outcomes demonstrate the value of long-term infrastructure rather than any single mentorship metric.

Evaluation should distinguish what can be assessed during training from outcomes that emerge years later. Near-term indicators could include:

- Quality and regularity of mentorship.
- Access to protected time, methods training, collaborative networks, and professional development.

- Progress toward individualized scientific and career goals.
- Trainee assessment of the mentoring environment.
- Development of scientific judgment, rigor, independence, and leadership.

Long-term evaluation may consider persistence in research, scientific contributions, mentorship of others, and careers across academia, government, health care, nonprofit organizations, and industry. Subsequent NIH funding should not be treated as the sole definition of success.

NIH should recognize co-mentorship, team mentorship, mentorship by research professionals, and the work required to create productive research environments. Incentives could include funded mentor effort, training supplements, bridge support during career transitions, and qualitative recognition in biosketches and progress reports.

Funding instability, limited protected time, uncertain career pathways, and increasing training costs threaten workforce development. Grant terminations, delayed awards, and the premature ending of mentored career-development support during 2025–26 have disrupted training and transitions to independence, compromising continuity in the biomedical trainee pipeline. Changes to federal graduate and professional education financing may compound these pressures, but their effects should be evaluated using national data on enrollment, completion, debt, and career outcomes. More broadly, NIH should evaluate workforce policy using these structural indicators rather than assuming that mentorship metrics can compensate for structural funding problems.

Collaboration

Modern biomedical research depends on interdisciplinary teams, shared facilities, research professionals, health systems, community organizations, government, nonprofit organizations, and industry. NIH should continue to support multi-investigator awards, research networks, centers, and collaborative infrastructure.

NIH's collaborative awards are most effective when complemented by institutional structures that help teams form, compete for support, and execute complex research programs. Yale's Office of Team Science supports large interdisciplinary proposals, reduces administrative barriers, connects investigators, and provides seed funding and expert review. YCCI similarly connects investigators across Yale's schools, Yale New Haven Health, the VA, community organizations, industry, and other CTSA hubs. These models demonstrate that productive collaboration requires coordination and infrastructure, not simply a larger number of investigators.

NIH should recognize substantive contributions rather than relying primarily on principal-investigator status, authorship position, publication counts, or the number of collaborators. Standardized contribution statements could identify responsibility for:

- Scientific conception and leadership.
- Methods, statistics, data, software, and model development.
- Clinical-trial execution and site leadership.
- Research operations, regulatory work, and participant engagement.
- Core-facility and research-professional expertise.
- Implementation, dissemination, and community partnership.

Contribution information should be entered once, certified by the team, and reused in progress reports and biosketches. It should inform expert review rather than produce another numerical score.

Federal awards should continue to be made through accountable institutions. Institutions provide human-subject protections, financial stewardship, cybersecurity, shared facilities, training, data governance, and continuity that cannot be supplied by an individual investigator alone. Recognition of individual contributions should not come at the expense of the institutional infrastructure that makes team science possible.

Current systems can undervalue site leadership, technical expertise, research operations, and collaborative contributions that do not correspond to conventional authorship. Short funding horizons and fragmented administrative requirements can also make durable partnerships difficult. NIH's proposed cap on simultaneous Research Project Grants should distinguish single-PI leadership from MPI participation and avoid counting collaborative awards in ways that discourage investigators from contributing specialized expertise to large team-science efforts. Policies that destabilize reimbursements for facilities and administrative expenses or substitute political pre-issuance review for expert scientific judgment could weaken the infrastructure and trust on which collaboration and discovery depends.

Entrepreneurship and Translation

NIH should continue supporting a translational ecosystem that includes investigator-initiated discovery, NCATS and other translational programs, SBIR/STTR, academic-industry research, licensing, startup formation, and clinical and implementation partnerships. These mechanisms address different stages and risks. Industry contributes development, regulatory, manufacturing, and commercialization expertise, while federal funding remains necessary for foundational discovery, early validation, and scientific or public needs without an immediate commercial return.

Yale's experience illustrates several complementary pathways to Entrepreneurship and Translation. Craig Crews' academic chemical-biology research, including NIH-supported work advancing PROTAC (proteolysis-targeting chimera) technology, led to university licensing, startup formation, sponsored research, industry partnership, and ultimately FDA approval of *Vepdegestrant,* the first approved PROTAC therapy. Ranjit Bindra's work on DNA-repair vulnerabilities in IDH1/2-mutant tumors provides a complementary example: investigator-led discovery advanced through biomarker-driven early-phase trials and a multisite NCI-sponsored study, illustrating how public support can sustain translation alongside commercial development. In total, Yale research discoveries have resulted in the creation of 186 new startup companies that have collectively created over 11,000 jobs in the United States.

Structured alliances provide another model. The Yale-AstraZeneca Oncology Alliance connects academic cancer biology with industry translational and clinical capabilities. Yale's partnership with Boehringer Ingelheim combines collaborative research with internships, joint seminars, and co-mentored postdoctoral training, including a Biomedical Data Science Fellowship focused on AI-enabled drug discovery, supported by faculty mentors across multiple disciplines. These models allow academic investigators to engage industry knowledge of development needs while preserving scientific judgment. NIH should recognize stage-appropriate evidence across this continuum, including validated targets, sponsored research, shared capabilities, licenses, startups, clinical and regulatory milestones, workforce development, and eventual public benefit, rather than treating patents, revenue, or product approval as the sole measures of translation.

NIH should support the full knowledge lifecycle across its portfolio without requiring every award to span every stage. Measures should be appropriate to maturity:

- Early translation: target, mechanism, assay, or platform validation.
- Product development: readiness, regulatory, manufacturing, licensing, or investment milestones.
- Clinical translation: safety, effectiveness, comparative value, and usability.
- Implementation: acceptability, adoption, reach, affordability, sustainability, and real-world performance.

Patents, licenses, startups, and investment are useful indicators but not ends in themselves. NIH should also recognize clinical guidelines, public-health practices, workflow improvements, open tools, and nonproprietary interventions.

Important work may fall between funding mechanisms or lack adequate commercial incentives, including replication, comparative effectiveness, implementation, open infrastructure, and studies involving small or biomarker-defined populations. NIH should identify gaps through portfolio evidence, improve continuity

between stages, and assess review-to-award time and avoidable administrative delays. Because translational research often combines federal, industry, nonprofit, and international partners, inconsistent and needlessly burdensome disclosure requirements can delay sponsored-research agreements, data and material exchange, licensing, and progression to clinical evaluation. NIH should build on the federal common disclosure forms by harmonizing conflict-of-interest, conflict-of-commitment, and foreign-relationship requirements across agencies; clearly distinguishing gifts, research support, and scientific collaborations; and applying risk-based thresholds tied to overcommitment, duplication, financial conflict, or national-security concerns. International activities presenting no material risk should not trigger duplicative reporting or delay. Greater speed would come from removing administrative processes that do not substantively elevate risk or improve scientific quality, stewardship, or participant protection, not from weakening expert review.

Foundational Scientific Exploration

Foundational science is not an exception to public impact; it is one of its principal sources. NIH's greatest contributions include discoveries whose applications could not have been predicted when the work began. An analysis of 210 drugs approved from 2010 to 2016 found NIH-funded research associated with every drug, with more than 90% of the funding supporting basic research on biological targets rather than the drugs themselves.

Artificial intelligence provides a contemporary illustration. Modern machine learning draws in part on decades of foundational neuroscience, alongside advances in mathematics, statistics, and computer science, much of which preceded any clear biomedical application. These capabilities are now reshaping how scientists generate hypotheses, analyze complex data, design experiments, and pursue new diagnostics and treatments. NIH should sustain foundational research even when its eventual applications cannot yet be predicted.

NIH should also preserve investigator-initiated research, field-specific expert review, stable support, and explicit tolerance for scientific risk. High-risk research should not be confined to special programs. The broader portfolio must retain room for unconventional questions, rare diseases, new investigators, enabling technologies, and work that may challenge prevailing assumptions.

NIH's High-Risk, High-Reward Research programs provide one important model for protecting this space within a broader investigator-initiated portfolio. The 2024 NIH High-Risk, High-Reward portfolio included five awards involving six Yale researchers across the New Innovator, Early Independence, and Transformative Research programs. These mechanisms demonstrate how NIH can create protected pathways for unconventional ideas, cross-disciplinary research, and investigators at different career stages without requiring immediate clinical application.

Foundational proposals should be evaluated for the importance of the question, originality, scientific plausibility, quality of reasoning, learning value, and potential to create new knowledge or capability. Excessive requirements for preliminary data can exclude the very ideas that high-risk programs are intended to support.

Possible long-term portfolio indicators include:

- New mechanisms, hypotheses, or conceptual frameworks.
- Methods, tools, datasets, models, or platforms that enable subsequent work.
- Findings that overturn unsupported assumptions or redirect a field.
- Downstream use across disciplines or applications over an appropriate time horizon.
- Productive knowledge generated from rigorous studies that do not confirm the original hypothesis.
- New constructs, taxonomies, contextual understanding, or hypotheses generated through rigorous qualitative or exploratory research.

These indicators should support retrospective portfolio learning, not near-term scoring of individual investigators. Short-term outcome requirements, unstable funding, and pressure for immediately demonstrable results can narrow the range of questions investigators pursue. Research portfolios require both immediately

demonstrable results and longer-term breakthrough potential. NIH should preserve that balance through expert scientific review, without political or formulaic screens.

Public Impact

NIH's mission encompasses both the creation of knowledge and its eventual contribution to longer, healthier lives. Public impact must therefore include foundational discovery while more deliberately addressing whether mature evidence reaches the American people.

Through NCATS and the Clinical and Translational Science Awards Program, NIH has helped institutions build the durable infrastructure needed to move discoveries across the research lifecycle and into practice. YCCI's clinical and translational infrastructure, dissemination and implementation programs, health-system relationships, and community partnerships demonstrate how academic research can connect discovery with real-world practice. Its community-engagement model includes joint priority setting, research participation, dissemination, and implementation.

NIH should use disease burden, unmet need, preventability, potential reach, and scientific opportunity to inform strategic planning across portfolios, not to impose a uniform public-impact score on individual proposals.

For mature research, relevant indicators may include:

- Incorporation into clinical guidelines, decision support, or public-health practice.
- Adoption and sustained use in academic, community, rural, non-health care, and other real-world settings.
- Reach among the populations expected to benefit.
- Improvements in access, safety, quality, morbidity, mortality, or other patient-centered outcomes.
- Affordability, scalability, sustainability, and time from convincing evidence to routine use.

NIH should make implementation science and community outcomes a major component of its public-impact strategy. A proven intervention has limited public value if it remains unavailable outside specialized research settings. This requires support for pragmatic evaluation, adaptation, de-implementation of ineffective practices, implementation infrastructure, and ongoing assessment after adoption.

NIH should support learning health system partnerships and community partnerships that integrate research with routine care; use clinical, non-clinical, and operational data to generate evidence; and continuously evaluate adoption, outcomes, unintended effects, and opportunities for improvement. These partnerships can shorten the cycle from discovery to implementation, thereby improving the public's return on taxpayer dollars, while rigorously and reliably testing whether interventions work across varied real-world settings.

Public trust should be strengthened through transparent explanation of portfolio priorities, methods, uncertainties, findings, and changes made when evidence evolves, as well as by demonstration of longer-term outcomes of research. NIH should report both successes and credible null results and should involve patients, clinicians, communities, and other partners without converting public engagement into political conformity.

Fragmented funding, slow transitions between research stages, inconsistent real-world infrastructure, and limited incentives for implementation can delay the use of effective discoveries. Conversely, emphasizing immediate health outcomes too early could divert support from the foundational science on which future advances depend.

NIH should therefore judge public impact at the appropriate stage and level. It should assess individual awards on what investigators can influence and assess longer-term health, economic, and societal outcomes across programs and portfolios.

Conclusion

Yale supports a research enterprise that is more rigorous, faster, efficient and accountable while retaining the curiosity, independence, collaboration, and risk tolerance that make transformative discovery possible. Such an approach would advance Yale's commitment to creating and disseminating knowledge and our mission to promote curiosity, advance discovery, nurture scientific leaders, and improve the health of all people. Yale welcomes continued collaboration with the NIH and the American people to advance this mission.

Sincerely,

Michael C. Crair, Ph.D.

1. Rigor and Reproducibility: At present, the most commonly-used method of measuring scientific impact is with citation counts. As typically implemented, citation counts treat all citations as equivalent, in that a citation presenting contrary evidence counts the same as one corroborating it. This means existing metrics cannot identify which findings are replicated and which are contested — precisely the information a replication initiative needs.

To facilitate this kind of measurement, citation classification, in which the text surrounding each citation is automatically classified as supporting, contrasting, or mentioning a given claim can be used. This is not a speculative proposal, as it has already been implemented by scite.ai. The methodology is presented in Nicholson et al. (2021; see attached PDF), and over 1.6 billion citation statements from the scholarly literature have already been classified. These data are available through a free API and can also be obtained through a bulk export though arrangements with Research Solutions, Inc. NIH could pilot these indicators on a defined collection of publications (e.g., from a given institution) and compare against expert judgment before broader adoption.
This approach directly addresses misaligned incentives within scientific institutions. Rewarding independently corroborated findings as opposed to raw citation volume does much to align incentives with rigor rather than visibility.

Of course, there are several limitations to this method: First, automated classification is imperfect and subject to error (see Nicholson et al. for F-scores across all citation types). Second, supporting and contrasting citations constitute a minority of all citations, which can limit the ability to derive meaningful signals from papers with a smaller number of citations. Third, any metric is potentially subject to gaming (e.g., authors deliberately using supporting or contrasting language depending on which claims they wish to elevate or demote. Given these limitations, we believe these indicators should inform, rather than replace, expert review.

However, because these indicators operate at the level of individual findings rather than cumulative output, they are less biased against early-career researchers and smaller institutions than other (e.g., h-index-style metrics), provided appropriate time windows and field-normalization techniques are properly applied.

7. Public Impact: Faculty Success Fellows in Response to NIH Request for Information: Measuring and Rewarding Public Impact in Biomedical Research (NOT-OD-26-087)
The comments that follow reflect the perspective of faculty with expertise in STEM fields, including biomedical engineering and neuroscience. They do not represent institutional policy, rather, they are informed by the observations of Faculty Success Fellows at The University of Texas at San Antonio, who participated in an university initiative exploring how faculty define, recognize, and demonstrate Public Impact Research (PIR). Through this collaborative effort, we examined how scientific contributions evolve over the course of faculty careers and how current evaluation systems capture—or fail to capture—the broader value of research.
One theme has emerged from our project: researchers already create public value in many different ways, but these contributions are often not fully recognized by current evaluation systems. Public impact is rarely a single event or an immediate outcome; rather, it often develops gradually over the course of a scientific career as investigators mature, build expertise, establish collaborations, mentor others, and contribute to the broader research ecosystem. Over time, faculty members may generate impact through advances in research methods, development of shared scientific resources, contributions to public policy, education and workforce development, collaborative networks, community engagement, and efforts that strengthen public trust in science.
These following comments below provide our collective observations and offer suggestions in response to NIH's Request for Information on assessing the public impact of biomedical research, with the goal of helping NIH better recognize, encourage and reward the full spectrum of scientific contributions that ultimately benefit society over the long term.
Comment 1: Definition of Public Impact Research, Recognition of Multiple Pathways to Impact, and Long-

Term Scientific Contributions.

A definition of PIR is needed that clearly distinguishes it from translational research while recognizing its important connection to fundamental discovery. Although translation into clinical practice, commercialization, and implementation are important pathways for improving health, they represent only one component of the broader biomedical research ecosystem. Public impact in biomedical research should be defined as research that contributes to improving human health, societal well-being, scientific capability, or evidence-based decision making.

This definition should recognize that public impact can arise from many forms of research contributions, including advancing fundamental knowledge that enables future discoveries, developing new methods, datasets, software, and shared research infrastructure, improving clinical care and public health, informing policy and regulatory decisions, supporting education and workforce development, promoting open science, and strengthening public understanding and trust in science. Research that produces these outcomes may have substantial public value even when the impact is indirect, cumulative, or realized over a longer timeframe.

NIH should also recognize that the public benefit of biomedical research arises through different pathways. For some investigators, impact may be demonstrated through new therapies, diagnostics, or improvements in patient care. For others, it may occur through computational tools, engineering approaches, standardized protocols, research resources, policy guidance, or community-engaged approaches that advance health. These diverse contributions are essential to NIH's mission and should not be evaluated solely through a commercialization or clinical implementation lens.

At the same time, recognizing public impact should not diminish the importance of fundamental, discovery-driven research. Many transformative advances in medicine have originated from basic science discoveries whose eventual applications were not foreseeable at the time of discovery. Fundamental research is often the foundation upon which future clinical and public health advances are built, and the absence of immediate application should not be interpreted as a lack of public value. The definition of PIR should therefore recognize both near-term contributions and long-term scientific investments that enable future improvements in health.

A flexible definition that accounts for differences across biomedical disciplines—including basic science, clinical research, computational biology, biomedical engineering, population health, and community-engaged research—will better capture the full range of ways NIH-supported research advances health and benefits society.

Comment 2: Metrics for Assessing and Recognizing Public Impact in Biomedical Research.

Because public impact is multidimensional, NIH should implement an assessment approach that recognizes multiple forms of evidence rather than relying on a single metric or score. Evaluation of public impact should complement, rather than replace, traditional measures of scientific excellence, such as research quality, rigor, and scholarly contributions. The goal should be to provide a broader view of research value while allowing flexibility across disciplines, research areas, and career stages.

NIH could encourage investigators to document evidence of public impact through an "Impact Portfolio" that captures contributions appropriate to their research program. Such evidence may include, but should not be limited to, open science practices, transparent reporting, sharing of protocols, software, datasets, and other research resources, development of community tools, contributions to standards and guidelines, engagement with patient or community groups, and participation in activities that inform public health policy or government decision making.

Importantly, not every investigator should be expected to demonstrate every type of public impact. The

most meaningful contributions will differ depending on the scientific field, the goals of the research, and the investigator's career stage. Assessment frameworks should therefore allow multiple pathways for demonstrating impact rather than creating incentives that favor only highly visible or immediately measurable outcomes.

NIH could incorporate consideration of public impact across the research lifecycle, including grant applications, peer review, progress reports, competing renewals, investigator recognition programs, and training or career development activities. However, public impact should not be measured primarily through popularity-based indicators such as social media engagement, media attention, or online visibility, as these do not necessarily reflect scientific significance, rigor, or lasting contribution. A balanced approach that considers meaningful evidence of impact will better recognize the diverse ways NIH-supported research contributes to improving health and advancing biomedical science.

Comment 3: Reward the Ecosystem - not Only the Individual Investigator

One important lesson from our Faculty Success Fellow discussions is that public impact rarely results from the efforts of a single investigator or from a single research outcome. Rather, meaningful impact develops gradually over the course of a scientific career as investigators mature, build expertise, and contribute to the broader research ecosystem. While individual researchers make critical contributions to scientific discoveries that improve health, fundamental change often depends on a broader ecosystem that includes regulatory pathways, health system adoption, industry partnerships, public policy, institutional resources, and meaningful engagement with communities. Public impact should therefore be viewed not only as an individual achievement, but also as the outcome of a collaborative research environment.

NIH can promote greater public impact by supporting institutions in building the infrastructure and culture needed for research translation and broader societal benefit. This includes investments in faculty development, interdisciplinary collaboration, mentorship, community partnerships, data-sharing and research infrastructure, and institutional policies that recognize diverse forms of scientific contribution across the research lifecycle. Supporting researchers as they develop expertise, build collaborative networks, and contribute to shared scientific resources may generate greater long-term societal benefit than evaluating investigators solely through individual outcomes. A public impact framework that recognizes both individual contributions and the institutional ecosystems that enable them will better reflect how biomedical advances are developed, sustained, and translated into meaningful benefits for society.

Conclusion: Scientific discoveries improve society through many interconnected pathways. Some lead directly to new therapies, diagnostics, or clinical applications, while others create the foundational knowledge, research tools, infrastructure, policies, and trained workforce that enable future advances. A meaningful framework for Public Impact Research should recognize this full continuum of contributions while maintaining rigorous standards for scientific quality and evidence. NIH has an opportunity to lead the research community by adopting a multidimensional approach that values diverse pathways to impact, strengthens the biomedical research ecosystem, and maximizes the long-term public benefit of federally supported research. Such an approach should remain evidence-based, nuanced, and designed to recognize meaningful contributions without creating incentives that favor visibility or easily measured outcomes over lasting scientific value.

Description: Comments in response to request for input from community about rewarding replicability

Comments on “how to measure and reward scientific impact and replicable research practices?”

Bradley E. Alger, Ph.D.

I. Efforts must begin with a few definitions and clarifications.

I. A. What exactly do we mean by “replication” (or “reproducibility, I will use the terms interchangeably)?” Four definitions or types of reproducibility have been identified by the American Society for Cell Biology (ref. 1, for discussion). Briefly, they are:

1. Analytical – reanalyze experimental dataset and attempt to confirm conclusions.
2. Direct – repeat original experiment as exactly as possible and compare results.
3. Systematic – repeat original experiment, but systematically alter one (or more) variable to test generality of conclusions
4. Conceptual – tests previous conclusions using different methods, variables, etc.

Notice that definitions I.A.1 and IA.2 genuinely refer to attempts to confirm or disconfirm original reports, in other words to replicate them.

Definitions I.A.3 and I.A.4 should not be considered “replicability” issues at all because their focus is not on reproducing the original experiments and data, but on the testing the conclusions or inferences that were drawn from the those experiments.

Definitions I.A.3 and I.A.4 are actually about testing hypotheses that arise from, are suggested by, or are consistent with, the original conclusions. If they are not replicated (or confirmed, reproduced, etc.) it may well mean that a hypothesis has been tested and found to be incorrect, “falsified.” Testing and falsifying hypotheses are integral aspects of the scientific method, they are key making scientific progress, not problems to be done away with.

It is important to make such distinctions in order to reduce the confusion often present in discussions of replicability.

I.B. Modern scientific papers typically include many different experiments—ideally they are all related to a central idea. Nevertheless, they are different experiments. If one is not confirmed, does that mean the whole paper is “irreproducible”? Do all of the sub-experiments have to be reproduced in order to conclude that the paper is indeed “reproducible?”

I.C. It is necessary to realize that despite the great importance of reproducibility for science, a single failed attempt at replication of a previous finding is, on its own, generally uninformative:

1. the first study may be wrong and the second right or
2. the second study wrong and the first right or
3. both are wrong or
4. both are right.

The history of science includes numerous examples of I.C.3. or I.C.4. being the case.

I.D. Given the continued rapid growth in the numbers of scientific papers published annually, particularly when most are multi-part reports (see I.B. above), attempts to ensure reproducibility will become increasingly out of reach.

For these reasons and more, a perfect solution to the reproducibility problem is not in the cards.

II. Some suggestions for improving the situation include:

II.A. A definition of "reproducibility" should be developed and provided by a respected scientific committee to address the issues raised under I.A. and I.B. This should help remove some of the confusion present in discussions of reproducibility and focus attempts to improve true reproducibility.

II.B. Given the impossibility of attempting to replicate every experiment in a paper, authors could be required/encouraged to identify explicitly the key finding in their paper. The purpose would be to pinpoint the experiment or experiments that are crucial to its main conclusions. If that experiment could not be replicated, then the authors would acknowledge that either their conclusion(s) were in error, or that some greater problem existed.

II.B.1. Papers that are successfully replicated in follow up publications should be distinguished by a sign or "badge" highlighting that fact.

II.B.2. The widespread practice of announcing in a paper's abstract that such-and-such an issue is "not well understood," as motivation for the paper is generally uninformative—presumably the reader already assumes that. In place of this vague indication of the general topic, authors should be encouraged to be more explicit about the gap(s) in knowledge that they aimed to fill.

II.B.3. Most significantly for improving reproducibility. this practice would provide an explicit focal point for reproducibility attempts. Rather than having to decide how to proceed to check an important result, follow up studies would be directed at the experimental result that the original authors themselves deem to be the main one.

This practice would encourage/require authors to think and communicate more explicitly and clearly about the key significance of their work than they often do.

It would clarify for the community what conclusions could or could not legitimately be drawn from the results obtained.

II.C. The remarks in I.A. imply that the significance of reproducibility or replicability is not the same for every study. For many "kinds" of science— "curiosity-driven, "open-ended questioning," "discovery science," etc., the issue is simply whether or not the original measurements were accurate, thorough, etc. A failure of reproducibility can often be corrected by improved, higher-resolution, or simply greater numbers of measurements. These are critically important matters for scientific validity but normally do not involve major matters of scientific reasoning or thinking.

II.C.1. Definitions I.A.3. and I.A.4. directly involve the broader issues of the generality or interpretations of experimental results. Addressing these matters usually involves strategies that are lumped under the rubrics of "hypothesis-testing, or hypothesis-driven," science. This category is fundamentally different from the others. The purpose of a hypothesis is to *explain* data or other observations. It tries to account for why they are what they are.

Hypothesis-testing experiments are not *opposed* to the other kinds of science. Rather, hypothesis-testing fundamentally depends on the existence or experimental results or observations that need to be explained. Not infrequently the results of an initial "curiosity-driven" effort leads naturally into hypothesis testing.

The hypothesis is an inescapable part of scientific procedure. Efforts to characterize a field give rise to prompt attempts to explain the data collected. This does not mean that every paper or project must be explicitly aimed at testing a hypothesis. Observations, curiosity, discovery science, questioning, etc.—will always play a vital role. These investigations provide the bedrock information necessary for science. They answer the questions: "what?" "where?" "how much?" "when?" etc.

In contrast, the answer to the question, "why?" depends on reasoning and interpretation, not bare observation or measurement, no matter how motivated. Attempts to say "why" begin with one or more, suspected, proposed, or putative, explanations. These cognitive constructs cannot truly be tested "directly" by an experiment or observation of the world. Instead, each proposed explanation, if true, predicts outcomes of experiments or observations that *must* be true if the hypothesis is true. Otherwise, the hypothesis is false.

II.C.2. These basic points are intimately intwined with the replicability problem.

Falsification of hypotheses is often considered a "null result." Null results are often considered "negative data," and not published.

A recent report in *The Journal of Reproducibility in Neuroscience*[2] on the impact of various "questionable research practices," identifies "not publishing null results," as "perhaps the most problematic" contributor to the "false discovery rate," which is a major driver of irreproducibility.

II.C.3. Encouraging and rewarding the publication of “null results” will therefore help improve the reproducibility of published science. Recognizing the often-hidden existence of hypotheses as inherent components of investigations (as suggested by the discussion in I.A.3. and I.A.4.) can foster this practice in several ways:

a. It will decrease the stigma attached to “null results” and “negative data” by calling attention to the value of such results as tests that can falsify a hypothesis. The process of hypothesis proposal and falsification is a major factor in scientific progress.

b. As a falsification of a significant hypothesis, “null” results will find more ready acceptance by journals.

c. This will motivate investigators to undertake reproducibility studies by rewarding their efforts with journal publications and their associated benefits to their CVs, grant and promotion prospects etc.

Conclusions: The problem of scientific reproducibility is vast and will not be solved by any single recommendation or change. More comprehensive solutions will include improved statistical practices, greater funding levels, alterations in the reward systems of science and many more. Nevertheless, clarification of the reproducibility problem and related matters of scientific reasoning and communication can help alleviate its detrimental effects.

I am responding: On behalf of an organization

Name: Stephen J. Susalka

Name of Organization: AUTM - Association of University Technology Managers, Inc.

Type of Organization: Professional Organization/Association

Role: Organizational Official

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: Reproducible and replicable biomedical approaches are foundational to rigorous research. New strategies are needed to identify areas ripe for replication and reproducibility efforts, as well as incentives and infrastructure to support the reproduction and replication of existing findings. NIH also seeks comments on rigor, including with regard to defining causal research.

First, validated patient recruitment biomarkers can lead to more focused clinical trials, thereby enabling more reproducible research.

Patient recruitment biomarkers have been shown to increase the probability of success, thus making pre-clinical research and earlier clinical trial results more likely to be reproduced in later stage results. A 2018 paper (Estimation of clinical trial success rates and related parameters) finds: "... trials that use biomarkers in patient-selection have higher overall success probabilities than trials without biomarkers."

A 2021 report ("Clinical Development Success Rates and Contributing Factors 2011–2020") confirms: "Indications are increasingly segmented by biomarkers in order to match patients with the treatments most likely to show the greatest benefit, according to the underlying drug mechanism and disease pathophysiology. Drug development programs with trials employing patient preselection biomarkers have a two-fold higher LOA (likelihood of approval) (15.9%) than those that do not (7.6%)."

Second, AUTM supports incentivizing discovery and publication of biomarkers by i) restoring broad patent eligibility as the Patent Eligibility Restoration Act (PERA) is intended to do, and ii) creating and using regulatory and funding incentives for data publication and sharing.

With respect to restoring broad patent eligibility, AUTM's prior comments summarize our position:
• August 16, 2023 letter to Senators Tillis and Coons: https://autm.net/AUTM/media/About-AUTM/Documents/AUTM_PERA_Support_August_2023.pdf
• September 2024 letter, joint with the Association of American Universities (AAU), The Association of Public Land Grant Universities (APLU) and ACE (American Counsil on Education) to the Senate Judiciary Committee: https://autm.net/AUTM/media/About-Tech-Transfer/Documents/AAU-Patent-Bill-Markup-Letter.pdf
• August 29, 2025 letter to Senators Thom Tillis and Senator Adam Schiff: https://autm.net/AUTM/media/About-Tech-Transfer/Documents/Support-for-PERA-2025-FINAL.pdf

Third, NIH could create incentives, such as funding sources, for confirmatory studies, publication of negative results, and transparent and enabled method sections.

Finally, with respect to research using electronic health records containing protected health information (PHI), AUTM suggests using synthetic datasets to enable replication of results, as discussed in Section II.e. of AUTM's Comments on Intellectual Property Protections for Artificial Intelligence Innovation (Docket No. PTO-C-2019-0038).

Creating regulatory and funding incentives for data publication and sharing are discussed below.

2. Data, Software, and Model Sharing: Sharing scientific data and tools accelerates biomedical research discovery, in part by enabling validation of research results, providing accessibility to high-value datasets, and promoting data reuse for future research studies. NIH seeks to incentivize and reward these activities to maximize the value of research investments, catalyze collaborations, and accelerate scientific impact.

To accomplish these goals, NIH could:

(A) Incentivize data sharing by creating databases for unique or important datasets and providing in-kind access to researchers. This would promote growth of the databases and encourage data sharing.

Examples of such special data sets include i) normative pediatric databases containing, for example, normal ranges of certain parameters for pediatric populations, ii) validation sets, such as the protein structure database used to help train and validate protein folding predictions (Protein Structure Prediction Center), and iii) authoritatively labeled and annotated databases, such as the OPTIMAM Mammography Image Database.

(B) Incentivize data sharing via regulatory incentives, such as priority review vouchers for sharing de-identified clinical trial data. Disclosure of de-identified secondary outcome data could also be incentivized. Often, secondary outcomes include biomarkers, which may be useful in subsequent clinical trials.

(C) Incentivize data sharing by encouraging publication of data structures or Electronic Relational Diagrams (ERDs) of interest. Known data structures could aid interinstitutional data sharing or multi-team collaborations as the databases would be inherently easier to combine.

(D) Convene stakeholders to foster consensus on best practices for data management. AUTM has previously commented on certain similarities between biological materials and data. (See paragraph III.c. of AUTM's Comments on Intellectual Property Protections for Artificial Intelligence Innovation (Docket No. PTO-C-2019-0038). AUTM noted that each resource requires time and commitment to produce and maintain, and there is a desire to share it with others, typically with conditions such as receiving appropriate credit. As data becomes an increasingly important research resource, it is timely for stakeholders to share their experience managing such resources, both commercially and for research purposes.

(E) Advise researchers on the most up-to-date best practices for i) data management, and ii) de-identification of PHI.

(F) Incentivize/ease data sharing via licensing by allowing managers of curated data to claim a sui generis data right in line with the EU Database Directive, which requires that such databases meet the conditions of i) systematic arrangement, ii) substantial investment, and iii) that the investment went toward obtaining, verifying, or presenting the data (and not the costs to create the data itself, e.g. cost of clinical trials). Such a sui generis right can be time limited, in which case extending the permitted period of the sui generis right can become one regulatory incentive. See in particular the discussion of data management in Section III of AUTM's Comments on Intellectual Property Protections for Artificial Intelligence Innovation (Docket No. PTO-C-2019-0038).

(G) To the extent that datasets provide support for patented inventions, the USPTO could allow the use of synthetic datasets to show possession and demonstrate enablement of such inventions. (See AUTM's Comments in Response to the United States Patent and Trademark Office's Request for Comments Titled "Unlocking the Full Potential of Intellectual Property by Translating More Innovation to the Marketplace" (Docket No. PTO-C-2024-004).

3. Training and Mentorship: NIH recognizes that advancing its mission requires promoting the growth and stability of the biomedical research workforce. While NIH supports training through existing policies and programs, additional indicators are needed to assess and quantify the impacts of these efforts. For example:

(A) The NIH can track and publish statistics on results of researchers utilizing entrepreneurs-in-residence and similar programs. How many lead to that researcher forming a start-up and engaging with industry, and how many of those engagements ultimately resulted in a new product?

(B) The NIH could ask for feedback from participating researchers to learn which aspects they found most helpful.

(C) The NIH could ask researchers to document interactions with industry they attribute to NIH programs, such as the NIH SEED program. These connections can be counted or mapped using Pajek or network diagrams to show the growth of connections across sectors from the NIH to industry.

4. Collaboration: As biomedical research becomes increasingly interdisciplinary and convergent, collaboration is growing in both scale and complexity. NIH seeks new approaches for assessing and recognizing contributions to team-based science. AUTM suggests:

(A) To streamline collaborations, retain the Bayh-Dole framework in all agreements, including Other Transaction Agreements (OTAs).

(B) Make federal funding available for multi-institutional or team projects committed to developing i) a sharable consensus on data structures and ii) data sharing.

(C) Create an ORCID system for multi-researcher and multi-institutional teams. The acronym ORCID stands for “Open Researcher and Contributor ID” and refers to individual people. Researchers use this throughout their career to show the impact of their work as evidenced by citations to it. There is no equivalent for multi-researcher and multi-institutional teams.

Looking for publications or other outputs associated with multi-researcher and multi-institutional team can be challenging because of spelling variations, misspellings, use of different abbreviations, or name changes. Teams could name themselves and register for a team ORCID to enhance their visibility.

However, AUTM cautions against overvaluing near-term metrics, such as publication counts, as these are not always reliable and dispositive indicators of the long-term public benefits we all want.

5. Entrepreneurship and Translation: To advance the translation of discoveries into actual products for people, NIH fosters the maturation of discoveries from bench to bedside and promotes innovation across sectors. More can be done to incentivize, assess, and integrate the impact of innovation and entrepreneurial efforts as critical to the NIH mission. For example:

(A) Committing stable SBIR/STTR funding is crucial, as these are important vehicles for partnerships between universities and industry.

(B) NIH could encourage researchers to work with Entrepreneurs in Residence (EiRs), other business consultants, or mentors through industry programs or workshops. As part of the program/workshop, industry partners could offer access to proposal review or potential investment through licensing or sponsored research.

(C) NIH could host workshops on AI-assisted invention, customer discovery, and business development.

(D) Using data in iEdison, NIH could track and publish aggregated data on the percentage of grants leading to new products, and time elapsed between invention, SBIR/STTR funding, and product introduction.
For additional recommendations, see AUTM’s December 22, 2025 Response to the Notice of Request for Information; Accelerating the American Scientific Enterprise (No. 2025-21150) (https://autm.net/AUTM/media/About-Tech-Transfer/Documents/OSTP-RFI-Response-by-AUTM-Dec-2025.pdf).

6. Foundational Scientific Exploration: Basic research and high-risk, high-reward initiatives represent foundational scientific exploration with an inherent risk of failure and the potential for paradigm-shifting breakthroughs. Further embedding these approaches within the academic enterprise is essential to ensuring continued support for bold and innovative research directions.

AUTM supports predictable and stable grant funding. AUTM supports and enables public-private partnerships between organizations with different and complementary skill sets. Most basic research in the U.S. is performed by nonprofits, such as the universities, academic medical centers, and research institutes that comprise AUTM’s membership. Most applied research and experimental development is performed by industry. We believe that basic research and high-risk, high-reward initiatives are well

embedded within the academic enterprise and look forward to continuing our role in America's vibrant innovation ecosystem.

7. Public Impact: NIH seeks approaches for assessing and recognizing the broader public impact of biomedical research, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit.

It is more straightforward to assess causation in focused, tightly controlled circumstances, such as lab experiments, or well-designed clinical trials, than in highly complex, interconnected systems, such as the public impact of innovation ecosystems, which is the subject of the last question in this RFI.

The AUTM data referenced above clearly show demand for public-private partnerships and provide information on the economic impact of these public-private partnerships (https://autm.net/AUTM/media/SurveyReportsPDF/AUTM-2025-US-Infographic-Fillable.pdf). However, the data focus on license agreements and lack details regarding product development timelines.

iEdison, however, may provide an opportunity to track invention and product development timelines and outcomes by funded project or by funding theme. The iEdison data include information on the entity type taking the first license, the names of the licensed products and the numbers sold, and the number of sublicenses granted. This data could be made available to select researchers for analysis of factors contributing to research programs producing visible outcomes, such as publications and patents, attracting public-private partnerships, and products on the market. Still, with respect to causal inference, such analysis should be interpreted with caution, since there is often more than one funding source per invention, and more than one invention per product. Additionally, the applied research and experimental development conducted by industry partners needed to bring products to market is an essential "cause" of the product being on the market.

Macroeconomic impacts of innovation are well documented, including notably in the 2025 Nobel Prize in Economic Sciences (https://www.nobelprize.org/prizes/economic-sciences/2025/press-release/), though the cited work was not limited to biomedical innovations and encompassed innovation overall. The first paper on "A Model of Growth Through Creative Destruction" was published in 1992.

The Bureau of Economic Analysis (BEA) identifies contributions to GDP by industry (https://www.bea.gov/data/gdp/gdp-industry). It is possible to isolate and compare over time, if desired, contributions to GDP by groups of North American Industry Classification System (NAICS) coded industries, such as research-intensive industries, chemical industries, or pharmaceutical industries. These data identify trends and relationships among industries, and shed light on factors contributing to a healthy ecosystem. The entire system of national accounts was built over decades, starting in 1947. The practical work needed to identify research-intensive industries started in 1992 and was deemed, by international consensus, complete enough to start using in 2008. See "The Evolving Treatment of R&D in the U.S. National Economic Accounts."

8. Other Areas: N/A

Description: For you conviencence, please see AUTM's attached comments in response to the Request for Information on Measuring and Rewarding Scientific Impact, Notice Number: NOT-OD-26-087 Sincerely, Stephen J. Susalka AUTM CEO

August 13, 2026

Response to Request for Information on Measuring and Rewarding Scientific Impact Notice Number: NOT-OD-26-087

Introduction

AUTM is the non-profit leader in technology transfer, representing more than 3,000 technology transfer professionals at universities, research centers, and hospitals. Our members turn basic scientific discoveries into the life-saving medicines, transformative technologies, and advanced computing engines of tomorrow.

AUTM is committed to enabling and implementing well-informed, transparent technology transfer and intellectual property policies and practices for public benefit. AUTM started collecting information about the public benefits of technology transfer in 1991 and continues to do so today. The AUTM database (https://autm.net/surveys-and-tools/databases/statt/new-accessing-statt-database) includes information on research funding, invention disclosures, patents, licenses, start-ups formed, and license revenue received, including royalty income from product sales.

The first AUTM Public Benefits Survey was conducted in 1994. It tabulated 177 products associated with 440 license agreements and grouped them by type of license (exclusive or nonexclusive), by type of business (small business or large business), by state, and by responding institution. AUTM continues to gather data on licensed technologies, which it publishes annually, and also collects university innovation narratives via its Better World Project (https://autm.net/about-tech-transfer/better-world-project).

Because this RFI seeks comments on rigor and causal research, it is helpful to note the widely acknowledged Bradford-Hill criteria for causal inference used in the scientific process, and randomized clinical trials in particular. See "The Environment and Disease: Association or Causation?" (available at https://pmc.ncbi.nlm.nih.gov/articles/PMC1898525/). The identified criteria include temporality, strength, consistency, and specificity. Moreover, there should be a plausible mechanism explaining how the cause leads to the effect, and the mechanism should be consistent with prior knowledge.

This methodical perspective has been used broadly in biology and economics. With the surge in the amount of available data, a "cause" is often a combination of causes. The effects—whether good health, a robust economy, or scientific impact—evolve over years, if not decades. Many causes interact with each other and are interdependent. Therefore, it is important not to isolate and overvalue any one factor and to keep long-term effects in mind.

(1) Rigor and Reproducibility. Reproducible and replicable biomedical approaches are foundational to rigorous research. New strategies are needed to identify areas ripe for replication and reproducibility efforts, as well as incentives and infrastructure to support the reproduction and replication of existing findings. NIH also seeks comments on rigor, including with regard to defining causal research.

First, validated patient recruitment biomarkers can lead to more focused clinical trials, thereby enabling more reproducible research.

Patient recruitment biomarkers have been shown to increase the probability of success, thus making pre-clinical research and earlier clinical trial results *more likely to be reproduced in later stage results.* A 2018 paper (Estimation of clinical trial success rates and related parameters) finds: "... trials that use biomarkers in patient-selection have higher overall success probabilities than trials without biomarkers."

A 2021 report ("Clinical Development Success Rates and Contributing Factors 2011–2020") confirms: "Indications are increasingly segmented by biomarkers in order to match patients with the treatments most likely to show the greatest benefit, according to the underlying drug mechanism and disease pathophysiology. Drug development programs with trials employing patient preselection biomarkers have a two-fold higher LOA (likelihood of approval) (15.9%) than those that do not (7.6%)."

Second, AUTM supports incentivizing discovery and publication of biomarkers by i) restoring broad patent eligibility as the Patent Eligibility Restoration Act (PERA) is intended to do, and ii) creating and using regulatory and funding incentives for data publication and sharing.

With respect to restoring broad patent eligibility, AUTM's prior comments summarize our position:

- August 16, 2023 letter to Senators Tillis and Coons: https://autm.net/AUTM/media/About-AUTM/Documents/AUTM_PERA_Support_August_2023.pdf
- September 2024 letter, joint with the Association of American Universities (AAU), The Association of Public Land Grant Universities (APLU) and ACE (American Counsil on Education) to the Senate Judiciary Committee: https://autm.net/AUTM/media/About-Tech-Transfer/Documents/AAU-Patent-Bill-Markup-Letter.pdf
- August 29, 2025 letter to Senators Thom Tillis and Senator Adam Schiff: https://autm.net/AUTM/media/About-Tech-Transfer/Documents/Support-for-PERA-2025-FINAL.pdf

Third, NIH could create incentives, such as funding sources, for confirmatory studies, publication of negative results, and transparent and enabled method sections.

Finally, with respect to research using electronic health records containing protected health information (PHI), AUTM suggests using synthetic datasets to enable replication of results, as discussed in Section II.e. of AUTM's Comments on Intellectual Property Protections for Artificial Intelligence Innovation (Docket No. PTO-C-2019-0038).

Creating regulatory and funding incentives for data publication and sharing are discussed below.

(2) Data, Software, and Model Sharing. Sharing scientific data and tools accelerates biomedical research discovery, in part by enabling validation of research results, providing accessibility to high-value datasets, and promoting data reuse for future research studies. NIH seeks to incentivize and reward these activities to maximize the value of research investments, catalyze collaborations, and accelerate scientific impact.

To accomplish these goals, NIH could:

(A) Incentivize data sharing by creating databases for unique or important datasets and providing in-kind access to researchers. This would promote growth of the databases and encourage data sharing.

Examples of such special data sets include i) normative pediatric databases containing, for example, normal ranges of certain parameters for pediatric populations, ii) validation sets, such as the protein structure database used to help train and validate protein folding predictions (Protein Structure Prediction Center), and iii) authoritatively labeled and annotated databases, such as the OPTIMAM Mammography Image Database.

(B) Incentivize data sharing via regulatory incentives, such as priority review vouchers for sharing de-identified clinical trial data. Disclosure of de-identified secondary outcome data could also be incentivized. Often, secondary outcomes include biomarkers, which may be useful in subsequent clinical trials.

(C) Incentivize data sharing by encouraging publication of data structures or Electronic Relational Diagrams (ERDs) of interest. Known data structures could aid interinstitutional data sharing or multi-team collaborations as the databases would be inherently easier to combine.

(D) Convene stakeholders to foster consensus on best practices for data management. AUTM has previously commented on certain similarities between biological materials and data. (See paragraph III.c. of AUTM's Comments on Intellectual Property Protections for Artificial Intelligence Innovation (Docket No. PTO-C-2019-0038). AUTM noted that each resource requires time and commitment to produce and maintain, and there is a desire to share it with others, typically with conditions such as receiving appropriate credit. As data becomes an increasingly important research resource, it is timely for stakeholders to share their experience managing such resources, both commercially and for research purposes.

(E) Advise researchers on the most up-to-date best practices for i) data management, and ii) de-identification of PHI.

(F) Incentivize/ease data sharing via licensing by allowing managers of curated data to claim a sui generis data right in line with the EU Database Directive, which requires that such databases meet the conditions of i) systematic arrangement, ii) substantial investment, and iii) that the investment went toward obtaining, verifying, or presenting the data (and *not* the costs to create the data itself, e.g. cost of clinical trials). Such a sui generis right can be time limited, in which case extending the permitted period of the sui generis right can become one regulatory incentive. See in particular the discussion of data management in Section III of AUTM's Comments on Intellectual Property Protections for Artificial Intelligence Innovation (Docket No. PTO-C-2019-0038).

(G) To the extent that datasets provide support for patented inventions, the USPTO could allow the use of synthetic datasets to show possession and demonstrate enablement of such inventions. (See AUTM's Comments in Response to the United States Patent and Trademark Office's Request for Comments Titled "Unlocking the Full Potential of Intellectual Property by Translating More Innovation to the Marketplace" (Docket No. PTO-C-2024-004).

(3) Training and Mentorship. NIH recognizes that advancing its mission requires promoting the growth and stability of the biomedical research workforce. While NIH supports training through existing policies and programs, additional indicators are needed to assess and quantify the impacts of these efforts. For example:

(A) The NIH can track and publish statistics on results of researchers utilizing entrepreneurs-in-residence and similar programs. How many lead to that researcher forming a start-up and engaging with industry, and how many of those engagements ultimately resulted in a new product?

(B) The NIH could ask for feedback from participating researchers to learn which aspects they found most helpful.

(C) The NIH could ask researchers to document interactions with industry they attribute to NIH programs, such as the NIH SEED program. These connections can be counted or mapped using Pajek or network diagrams to show the growth of connections across sectors from the NIH to industry.

(4) Collaboration. As biomedical research becomes increasingly interdisciplinary and convergent, collaboration is growing in both scale and complexity. NIH seeks new approaches for assessing and recognizing contributions to team-based science. AUTM suggests:

(A) To streamline collaborations, retain the Bayh-Dole framework in all agreements, including Other Transaction Agreements (OTAs).

(B) Make federal funding available for multi-institutional or team projects committed to developing i) a sharable consensus on data structures and ii) data sharing.

(C) Create an ORCID system for multi-researcher and multi-institutional teams. The acronym ORCID stands for "Open Researcher and Contributor ID" and refers to individual people. Researchers use this throughout their career to show the impact of their work as evidenced by citations to it. There is no equivalent for multi-researcher and multi-institutional teams.

Looking for publications or other outputs associated with multi-researcher and multi-institutional team can be challenging because of spelling variations, misspellings, use of different abbreviations, or name changes. Teams could name themselves and register for a team ORCID to enhance their visibility.

However, AUTM cautions against overvaluing near-term metrics, such as publication counts, as these are not always reliable and dispositive indicators of the long-term public benefits we all want.

(5) Entrepreneurship and Translation. To advance the translation of discoveries into actual products for people, NIH fosters the maturation of discoveries from bench to bedside and promotes innovation across sectors. More can be done to incentivize, assess, and integrate the impact of innovation and entrepreneurial efforts as critical to the NIH mission. For example:

(A) Committing stable SBIR/STTR funding is crucial, as these are important vehicles for partnerships between universities and industry.

(B) NIH could encourage researchers to work with Entrepreneurs in Residence (EiRs), other business consultants, or mentors through industry programs or workshops. As part of the program/workshop, industry partners could offer access to proposal review or potential investment through licensing or sponsored research.

(C) NIH could host workshops on AI-assisted invention, customer discovery, and business development.

(D) Using data in iEdison, NIH could track and publish aggregated data on the percentage of grants leading to new products, and time elapsed between invention, SBIR/STTR funding, and product introduction.

For additional recommendations, see AUTM's December 22, 2025 Response to the Notice of Request for Information; Accelerating the American Scientific Enterprise (No. 2025-21150) (https://autm.net/AUTM/media/About-Tech-Transfer/Documents/OSTP-RFI-Response-by-AUTM-Dec-2025.pdf).

(6) Foundational Scientific Exploration. Basic research and high-risk, high-reward initiatives represent foundational scientific exploration with an inherent risk of failure and the potential for paradigm-shifting breakthroughs. Further embedding these approaches within the academic enterprise is essential to ensuring continued support for bold and innovative research directions.

AUTM supports predictable and stable grant funding. AUTM supports and enables public-private partnerships between organizations with different and complementary skill sets. Most basic research in the U.S. is performed by nonprofits, such as the universities, academic medical centers, and research institutes that comprise AUTM's membership. Most applied research and experimental development is performed by industry. We believe that basic research and high-risk, high-reward initiatives are well embedded within the academic enterprise and look forward to continuing our role in America's vibrant innovation ecosystem.

(7) Public Impact. NIH seeks approaches for assessing and recognizing the broader public impact of biomedical research, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit.

It is more straightforward to assess causation in focused, tightly controlled circumstances, such as lab experiments, or well-designed clinical trials, than in highly complex, interconnected systems, such as the public impact of innovation ecosystems, which is the subject of the last question in this RFI.

The AUTM data referenced above clearly show demand for public-private partnerships and provide information on the economic impact of these public-private partnerships (https://autm.net/AUTM/media/SurveyReportsPDF/AUTM-2025-US-Infographic-Fillable.pdf). However, the data focus on license agreements and lack details regarding product development timelines.

iEdison, however, may provide an opportunity to track invention and product development timelines and outcomes by funded project or by funding theme. The iEdison data include information on the entity type taking the first license, the names of the licensed products and the numbers sold, and the number of sublicenses granted. This data could be made available to select researchers for analysis of factors contributing to research programs producing visible outcomes, such as publications and patents, attracting public-private partnerships, and products on the market. Still, with respect to causal inference, such analysis should be interpreted with caution, since there is often more than one funding source per invention, and more than one invention per product. Additionally, the applied research and experimental development conducted by industry partners needed to bring products to market is an essential "cause" of the product being on the market.

Macroeconomic impacts of innovation are well documented, including notably in the 2025 Nobel Prize in Economic Sciences (https://www.nobelprize.org/prizes/economic-sciences/2025/press-release/), though the cited work was not limited to biomedical innovations and encompassed innovation overall. The first paper on "A Model of Growth Through Creative Destruction" was published in 1992.

The Bureau of Economic Analysis (BEA) identifies contributions to GDP by industry (https://www.bea.gov/data/gdp/gdp-industry). It is possible to isolate and compare over time, if desired, contributions to GDP by groups of North American Industry Classification System (NAICS) coded industries, such as research-intensive industries, chemical industries, or pharmaceutical industries. These data identify trends and relationships among industries, and shed light on factors contributing to a healthy ecosystem. The entire system of national accounts was built over decades, starting in 1947. The practical work needed to identify research-intensive industries started in 1992 and was deemed, by international consensus, complete enough to start using in 2008. See "The Evolving Treatment of R&D in the U.S. National Economic Accounts."

Conclusion

Some research questions can be focused, such that it is possible to observe causes and effects. Systems, such as the economic innovation systems noted in this response evolve over time as a result of many interactions. In due course, they reveal trends and groups of factors contributing to a particular outcome.

Some of these suggestions, such as more and better managed data sharing, are likely to produce near-term improvements. Others, such as a continuing commitment to fund basic research, take longer to produce public impact.

Thank you for the opportunity to respond to this RFI, and we welcome the opportunity to work with you on ways to measure and grow the impact of federally funded scientific research.

Sincerely,

Stephen J. Susalka
AUTM CEO

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: The NIH should focus on the creation, preservation, and re-establishment of viable career paths for physician-scientists, often described as an endangered species.

NIH support for physician-scientist training should equally emphasize both training paths – namely, the MD-PhD route (which remains disproportionately over-emphasized in my opinion), as well as the path by which physicians complete their clinical training, without a PhD, and then undertake a research fellowship. This latter path is not as well supported financially as the MD-PhD route. Advantages of this latter path include choosing a research area when the physician is a fully trained clinician (instead of a second-year medical student) and being able to stick with the research without interruption (instead of years away from a focus on research to complete clinical training, which starts at the end of the PhD period of an MD-PhD program and lasts through the third and fourth years of medical school, then internship and residency, and then a clinical subspeciality fellowship).

Moreover, the NIH's current emphasis on basic science disfavors physician-scientists. Full-time PhD scientists have inherent advantages under the current system, such as no clinical duties to compete for their time and fewer clinically related interests to distract them from what is most likely to be funded, e.g., minutiae in animal and cell-culture models.

4. Collaboration: Big Science is not always the answer. The NIH should not neglect the individual investigator with a small laboratory.

One approach would be a formal split in funding amongst large, medium, and small laboratories or groups, so that allocations to big vs small science become a matter of policy rather than mere preferences of study section members.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: For foundational scientific exploration, I would again emphasize that the NIH should adopt policies to explicitly support and protect individual investigators with small laboratories.

7. Public Impact: Regarding your request for "specific examples of measurable indicators", NIH-supported biomedical research has a terrible problem with entrenched Big Ideas that underperform, or do not perform, for human health. The measurable indicators would be preventive strategies, medicines, and/or diagnostic tests that arise from these ideas.
Often, there are none, even after decades of support. Yet study sections still lavishly support these ideas. It's a self-reinforcing loop that relies on "friend groups" whose unelected members use their power to direct taxpayer dollars to fund each other. Based on this extensive record, I no longer believe that peer review can solve this problem.

Here is a possible solution. Grant proposals, existing extramural grants, and intramural projects studying ideas that have received US taxpayer support for ≥20 years, with little or no clinical benefit, should be subjected to special scrutiny – but outside of peer review. Ideas that are 10-19 years old, with little or no clinical benefit, should also be re-evaluated, but less stringently. Existing literature supports these thresholds, e.g., “Promising technologies that did not lead to a published human study within 10 to 12 years were unlikely to be tested in humans subsequently.” (doi: 10.1016/s0002-9343(03)00013-5)

Of course, persistent lavish funding for under- or non-performing Big Ideas means less support, or no support, for approaches that might actually improve human health.

Here are relevant citations that contain specific examples of the problem:

4. Williams KJ. Inflammation in atherosclerosis: a Big Idea that has underperformed so far. Curr Opin Lipidol. 2025;36:78-87. doi: 10.1097/MOL.0000000000000973. Open access hypertext at https://journals.lww.com/co-lipidology/fulltext/9900/inflammation_in_atherosclerosis__a_big_idea_that.106.aspx ; open-access PDF at https://pmc.ncbi.nlm.nih.gov/articles/PMC11888836/pdf/colip-36-78.pdf (which has remarks on the citations that were highlighted with bullets).
5. Williams KJ. Anti-inflammatory agents in atherosclerosis—and a need for reform: Extraordinary claims require extraordinary evidence. J Intern Med. 2026;300:258-283 (ePub 2026 July 12). doi: 10.1111/joim.70128. Open-access at https://onlinelibrary.wiley.com/doi/10.1111/joim.70128 .

References #4 and #5 deal with the Big Idea that inflammation must be a definitive therapeutic target in atherosclerotic arterial disease, the biggest killer in the USA and worldwide. My search today of the NIH RePORTER database for "inflammation" and "atherosclerosis" identified over 16,000 grants with those keywords, spanning decades and totaling well over US$6,500,000,000. PubMed lists over 34,000 articles with those keywords. Reference #5 listed at least 57 (fifty-seven) published human clinical trials of anti-

inflammatory agents in this disease, with no signs of slowing.

And yet, there is nearly nothing to show for human health. There is just one anti-inflammatory medication – colchicine – with FDA approval for patients with atherosclerotic arterial disease. But cardiologists are not using it because the most recent clinical trials of this agent showed no benefit or even harm (see ref. #5). Reference #5 suggests that these new trial data should prompt the FDA to re-examine its cardiovascular indications for colchicine.

The field of inflammation in atherosclerosis has produced just one approved diagnostic marker – serum levels of CRP – but CRP adds only slight predictive power beyond conventional risk factors for ASCVD events. Far more useful are recent advances in technologies to image the arterial wall, which outperform every additional marker in plasma or serum in the clinical assessment of ASCVD event risk (see ref. #4).

Many of these points are summarized in the Graphical Abstract of reference #5.

Shortly after reference #5 was published online, Novo Nordisk announced that its much-anticipated ZEUS trial of IL6 inhibition (an anti-inflammatory strategy) in patients with ASCVD, CKD, & elevated CRP levels showed no benefit. see
6. https://finance.yahoo.com/healthcare/articles/novo-nordisk-stock-tumbles-10-120558178.html and
7. https://www.nytimes.com/2026/08/06/health/heart-disease-drug-fails-novo-nordisk.html , among others.

These sentences from reference #5 seem relevant.
"How many dozen clinical trials that failed to bring a new therapy to patients in need, over how many decades, and at what personal and financial cost will it take for us to move past a concept that has produced so little for patient care? Table 1, Table S1, and this text list a total of at least 57 human clinical trials of anti-inflammatory agents in patients with atherosclerotic arterial disease, spanning more than the past third of a century, without clear benefit and with no signs of stopping. Do we need a 58th trial? A 98th?"

Well, now we have our 58th.

Moreover, 2026 is on track to being another banner year of NIH support for "inflammation" and "atherosclerosis": 400 projects so far. Every year since 2007, two decades ago, shows at least 400 NIH-supported grants with those keywords.

Reference #5 also briefly reviewed the closely related theory of LDL oxidation in atherosclerosis. That idea has also been lavishly supported by the NIH. Yet "Decades of highly funded work on that hypothesis ended in ashes: no approved antioxidant medications in atherosclerosis and no approved diagnostic tests" (ref. #5).

"Sometimes peer review fails in this way." Why are theories that come to nothing still supported?

Because no outside authority that answers directly to the voting, taxpaying public ever steps in to stop this self-serving waste.

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: Improving scientific rigor and reproducibility is urgent, and it requires strengthening the institutional review process. The program officer is the most important hub for tracking trends within a scientific field and for overseeing both the scientists in a portfolio and new applicants. Experienced program officers have a better understanding of the field than out-of-field reviewers on study sections, and are therefore better placed to judge fairly.

Science today cannot be assumed to run on goodwill alone. NIH needs the resolve to confront the minority of scientists who damage public trust in science and to impose real consequences. Once a scientist is flagged for failures of rigor or reproducibility, program officers can weigh that record in the next grant review or terminate an existing award. To equip program officers to judge fairly, NIH should build a system that collects and analyzes the information they need.

1. Poor data quality in publications:
Establish an office that, at a program officer's request, analyzes data quality in the publications of portfolio scientists and applicants. The problems extend well beyond duplicated images. For example, animal behavior experiments in high-profile journals frequently rely on very small sample sizes (n = 7–8). In my experience, animal behavior is highly variable, so samples of that size cannot support firm conclusions. Statistical anomalies are a further warning sign of fabrication.

2. Misconduct by PIs within their laboratories:
Establish an anonymous reporting system for research misconduct.
a) Data fabrication in published papers. PubPeer records should be incorporated as additional input.
b) PIs pressuring subordinates to produce favorable data. Complaints of this kind are heard regularly from graduate students and postdocs, including in laboratories that publish in high-profile journals. In most cases, the complainants leave the laboratory quietly.

3. False collaborations:
Inflating the number of authors in publications dilutes achievements and obscures responsibility when fraud is identified. NIH should require a fractional measure of each author's contribution, with the contributions for any publication summing to 1. The distribution should be agreed upon among the authors at the time of publication. Until such a system exists, credit should be divided equally, at 1/n per author. When a paper is retracted, all authors should be flagged equally. Critics may object that this

would discourage collaboration; in my view, genuine collaboration would be unaffected.

4. Institutional incentives favor the business of science over its quality:
University administrators pressure PIs to have graduate students complete PhD theses within three years. By the time a thesis reaches the defense committee, it is difficult to intervene even when the work is immature. The academic research enterprise is oriented toward expansion: enrolling more graduate students and securing more federal funding. Indirect cost recovery, meanwhile, appears to be reinvested in recruiting additional faculty to sustain that expansion. The anonymous reporting system should also capture institutional behavior of this kind to inform HHS re-negotiations of indirect cost rates.

Description: We have attached our winning proposal for the NIH Data Sharing Index (S-Index) Challenge.

Introduction of Team

Thank you for the opportunity to participate in the NIH Data Sharing Index Challenge. We have devoted our careers to promoting open science and facilitating the sharing of data and scientific knowledge. Together, we represent *and have the ability to convene* **key stakeholder communities** required to advance NIH's goals of incentivizing and rewarding data sharing and data reuse and driving a culture of openness, transparency, and explainability in science. We are a multidisciplinary team of experts from academia (MIT, Northwestern U, PSU, U Colorado, Indiana U); publishing (arXiv, bioRxiv, medRxiv, MIT Press, CSHL Press); research materials and data sharing (Addgene); research information management systems (Digital Science, VIVO, Profiles); identity management (Crossref, ORCID, InCommon); and scientific funding (former associations with HHMI, Wellcome Trust, Health Research BC) and policy making. Our team includes inventors of widely used quantitative metrics (Dimensions, Altmetric) and data visualizations (Atlas of Science) related to scientific productivity and impact. We have attached **Letters of Support** from additional organizations that will join us in this effort, including the Gates Foundation, Novo Nordisk Foundation, Sloan Foundation, HHMI Janelia, Navigation Fund, DataCite, Data.org, Make Data Count, CRediT, Invest in Open Infrastructure, Zenodo, GREI, FASEB, Accountability in Research, CTSA Eval., NNLM-NEC, and university librarians. (A list of acronyms used in this document can be found in **Table S1**.)

Katy Börner, PhD
Professor of Engineering & Information Science, Indiana University; Atlas of Science; Human Reference Atlas
Data analysis and visualization

Amy Brand, PhD
Director and Publisher of the MIT Press; previously on Boards of Crossref, ORCID; Faculty Promotion and Tenure
Linguistics, cognitive science

Kristi Holmes, PhD
Assoc. Dean, Northwestern; Advisor: HELIOS Open, Make Data Count; InCommon, US Repository Network; Zenodo GREI lead
Evaluation, data repositories, libraries

Daniel Hook, MBA, PhD
CEO, Digital Science (Figshare, Altmetric, Symplectic, Dimensions, GRID); Research on Research Institute (RoRI)
Quantum statistical physics

John Inglis, PhD
Co-founder, bioRxiv, medRxiv; Founding Exec Dir., CSHL Press; previously *The Lancet Immunology*

Chonnettia Jones, PhD
Executive Director, Addgene; formerly HHMI, Wellcome Trust, Health Research BC and Chan Zuckerberg Initiative Open Science Advisory Board member
Research funding, policy & assessment

Arjun Krishnan, PhD
Assoc. Professor of Biomedical Informatics, Center for Health Artificial Intelligence, University of Colorado Anschutz
Biomedical informatics, machine learning, AI

Steinn Sigurdsson, PhD
Scientific Director, arXiv; Professor of Astrophysics, Pennsylvania State University
Theoretical physics

Griffin Weber, MD, PhD *(Team Captain)*
Assoc. Professor of Biomedical Informatics, Beth Israel Deaconess Medical Center; Profiles; Electronic Health Records (i2b2)
Medicine, clinical data, computer science

Engaging key stakeholder communities to promote data sharing and reuse and to understand impact through a composite S-Index

Introduction

Each member of our team has made significant contributions to advancing openness, transparency, and explainability in science. We understand the importance of this to performing high quality reproducible research, accelerating new discoveries, and understanding the meaningful impact of research. Even so, we also recognize that there is a need for creative new ways of incentivizing researchers to not only share data, but also to increase the "value" of their data (e.g., ensuring high-quality data, detailed metadata, and adherence to FAIR principles). The specific task of this NIH Challenge is to propose a person-level metric that rewards sharing high-value datasets. However, as the Landscape Report leading to this Challenge showed, defining a data-sharing index, or "S-Index", is not enough. We believe the larger impact of this Challenge will be bringing key stakeholder communities in the NIH Data Sharing and Scholarly Reward Ecosystem ("Data Ecosystem") together to catalyze a real culture change in which researchers, their research organizations, funders, editors, and the general public develop a greater appreciation for the scholarly contributions of sharing and reusing high value datasets, on par with publishing in high-impact journals. We start with a conceptual framework representing different components of a shared dataset's value and an initial composite S-Index prototype. Through a series of stakeholder workshops, we will refine the framework and its individual quantitative and qualitative measurements, which may be weighted differently based on context, and are linked to clear data sources. We will work with stakeholders on a phased implementation to integrate the S-Index into key stages in the data lifecycle. Maintaining trust with stakeholders throughout this process will be critical for success.

Conceptual Innovation

What makes our model unique? Our model uses a **participatory approach** that engages stakeholders in the co-development and implementation of the S-Index to ensure that it is understandable, usable, and meaningful (**Table 1**). Close collaboration with stakeholders has been essential to the widespread adoption of open science innovations and the S-Index will be no different. An important part of this is **trust**, because as with other metrics, there is a risk that an S-Index will have unintended negative consequences. For example, researchers must be assured that the S-Index won't favor certain disciplinary perspectives, negatively impact their promotion and tenure, or encourage competing labs to use their data without proper credit. The S-Index cannot achieve its intended utility, impact, and cultural change without this trust.

Stakeholder Group	Understandable	Usable	Meaningful
Researchers and data producers	Links data sharing to impact	Integrated into familiar tools; automatically generated	Shows academic value (for P&T); leads to collaboration
Funders and policy makers	Summarizes impact in policy terms	Pulls from existing reporting & monitoring systems	Demonstrates innovation & health impact; informs strategy
Data repositories and infrastructure providers	Measures usage/reuse clearly	Embedded in analytics/metrics; uses existing data processes & PIDs	Informs service; enhances metadata
Healthcare providers	Indicates real-world clinical relevance	Highlights trusted datasets; requires no additional input	Supports evidence-based practice
Patients and the public	Shows data; demonstrates clear health outcomes	No action required; openly available; presented in accessible formats	Builds trust & consent; accountability to taxpayers
Publishers, journals, aggregators	Connects datasets to publications, research objects	Integrated into editorial & peer review workflows	Enhances transparency & integrity
Universities and research organizations	Shows cross-institutional collaboration; links to patents	Can be aggregated at the person, department, or organization level	Enables benchmarking; helps promotion & tenure decisions

Table 1. Factors that will drive adoption of the S-Index while maintaining stakeholder trust.

How does it differ from existing methods? Our S-Index is a composite metric based on a **conceptual framework** (**Table 2**) that considers four distinct facets of the data: (1) *datasets as objects* that can be viewed, downloaded, or cited; (2) the *metadata* describing the quantity of

data and characteristics that indicate its "FAIRness"; (3) the *contents* of the data in terms of quality and informativeness; and (4) the broader *context* that shapes the impact and reputation of the data. Each facet has components with quantitative measures. These are complemented with additional qualitative assessments of the *context*.

Facet	Component	Measurements	Sources	Examples
1: Datasets as individual objects	Usage	Number of datasets, views, downloads	GREI Repositories	Figshare; Zenodo
	Reuse	Number of literature citations	Publishers and aggregators	Dimensions, Other aggregators
		Number of other citations	Internet, workspaces	Media mentions (Altmetric), Code (GitHub), Patents (IFI)
2: Metadata	Quantity	Number of records, features, bytes of data	Analysis of the metadata	A.I. & Machine Learning, NLP entity recognition, Knowledge graphs, Network analysis, Large language models
	FAIRness	Findable, Accessible, Interoperable, Reusable		
3: Contents	Quality	Machine readable, completeness, plausibility	Analysis of the dataset	
	Informativeness	Information content, entropy		
4: Context	Impact & Reputation	Supporting and contrasting citations	Analysis of other datasets	
		Derived datasets and other works		
		Qualitative assessment	Health, social, economic context	

Table 2. Conceptual framework of a composite S-Index.

How do these methods enhance the evaluation of data sharing? Although the composite S-Index is a single person-level metric, our framework and prototype emphasize transparency, trust, and explainability by providing easy access to the individual components, their measurements, and their underlying data sources. It makes the factors that contribute to the value of a dataset easier to understand; it allows the relative weights of these components to be adjusted by discipline, data type, use cases, or objectives; and it lowers the chance of misuse.

What creative methods are involved? We will host a series of **Stakeholders' Workshops** in Washington, DC, with attendees drawn from the wide range of stakeholder communities that our team represents (see our **Letters of Support** for examples), and other submitting teams to the S-Index Challenge. This will be critical to gaining acceptance of the S-Index, refining its framework, promoting its use, encouraging the sharing of high value data, and communicating meaningful impact. The NIH is considering an initial public event after the completion of the Challenge. In that case, our workshops will build on that momentum by working with the NIH to reconvene stakeholders regularly throughout the S-Index implementation process.

Validation and Testing

How will you validate and test your S-Index? We implemented as our main interpretable data sharing metric a **"GREI-Dimensions" Prototype**, available at (https://DataSharingIndex.org, password "sindex2024"). It aggregates datasets across more than 1,620 repositories, leveraging existing infrastructure and data made available by Daniel Hook, the CEO of Digital Science, whose portfolio of companies include **Figshare**, **Dimensions**, and **Altmetric**; and Kristi Holmes, **Zenodo** lead on the **NIH Generalist Repository Ecosystem Initiative** project (**GREI, Figure S1**) and Make Data Count advisor (**Figure S2**). This prototype demonstrates two facets of our composite S-Index framework, measuring ***reuse*** of datasets by adding both direct citations (to the datasets) and indirect citations (to the datasets' publications) and controlling for ***context*** by normalizing these citation counts by field and year.

However, stakeholder groups have different perspectives on what high value data sharing means and it will be essential to work with them in refining the S-Index. In line with this participatory approach, we have also implemented an **"Alternative PubMed" Prototype** (https://DataSharingIndex.org/Alt) to demonstrate to stakeholders the flexibility of our framework and to provide concrete examples of additional measurements that can be added to the final **consensus composite S-Index**. The prototype calculates a weighted sum of nine measurements representing each of the facets and components of our framework. To make these easy to explore, replicate, and validate, the "datasets" in this prototype are journal articles

in PubMed with associated Data Bank records in their metadata. The top Data Banks in PubMed are ClinicalTrials.gov, figshare, Dryad, and GenBank. The individual metrics include an h-index-like score (number of articles with data and at least that many citations); whether the articles are in PubMed Central (FAIRness); the number of other datasets the article cites (provenance, integration of existing data); relevance to human health; and others. All the data for these alternative measures are available at https://DataSharingIndex.org/Data.

Have you included preliminary results? Our GREI-Dimensions Prototype calculates an S-Index for 349,446 authors with 34,780,590 datasets; 1,690,784 direct citations; 132,517,596 indirect citations. The top fields of the datasets include physical sciences (61%), biological sciences (20%), engineering (16%), computer science (8%), and chemical sciences (8%). The mean S-Index is 0.677 (StDev 4.66, max 350.81). Our Alternative PubMed Prototype calculates an S-Index for 232,968 authors (with ORCID iDs) in PubMed who published 110,655 articles associated with 193,182 Data Bank records and cited 1,367,392 times. Most authors have very few data articles (mean 1.53) and 74.6% have just one (**Figure S3**). However, a composite S-Index with multiple measurements creates a clear spread (mean 18.8; StDev 6.84), which is important for comparing individuals and measuring change as they share more or higher value datasets (**Figure S4**). **Figure S5** shows the relationship between authors' h-index and S-Index.

Implementation considerations to be discussed at the Stakeholder Workshops: Publication metrics like h-index benefit from their context: there is general agreement on what a publication is; journal articles are relatively similar in length and number of references; and they are already aligned with criteria used for promotion, tenure, and professional awards and honors (providing a "gold standard" for metric validation). In contrast, there are many open questions about defining a "dataset" and how to handle certain types of data and ways of sharing data (**Table 3**).

Dataset Definitions	Assigning Credit	Policies
• Do we measure at the level of entire datasets and data collections, or at individual data records or files? • Are regular updates to an existing dataset as new data objects? • Do we count the digital objects required to use the data like software code, protocols, and codebooks?	• How do we distribute credit for massive datasets with thousands of contributors? • How do we handle the vast differences in data sizes, from KBs to PBs? • Should data with restricted access, such as hospital electronic health records, or data stored in secure enclaves be penalized?	• Should we require that data be indexed in a NIH or GREI repository? • Should specific types of data (molecular, clinical/health, behavioral, imaging, population, wearables) or data characteristics (simulated/synthetic, human/non-human, raw/processed, primary/secondary) be measured or weighted differently?

Table 3. Implementation considerations.

Feasibility

Can your idea be realistically implemented? What technologies and resources are needed? Are these attainable? As illustrated by our prototypes, our framework and composite S-Index can adapt to different data sources and measurements that can be expanded and refined over time. GREI research repositories, including Figshare and Zenodo (built on InvenioRDM), already compute basic metrics (e.g., number of shared datasets, usage statistics), and have adopted the GREI recommendations to support consistent practices to collect, expose and aggregate citations to open data (**Figure S6**). This is extended with citation data from Dimensions (**Figure S7**); open resources such as DataCite and CrossRef Event Data and EuropePMC, already integrated into Zenodo. The NLM Dataset Catalog has ingested GREI repositories.

What is the likelihood of acceptance by key stakeholders? How does the model align with current needs and contexts? Stakeholder buy-in and usability are central to the design and implementation of the composite S-Index, laying the groundwork for widespread acceptance, adoption, and impact. Our Stakeholder Workshops offer an opportunity to support active, meaningful, responsive, and sustainable collaboration with stakeholders from across the Data Ecosystem. Katy Börner, who has organized more than 40 conferences and workshops over the past decade, will lead the planning of these events.

User-Friendliness

How will you ensure the S-Index is easily accessible to researchers across disciplines and requires minimal training for effective use? Our prototypes have a simple intuitive interface that emphasizes transparency and enables exploration of the individual measurements that combine into the S-Index. We will conduct usability testing and obtain feedback on the prototypes at our Stakeholder Workshops. Our GREI-Dimensions Prototype covers all disciplines and normalizes by field. Our Alternative PubMed Prototype takes inspiration from Altmetric's use of colorful "badges" (**Figure S8**) to create one that concisely summarizes the components of the S-Index and provides context by listing the primary discipline (**Figure S9**). Help text defines each metric and lists the behaviors they are expected to encourage and their potential risks (**Figure S10**).

Scalability

Can your metric scale to handle large datasets, different types of data, formats and disciplines? Our GREI-Dimensions Prototype scans real-time internet sources using scalable infrastructure and computational methods developed by Altmetric. It normalizes by field, and our alternative prototype shows normalizing by data type. As we move beyond the prototypes we will use AI to assist in parsing metadata and examining the contents of datasets to measure their quality and informativeness. For example, Arjun Krishnan developed software that uses natural language processing and embeddings to map unstructured text descriptions of genomic data to controlled vocabularies (PMID:36347858); Griffin Weber implemented a machine learning model to characterize data completeness in electronic health records (PMID:37632234); and Kristi Holmes looked at the impact of generative AI in scholarly evaluation (in press).

Interoperability

How will your S-Index promote data standards and interoperability and integrate with existing data sharing tools, platforms and tools? The 7 GREI repositories represent some of the largest research repositories across commercial and non-profit organizations. Many universities and domain repositories use these platforms, and there will be future adoption through USRN. GREI repositories have implemented the COUNTER-based 'Make Data Count' standards that enable collection of standardized data usage (views and downloads) and data citation metrics. Key to interoperability will be machine readability; adherence to FAIR Principles; persistent identifiers; widely used metadata schemas and tools to support metadata mapping; standard formats (e.g., JSON-LD); APIs; and case study examples of successful implementations and use cases.

Adoption Strategy

What is your plan to promote the S-Index, involve the research community in adoption and use, and provide outreach and education to encourage widespread use? We have a five-year plan with a high-level goal to incentivize and reward high-value data sharing while producing a lasting cultural shift in how research outputs are assessed and valued. The phased plan will achieve (1) governance and pilots; (2) broad adoption and integration; and (3) global, trusted, FAIR-aligned, integrated open infrastructure (**Table 4**). Our team has collectively been successful in doing this across many initiatives. For example, Amy Brand helped develop governance frameworks for ORCID and CRediT. As Director of MIT Press she will coordinate outreach to journals and Stein Sigurdsson from arXiv and John Inglis from bioRxiv/medRxiv will engage with preprint servers.

Sustainability

What is your plan for long-term sustainability and potential funding partnerships? How will you ensure that the S-Index remains relevant and effective over time? The sustainability plan is aligned with the adoption strategy to ensure that the S-index remains open, trusted and adaptable to evolving research practices and community needs (**Table 4**). Chonnettia Jones is leading efforts to achieve sustainable financing through diversified funding sources. Several funders and partners have already indicated willingness to offer support (**Letters of Support**).

Phase	Adoption	Sustainability
Year 1 Governance and pilots	• Establish a governance ecosystem that builds trust, early institutional adoption, and coordination with the NIH • Present prototypes at stakeholder workshops • Reach out to journals to pilot extended metadata to better capture authors' contributions to data • Publish an article about the S-Index in a prominent journal • Identify influential academics to help us spread the word	• Achieve financing through diversified funding sources, including pooled funding from public and private funders and in-kind resources from partners • Commit a proportion of the Challenge Prize to fund knowledgeable staff with experience of managing stakeholder relationships
Years 2-3 Broad adoption and integration	• Expand to 30-50 institutions through partnerships with HELIOS Open, CoARA, others • Add S-Index to researcher profiling systems (e.g., ORCID, Profiles, Symplectic Elements) • Implement APIs for institutions, funders, and publishers • Use dashboards and benchmarking to highlight reproducibility and institutional cost-savings via data reuse	• Implement fee-for-service models, in collaboration with research institutions, libraries, infrastructure providers, and publishers, such as premium analytics and benchmarking, while upholding our collective commitment to openness and transparency
Years 4-5+ Global, trusted, FAIR-aligned, integrated open infrastructure	• Incorporate into P&T, funder reporting, and the global benchmarking ecosystem • Be on a standards pathway (similar to CRediT's NISO) • Implement real-time updating and predictive analytics. • Enable major longitudinal reports on research reproducibility and cost savings	• Establish an independent entity (inspired by the nonprofit 501(c)3 openRxiv) to manage pooled funds and structured to ensure broad stakeholder representation and to coordinate agile adaptation to changes in technology, research practices, standards

Table 4. Phased approach to adoption and sustainability.

Metrics for Success

How will you assess success and impact; track and report the performance of the S-Index and its effectiveness in promoting data sharing? Led by Kristi Holmes, we will have a clear and comprehensive approach to monitoring, reporting and evaluating the S-Index. Proposed key indicators and metrics (**Table 5**) will need input from the parties impacted by the S-Index (e.g., researchers, institutions, publishers, repositories, funders, etc.).

Success and Impact	Performance	Promoting Data Sharing
• Implementation (discoverable repositories/datasets, frictionless connection and onboarding) • Behavior (shared datasets, improved metadata quality and completeness) • Reuse outcomes (dataset citations, downloads, cross-disciplinary reuse) • Adoption (incorporation in P&T workflows) • Downstream impact (citations in policy documents, guidelines, patents)	• Monitoring the prototype interface usage and feedback • Dashboards for longitudinal context on dataset production and reuse • Quality control to ensure efficient data streams • Bias audits to monitor career stage, discipline, funders	• Increases in publications with linked datasets and higher rates of dataset citations • Improved linking of cited datasets in the PID graph to the works and people responsible • Institutional adoption of composite S-Index data in evaluation and P&T processes • Adoption demonstrated in NIH Biosketch, RPPR workflows, SciENcv

Table 5. Indicators for evaluation of the S-Index.

Impact

How will your model incentivize data sharing and impact researchers' behavior? Our framework offers stakeholders a nuanced tool to drill into **key facets of interest**, depending on need. Stakeholders' choice of weights in the composite S-Index will incentivize different behaviors. The Stakeholder Workshops will consider, for example, which components, if emphasized, would be valued in academic promotion or would encourage researchers to generate better metadata. How will your model identify, and reward widely used and impactful data resources? Our framework considers a range of different metrics to quantify use and impact. We have found that creative ways of using and visualizing metrics greatly aids in their adoption. These include adding eye-catching badges to expert finder systems (**Figure S11**), rendering dataset citation network graphs (**Figure S12**), and illustrating institution-level data sharing trends (**Figure S13**).

Conclusion

We present a conceptual framework and composite S-Index prototype that captures different facets of data sharing. However, key stakeholders must be involved in refining it and in its future implementation. They must trust both the final metric and the process that will get them there to (1) ensure its long-term impact, scalability, and sustainability and (2) lead to cultural change.

Table S1. Acronyms used in this proposal

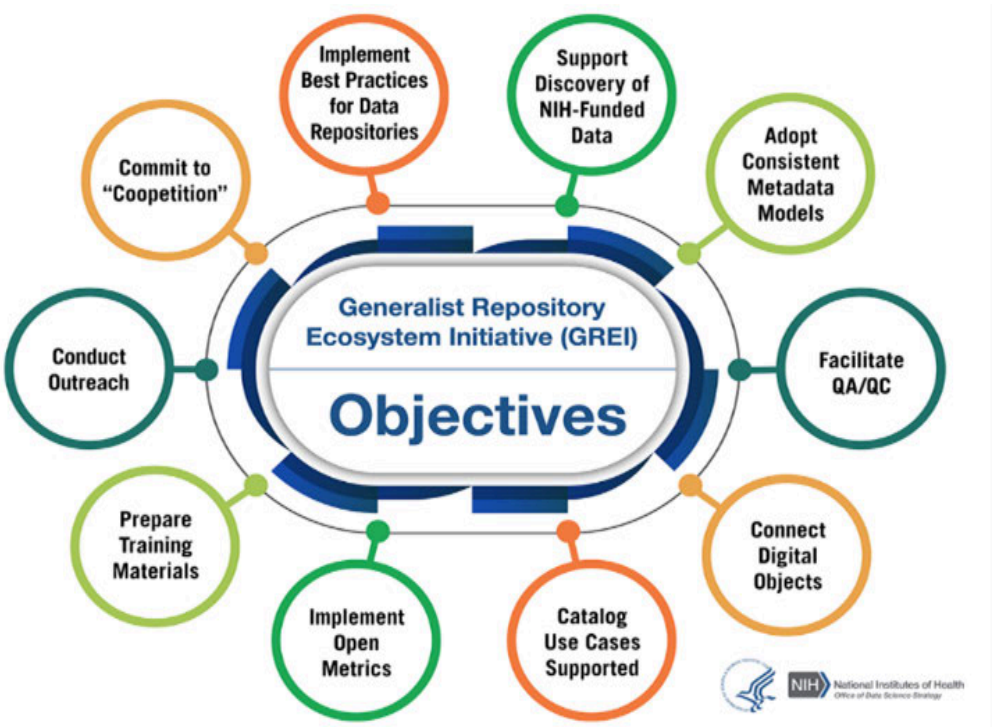

Figure S1. Vision of the NIH Generalist Repository Ecosystem Initiative (GREI) and established generalist repositories that work together to establish consistent metadata, develop use cases for data sharing, and educate researchers on FAIR data and the importance of sharing.

Figure S2. Make Data Count, a community-led initiative focused on driving transparent and meaningful open data metrics so that research data are valued research outputs across scholarly activities, evaluation, and communications.

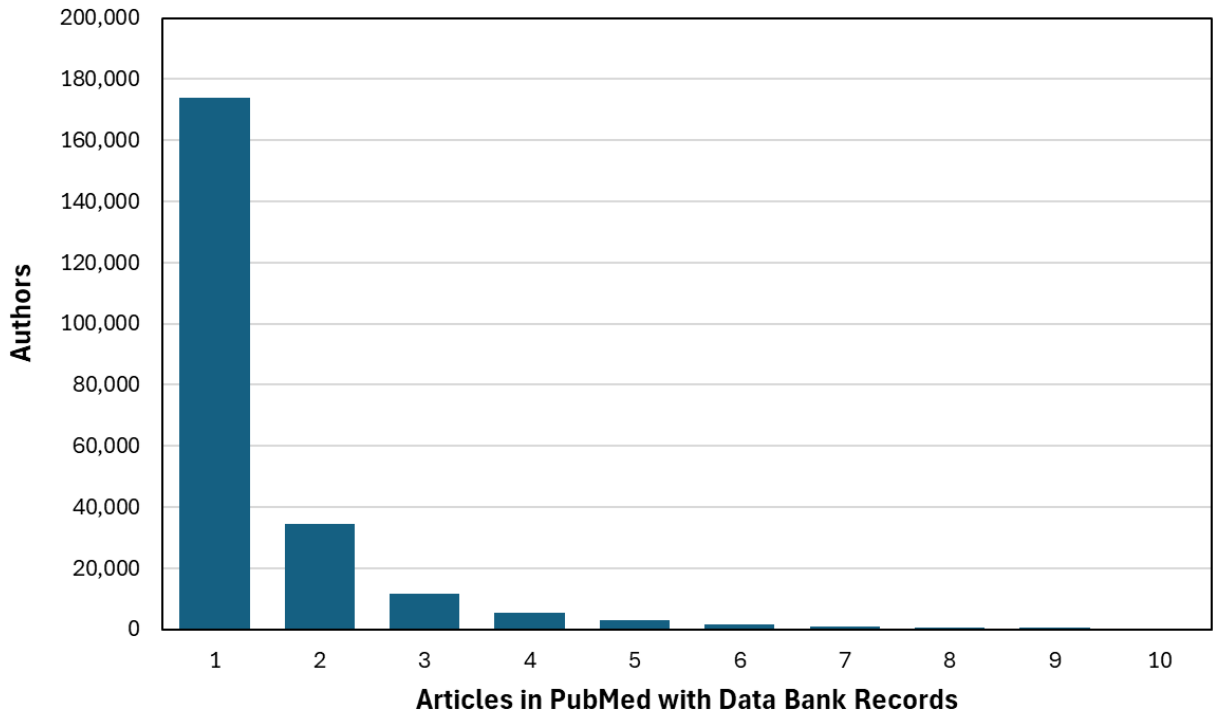

Figure S3. Distribution of the number of articles authors have published in PubMed with associated data bank records (from the Alternative PubMed Prototype). Note that 74.6% of authors have a single article, with an overall average of 1.53. As a result, an S-Index based only on “counting” metrics might show too little difference between people to be useful. A more nuanced composite metric is needed to compare the relative value of each article.

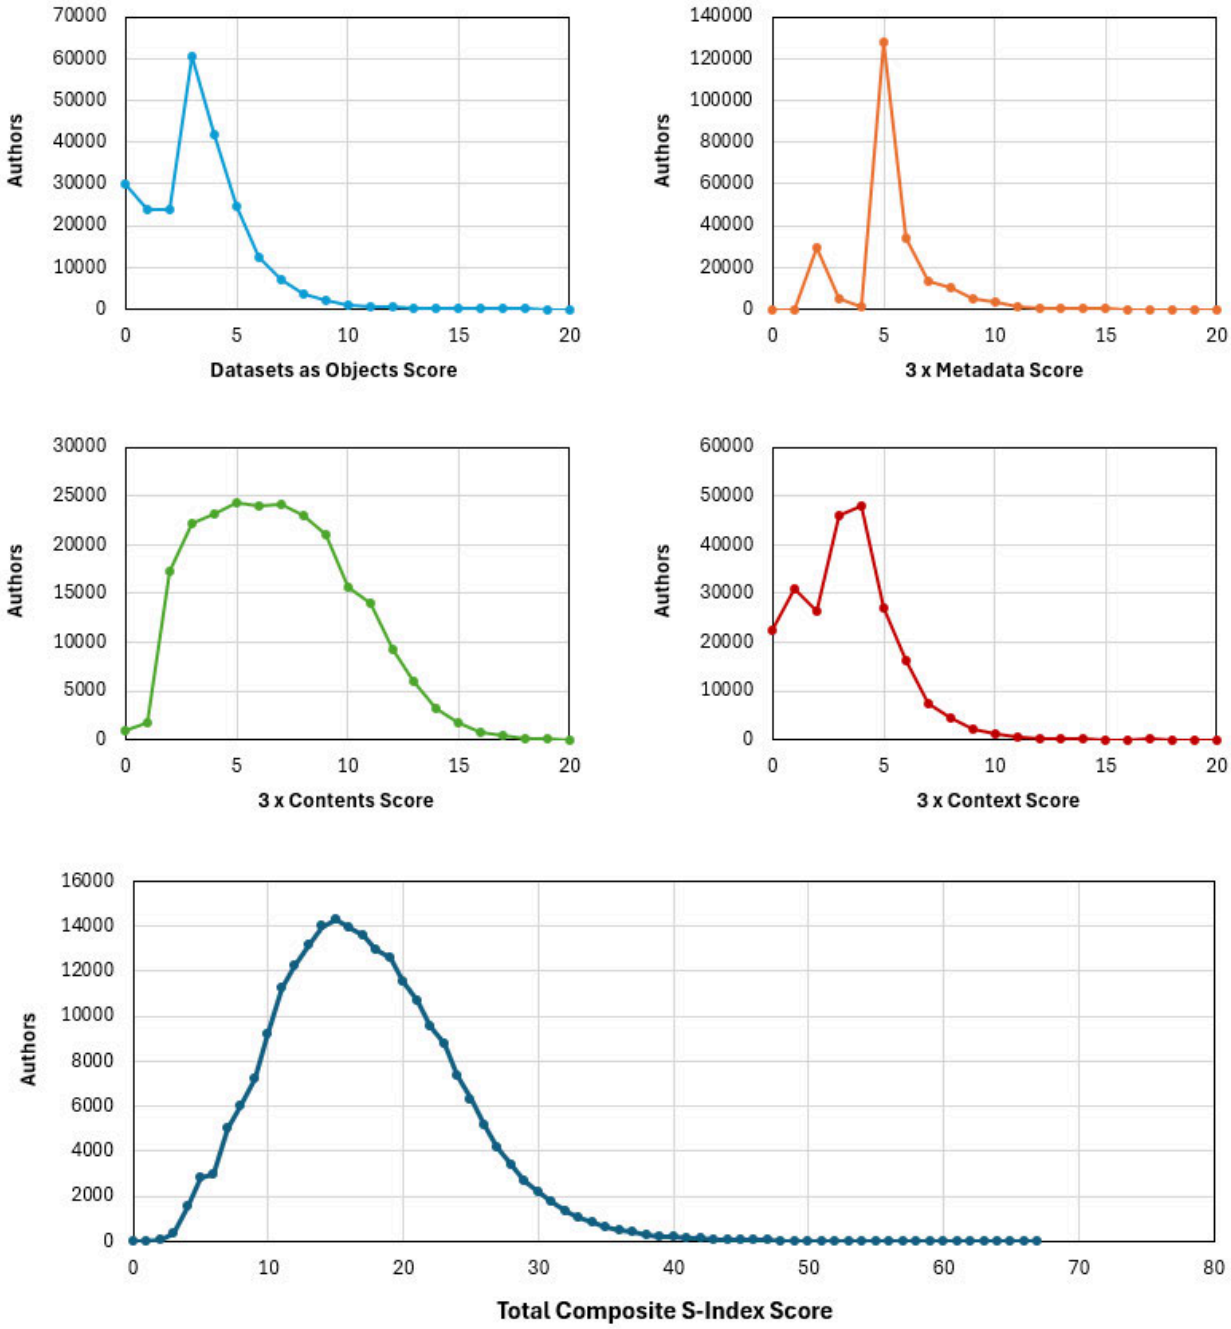

Figure S4. Distribution of S-Index values from the Alternative PubMed-based prototype. The top four graphs show the score distributions for each facet of data sharing. The bottom graph is the sum of individual scores, or the **Total Composite S-Index**. Note that a composite index creates a distribution that is smoother and with a greater spread than any facet alone. Its range is also similar to the familiar h-index (roughly 1 to 100), making it easy to interpret and remember.

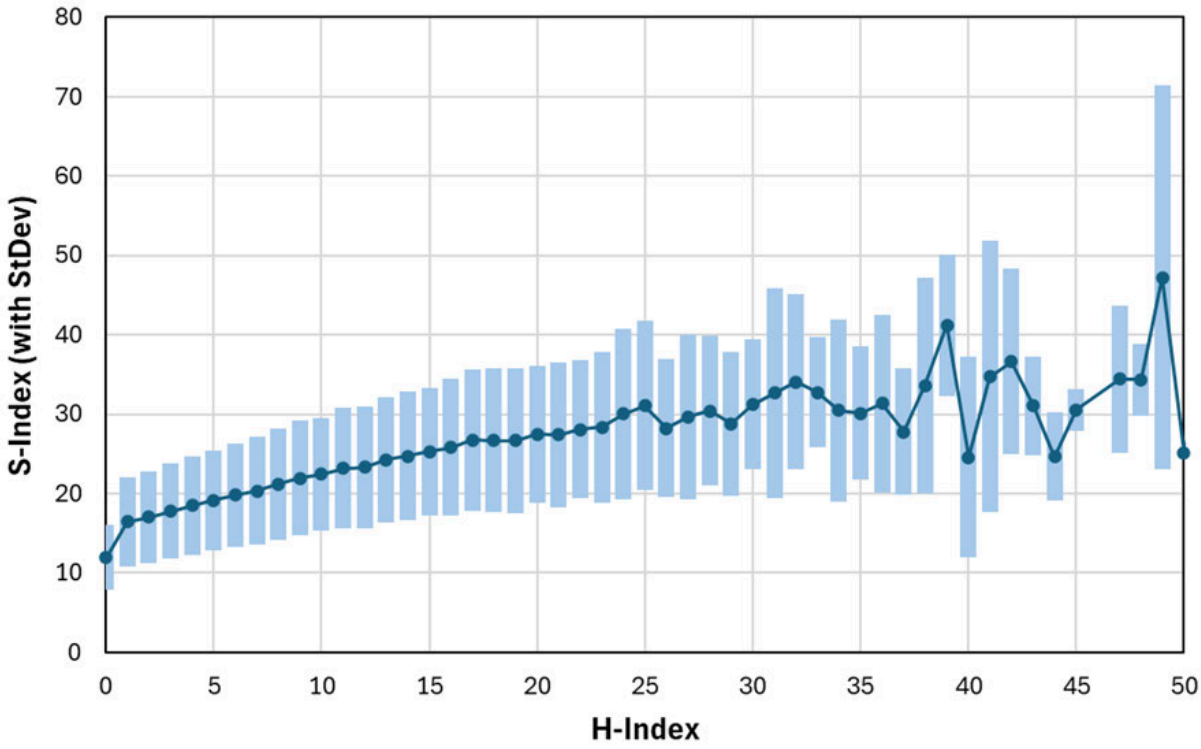

Figure S5. Relationship between authors' h-index and S-Index in the Alternative PubMed-based prototype. Bars show standard deviation. Although there is some correlation between authors' h-index and S-Index, authors with a small h-index can have an above average S-Index and vice versa. In other words, it emphasizes the need for an S-Index by demonstrating that sharing high value data is a unique characteristic of scholarly impact that isn't fully captured by the h-index.

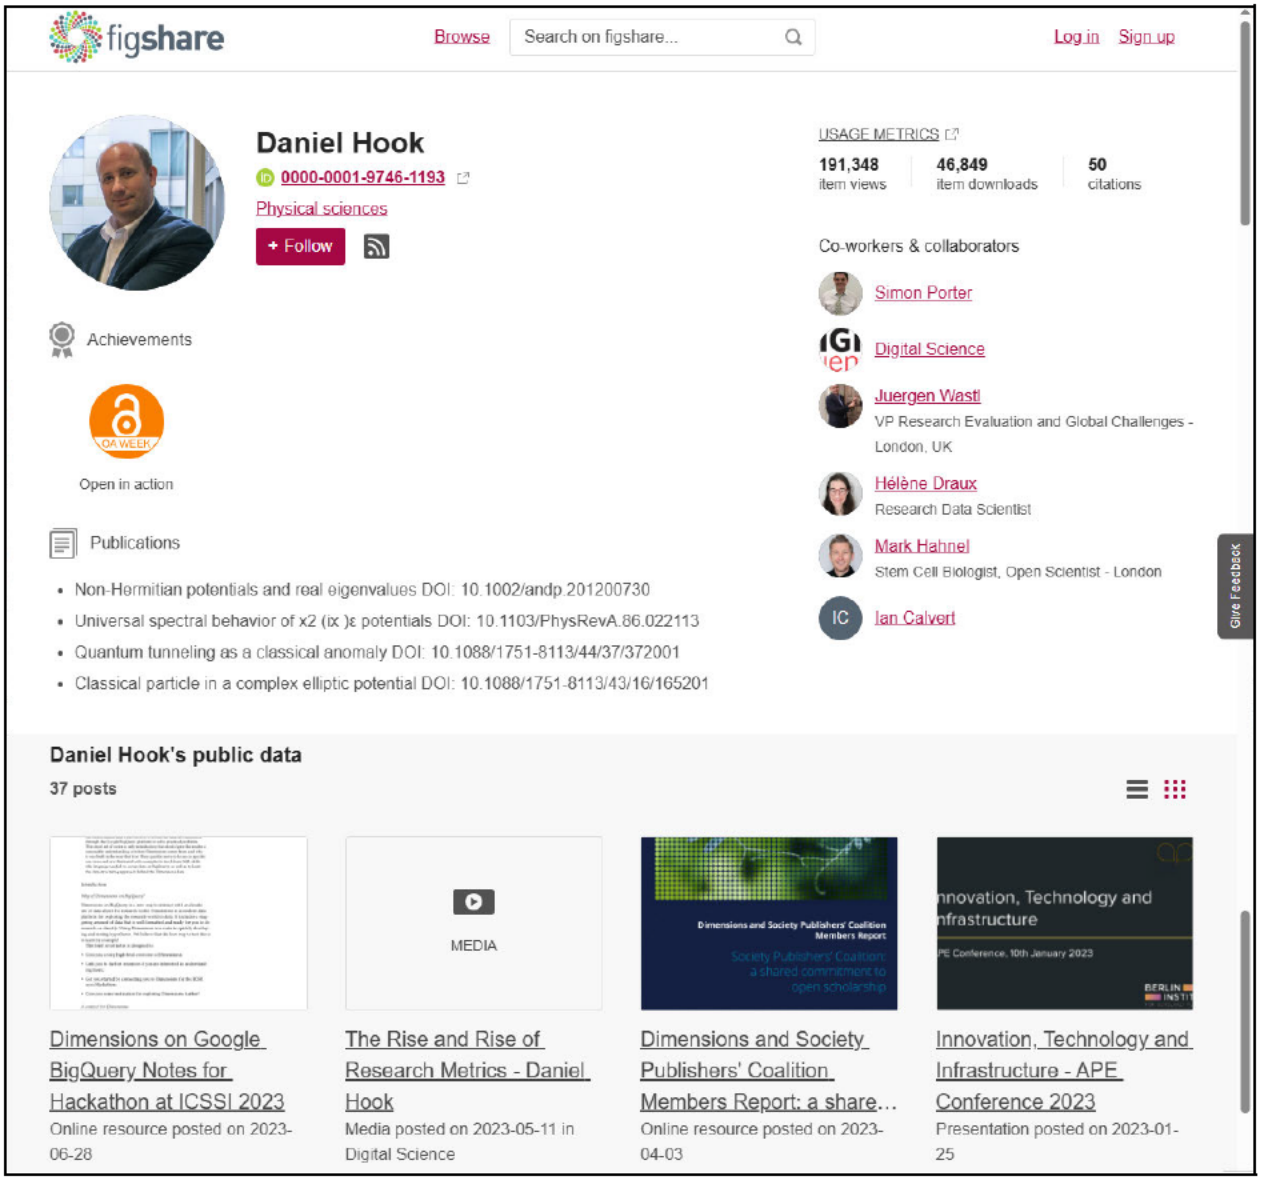

Figure S6. Author page on the Figshare repository website, an example GREI repository, showing posted data files and person-level usage and citation metrics.

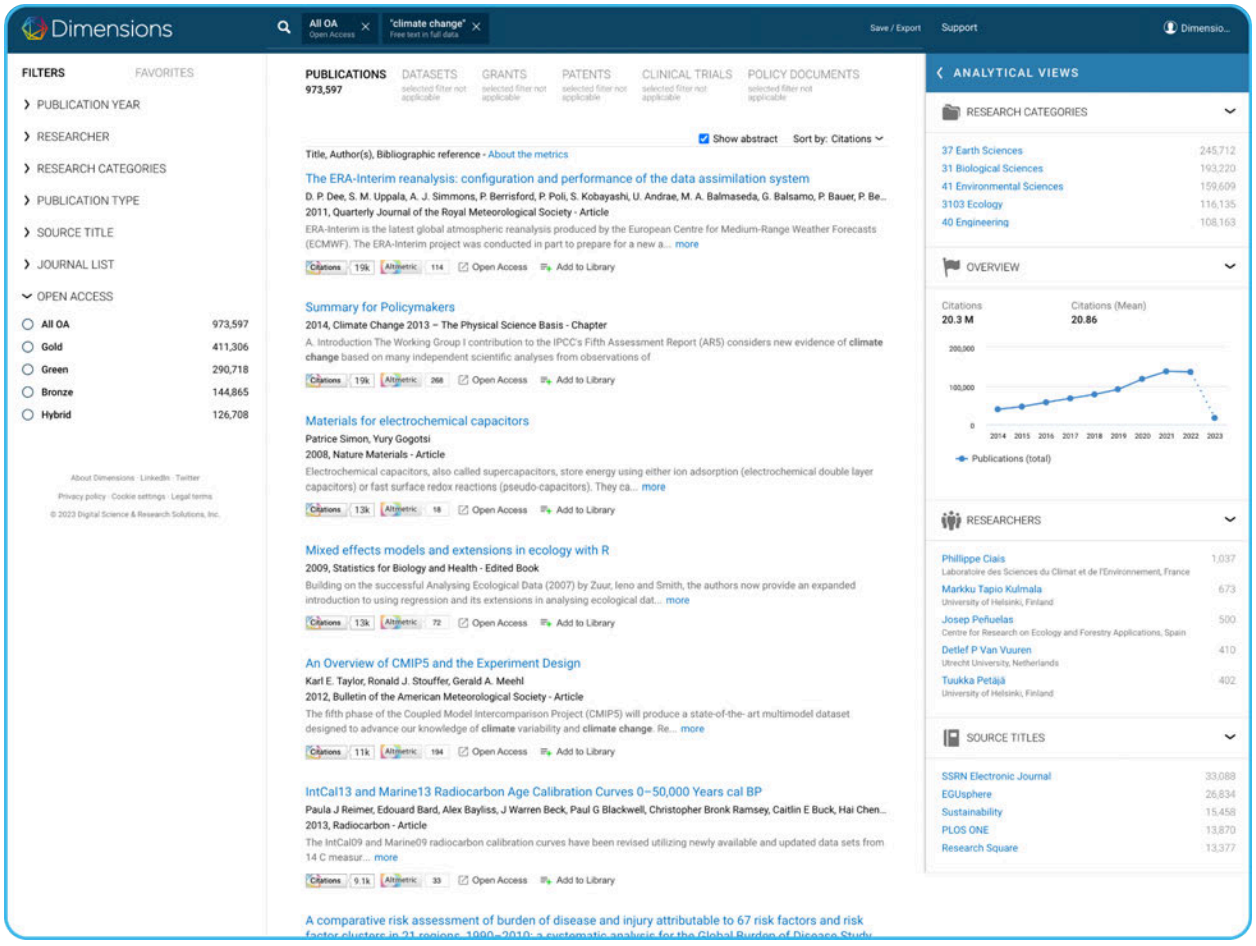

Figure S7. Search results in Dimensions, an example citation database with 29 million datasets and 140 million publications with linked funding, patents, clinical trials, and policy documents.

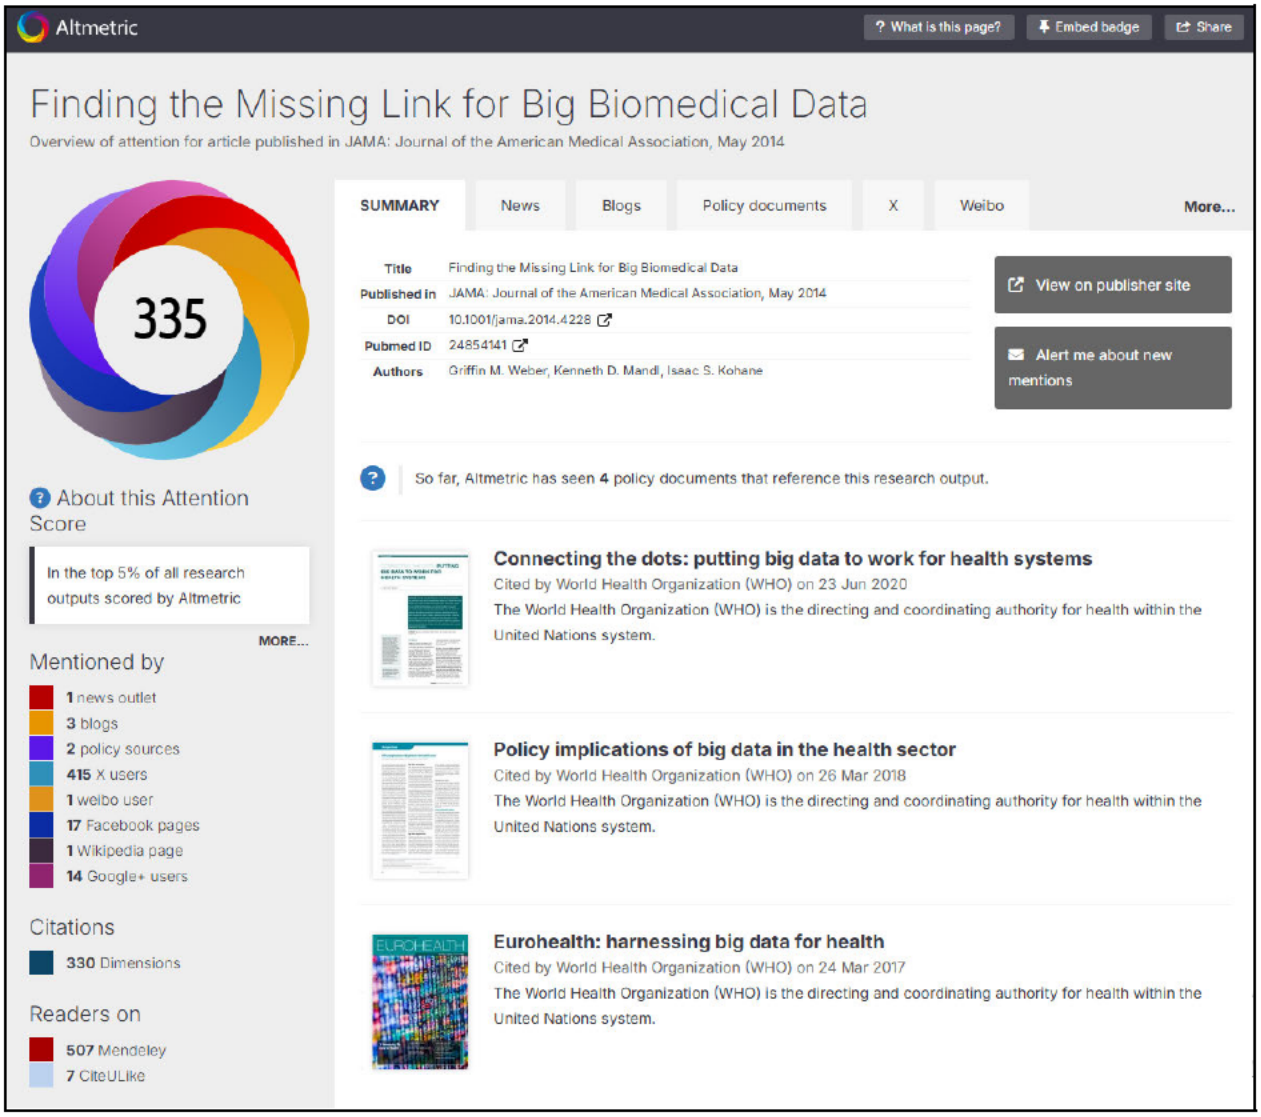

Figure S8. Journal article summary page on Altmetric, which uses eye-catching graphics to highlight metrics that track mentions in social media, news outlets, policy documents, and more.

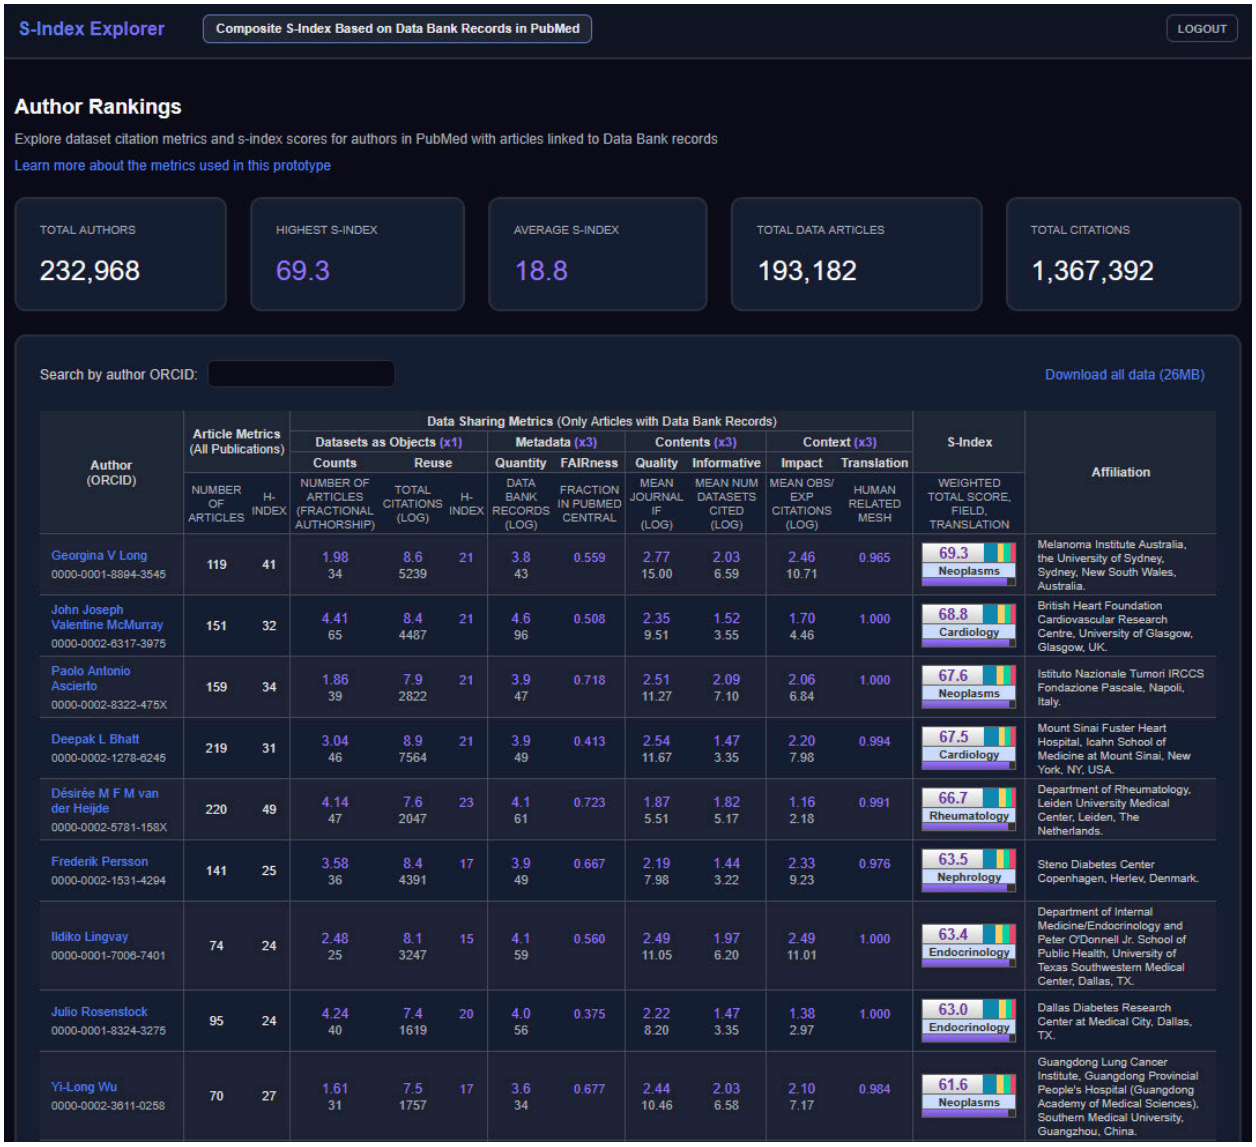

Figure S9. User interface of the Alternative PubMed S-Index prototype, based on data from PubMed, showing a list of top authors ranked by composite S-Index total score. (https://DataSharingIndex.org/Alt)

METRICS

Note that for several metrics, the natural log of the value plus one is used to reduce the effect of extreme values on the overall S-Index score.

COMPONENT	METRIC	DEFINITION	ENCOURAGES	POTENTIAL RISKS
Datasets as Objects (weight = 1)				
Counts	Number of Articles Fractional Authorship	The number of articles with at least one Data Bank record ("data articles"). For this metric, fractional authorship is used, where each article is weighted by the inverse of the number of authors. For example, an article with two authors is counted 0.5 and an article with ten authors is counted 0.1. This assumes authors contributed equally to creating and sharing the dataset. Alternative approaches might use CRediT (Contributor Roles Taxonomy) information in the article.	Sharing more datasets	Intentionally splitting data across multiple articles; sharing smaller low quality datasets; collaborating with fewer people
Reuse	Total Citations (Log)	The total number of citations of all the author's data articles.	Sharing more usable datasets	Self citations; measuring citations of the publication rather than the dataset
	H-Index	The h-index of the author's data articles. The h-index is calculated in the usual way, indicating the number of data articles that have at least that many citations. The metric combines both number of datasets and impact.	Adoption of the S-Index due to similarities to the well-known h-index	Similar limitations as the h-index, such as not controlling for field differences or career stage
Metadata (weight = 3)				
Quantity	Data Bank Records (Log)	The total number of Data Bank records for all the author's data articles.	Sharing larger amounts of data	Penalizes data formats that cannot be divided into smaller individual records
FAIRness	Fraction In PubMed Central	The fraction of the author's data articles that are in PubMed Central.	Open access to the articles describing the data	Does not measure the accessibility of the actual data
Contents (weight = 3)				
Quality	Mean Journal IF (Log)	The average impact factor (IF), calculated from PubMed citation data, of the journals that published the author's data articles. Note that this metric is a proxy for data quality, assuming that a high IF journal has screened out datasets with data quality problems during the peer review process.	Sharing higher quality datasets	Penalizes speciality journals with a lower IF that might have presented the data to a more targeted audience
Informative	Mean Num Datasets Cited (Log)	The average number of references to other data articles in the author's data articles. For example, an author's data article might cite three other data articles. Note that this is a proxy for novelty or integration of different data sources, without direct knowledge of how those data were used.	Reuse of existing data; documenting provenance; acknowledging others' contributions to data sharing	Authors are incentivized to cite many datasets even if they did not use them in a meaningful way
Context (weight = 3)				
Impact	Mean Obs/Exp Citations (Log)	The average number of citations of the author's data articles, normalized by Data Bank type and article year. For example, if a data article from 2021 contains GenBank records, its citation count (observed citations) is divided by the average citation count of all data articles with GenBank records in 2021 (expected citations). If the data article contains records from multiple Data Banks, then a weighted average of the expected citations is used.	Sharing data that is useful to many scientists	Discourages sharing niche data that might be essential to certain scientists, but is unlikely to have many citations; sensitive to the normalization method
Translation	Human Related MeSH	The average fraction of MeSH headings on the author's data articles that are related to humans, compared to MeSH headings on the article related to molecules, cells, or animals. Specifically, these are MeSH headings "Humans" and "Persons" and all their descendants in the MeSH hierarchy (e.g., "Adult", "Child", etc.). This metric indicates where the data articles fit on the translational spectrum from basic science to clinical medicine. The method is described in Weber 2013.	Generating data with direct applications to human health	Penalizes basic science research

Figure S10. Screenshot of help text within the Alternative PubMed S-Index prototype, with definitions of each metric, along with the behaviors they are expected to encourage and potential risks. (https://DataSharingIndex.org/Alt)

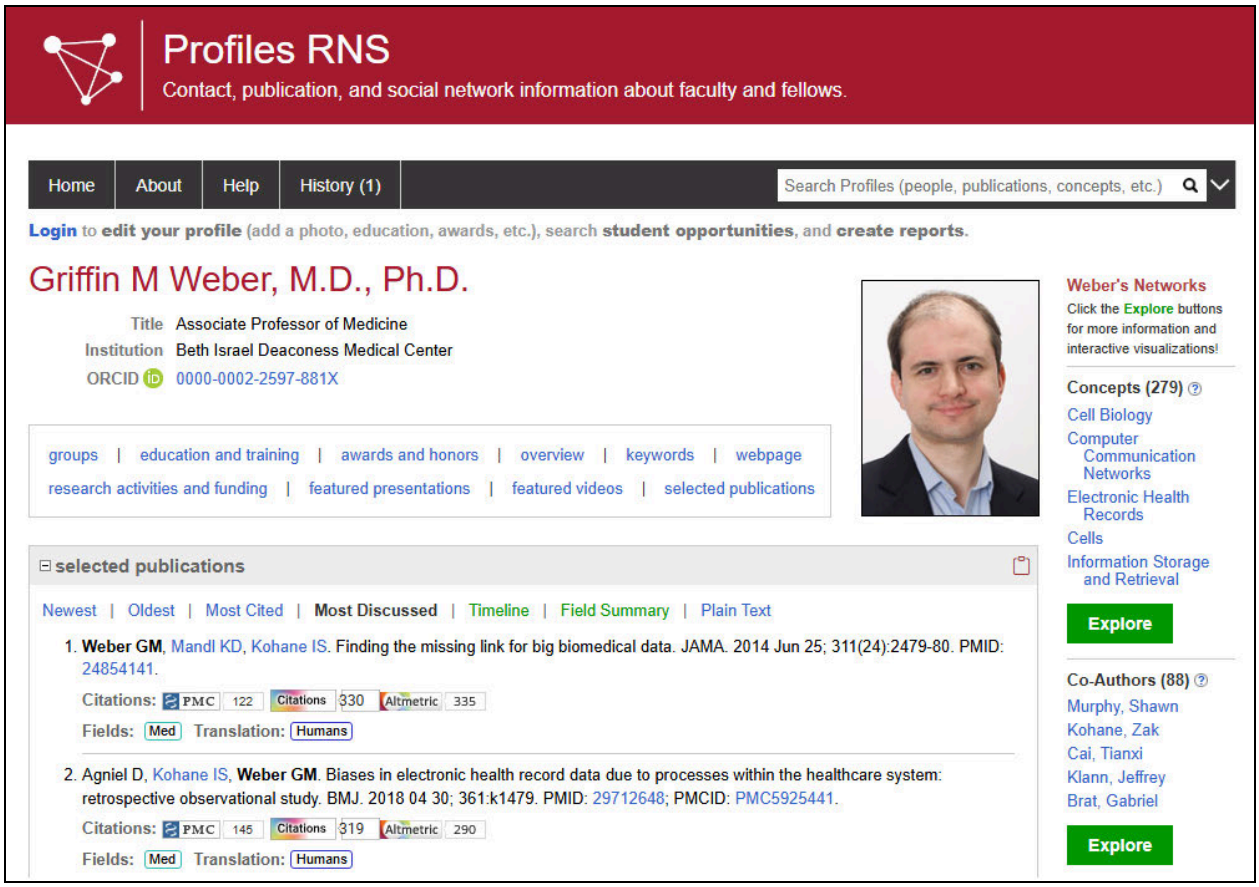

Figure S11. An investigator page on Profiles RNS, a widely-used open-source expert finder system, highlighting Altmetric and Dimensions badges and other publication metrics.

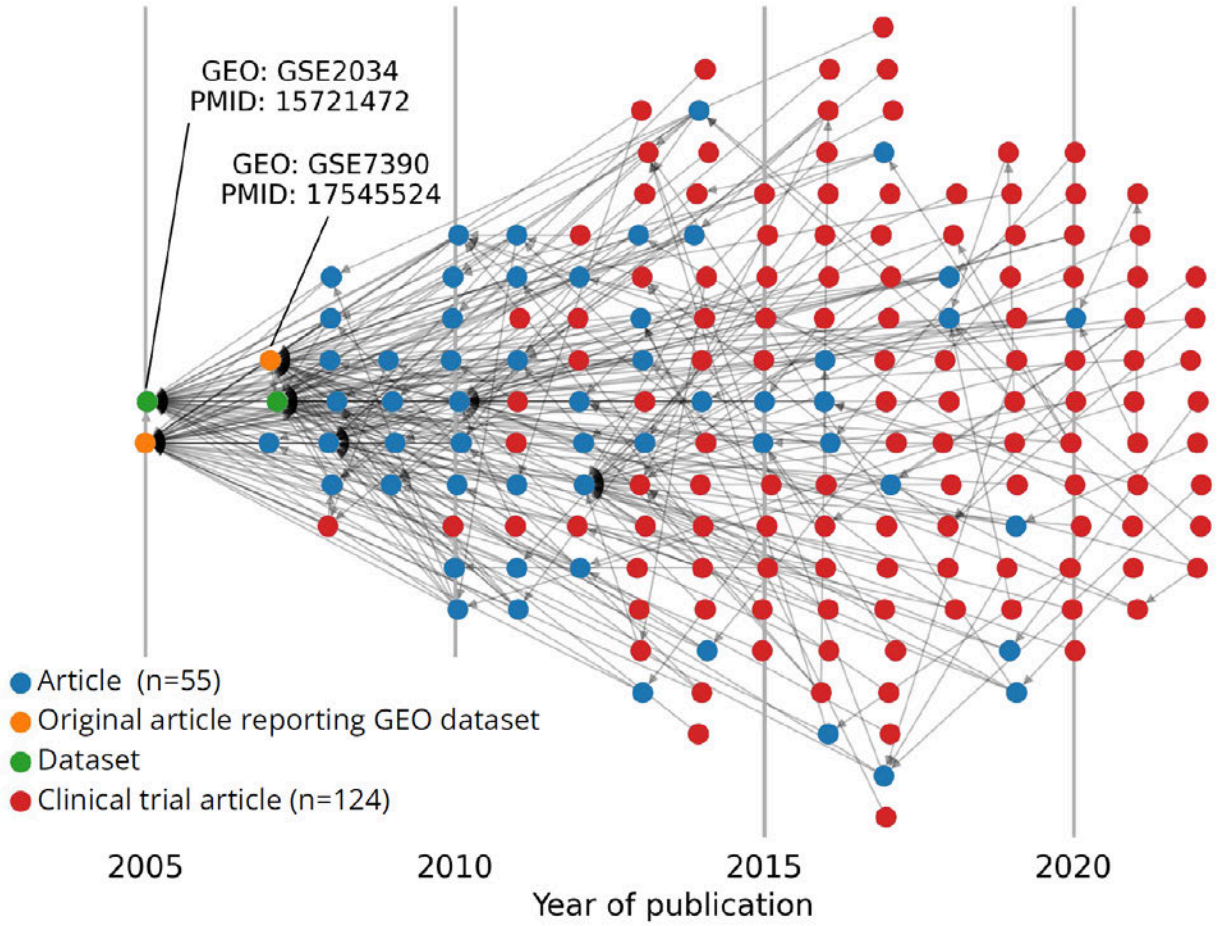

Figure S12. Tracing impact of data sharing using a network diagram of data citations for two Gene Expression Omnibus (GEO) datasets (green circles), one a derivative of the other, in the Make Data Count Data Citation Corpus.

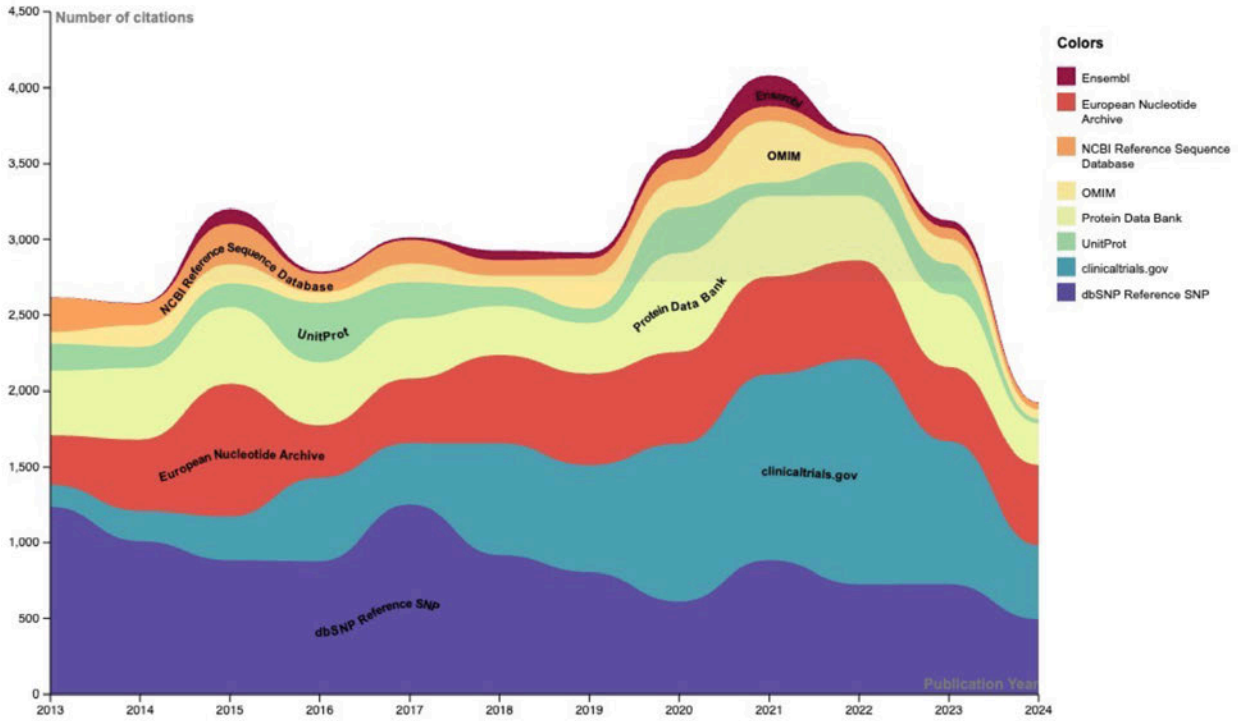

Figure S13. Breakdown of dataset citations by data type between 2013-2024. Example from Northwestern and University of Colorado Boulder analysis of impact of their life science data repositories.

Letters of Support

We have included the following letters of support as Supplementary Information:

Community	Organization	Signatories	Title
Evaluation	National Evaluation Center (NEC) for the Network of the National Library of Medicine (NNLM)	Verónica Hoyo	Executive Director
Evaluation	NIH CTSA Program Evaluators	Joe Hunt	Co-Chair

RE: NIH S-Index Challenge Proposal Letter of Support

Dear Katy, Amy, Kristi, Daniel, Chonnettia, Arjun, Steinn and Griffin

It is my pleasure to write on behalf of the National Evaluation Center (NEC) for the Network of the National Library of Medicine (NNLM) to offer strong support and partnership for your proposal submitted to the NIH Data Sharing Challenge "S-Index". We bring many years of multidisciplinary practice and extensive experience in evaluating a wide range of biomedical programs and assessing their impact. The NEC is committed to advancing responsible and transparent evaluation practices, and we are enthusiastic about the S-Index's potential to encourage meaningful, measurable, and socially valuable data sharing.

As Executive Director of the NEC, I affirm our commitment to collaborating with your S-Index development team in ways that emphasize the core principles of responsible metrics, including transparency, contextual relevance, fairness, and interestholder involvement. We value the project's commitment to making data impact more visible and understandable not only to researchers and institutions but also to the public, helping to build trust in scientific research and in the open sharing of data as a public good.

We envision several specific opportunities for potential collaboration and look forward to considering other ways we might work together:

- NEC staff can contribute to design and feedback for the collaborative workshops, offering expertise in evaluation methodology, responsible metrics, and the practical application of indicators in diverse research and community settings.
- Drawing on our deep understanding of NNLM member organizations, including academic centers, libraries, community health partners, and other community organizations, we can help ensure the S-Index reflects the range of values and priorities of information providers and the different communities they serve.
- We can help inform outreach efforts to engage public interestholders, emphasizing the importance of clear, accessible communication about what data sharing impact means, and how it supports community health, equity, and scientific progress.
- We can also contribute our evaluation experience to this effort. For example, we can consider prototypes of the S-Index, providing structured input on usability, interpretability, and alignment with responsible, public-facing metrics. We can also co-develop evaluation tools to help assess uptake, relevance, and public understanding, and relatedly, offerour expertise in tailored messaging of these outputs.

In summary, the NEC is proud to collaborate with you on this important initiative. The S-Index stands to advance a more transparent, inclusive, and effective data sharing culture. We are excited about the opportunity to grow a data sharing and reuse culture that recognizes meaningful contributions and serves both scientific and larger public interests. We look forward to supporting the project through the challenge and into broader implementation. Please don't hesitate to reach out if we can be of assistance.

Best regards,

Verónica Hoyo, PhD
Executive Director, NNLM National Evaluation Center

To Whom It May Concern:

I am writing to express my support and collaboration with your team for your proposal to the NIH Data Sharing Challenge (S-Index). I serve as Co-Chair of the Clinical and Translational Award Program Evaluators group, Co-Chair the Association for Clinical and Translational Science Evaluation Special Interest Group, and I also serve as the Director of the Tracking and Evaluation Program at the Indiana Clinical and Translational Sciences Institute, Indiana University School of Medicine.

In addition to extensive experience with formative, summative, and process evaluation methodologies, I have completed extensive work to understand clinical and translational research impact. Datasets play an important role in realizing this impact. I am excited about your team's efforts to advance innovative solutions that assess and incentivize responsible data sharing in biomedical research. The S-Index presents a compelling approach to quantifying the impact and reuse of shared datasets. I am certain this effort will be of interest to my CTSA evaluation colleagues across the country.

The NIH Clinical and Translational Science Awards (CTSA) Program, led by the National Center for Advancing Translational Sciences (NCATS), supports a national network of medical research institutions working to improve the efficiency, quality, and impact of translational research. By fostering innovation, collaboration, and workforce development, the CTSA Program accelerates the translation of scientific discoveries into clinical applications to improve human health.

I am eager to participate in your proposed collaborative workshops where I and other CTSA evaluators can provide input on the design and implementation of the proposed S-Index, and offer insights on metric usability for CTSA hubs, and alignment with translational research goals.

I can help engage the broader CTSA evaluation community, including the CTSA Translational Impact Working Group, to explore use cases, address implementation challenges, and identify opportunities for integration. Additionally, I can assist in disseminating findings through CTSA-affiliated channels to help broaden awareness and uptake of the S-Index across the translational science landscape.

The S-Index project aligns strongly with the CTSA mission to accelerate translation through data-driven decision-making and a culture of transparency and accountability.

Please do not hesitate to contact me should additional information be required. I look forward to the opportunity to support this project.

Sincerely,

[redacted]

Vice President and Program Director

ALFRED P. SLOAN
FOUNDATION

Driven by the promise
of great ideas.

May 26, 2025

Dear Chonnettia,

It is my pleasure to support your team's proposal to the NIH Data Sharing Index Challenge entitled "Engaging key stakeholder communities to promote data sharing with an S-Index."

The Alfred P. Sloan Foundation, where I serve as Vice President and Program Director, is a dedicated funder of Open Science. One recent and successful example, led by my colleague Josh Greenberg, has been our support for the establishment of Open Source Program Offices (OSPOs) on many university campuses. Another recent investment of this kind by Sloan is our involvement with Open Athena, a high-powered initiative to develop transparent foundational models for use by academic scientists.

Personally, I am especially excited about how the approach this team is taking emphasizes stakeholder engagement. It is a truism that you cannot manage what you cannot measure. But an S-Index will only "work" if it takes into account factors that may not be apparent to everyone. The eclectic and very distinguished team working on this Challenge represents many points of view—from academics to advocates and from commercial data providers to nonprofit data stewards.

With this remarkable array of experience and expertise, the team is exceptionally ready to take on all the challenges entailed by the Data Sharing Index Challenge—including thorny issues that I had to confront when promoting Open Science during my service as a government official. Examples of these are privacy and proprietary considerations, intellectual property rights, sustainable timing and costs, societal benefits measurement, as well as international research security protections.

For all these reasons, I would be delighted to see this project make progress on encouraging and evaluating better data practices among scientific researchers. I have every confidence this team is uniquely poised to make significant, welcome, and enduring progress. Above all, I am eager to participate in these activities and do what I can to make this work successful.

Sincerely yours,

Danny
Dr. Daniel L. Goroff

Dear Katy Börner (Indiana U), Amy Brand (MIT Press), Kristi Holmes (Northwestern), Daniel Hook (Digital Science), John Inglis (bioRxiv/medRxiv), Chonnettia Jones (Addgene), Arjun Krishnan (U Colorado), Steinn Sigurdsson (arXiv), Griffin Weber (Harvard),

I am writing in support of your proposal to the NIH Data Sharing Index Challenge titled "Engaging key stakeholder communities to promote data sharing with an S-Index".

The Gates Foundation is committed to advancing global health and development through the responsible sharing and reuse of data. We support policies and efforts that promote open access to high-quality data, foster data interoperability, and encourage collaboration across sectors. By enabling researchers, policymakers, and practitioners to build on existing evidence, we aim to accelerate innovation, increase transparency, and drive more equitable outcomes for communities around the world.

For these reasons, we understand both the benefits and challenges in incentivizing open science and sharing high value datasets. We are pleased to support your team's exciting plans to promote data sharing and data reuse to further drive a culture of openness, transparency, and explainability in science.

I am looking forward to participating in your stakeholder workshops and providing my guidance and expertise.

Best wishes,

Ashley Farley

RE: NIH S-Index Challenge Proposal Letter of Support

Dear Katy Börner, Amy Brand, Kristi Holmes, Daniel Hook, John Inglis, Chonnettia Jones, Arjun Krishnan, Steinn Sigurdsson, and Griffin Weber

On behalf of the Navigation Fund, I would like to express our support for your team's pitch to the NIH S-Index Data Sharing Challenge. As a philanthropy focused on open science, we support initiatives that explore ways to encourage broader data sharing in research.

Should you advance in this challenge, we would be pleased to participate in collaborative workshops to help ensure the S-Index reflects the needs and values of the research communities it serves. We can also help connect the project to our broader networks across open science and academic reform communities.

We look forward to potential collaboration with your team and the NIH in support of more open and sustainable science.

Best regards,

Dear colleagues,

On behalf of the Contributor Role Taxonomy (CRediT) project, we are pleased to offer our support for your submission to the NIH Data Sharing “S-Index” Challenge.

CRediT is a high-level taxonomy of contributor roles that enables transparent and standardized attribution for individuals involved in scholarly work. Originally developed to bring clarity to author contributions in journal articles, CRediT includes 14 distinct roles (Data Curation, Software, Methodology, and Supervision) designed to capture the full spectrum of activities essential to research. Notably, Amy Brand and I led the original development of CRediT, which is now a formal NISO standard (ANSI/NISO Z39.104-2022), and used by hundreds of journals and systems worldwide to improve the transparency and discoverability of research contributions.

Your proposal closely aligns with the values that underpin CRediT - namely, the importance of finding practical ways to recognize the diversity of research contributions. The collaborative approach to developing the S-Index that you outline, presents an exciting opportunity to develop quantitative and qualitative ways to better measure and incentivize data stewardship and reuse, and has the potential to ensure that data sharing achieves the status of a first-class scholarly activity.

The CRediT team looks forward to the opportunity to engage with you and the larger scholarly community in your workshops. We also welcome future opportunities to collaborate – for example to explore how CRediT can be optimized for research data activities. We commend your leadership in pushing this work forward and look forward to the impact your submission will have on the policy and practice of data sharing.

With appreciation and full support

[redacted]

Liz Allen, PhD
CRediT project Co-Chair

Veronique Kiermer, PhD

RE: Letter of Support | NIH Data Sharing Challenge

Dear Katy Börner (Indiana U), Amy Brand (MIT Press), Kristi Holmes (Northwestern), Daniel Hook (Digital Science), John Inglis (bioRxiv/medRxiv), Chonnettia Jones (Addgene), Arjun Krishnan (U Colorado), Steinn Sigurdsson (arXiv), and Griffin Weber (Harvard)

I am writing in support of your proposal to the NIH Data Sharing Index Challenge titled "Engaging key stakeholder communities to promote data sharing with an S-Index".

As you know, DataCite is dedicated to making research more effective by connecting research outputs and resources—from data and preprints to images and samples. We support the creation and management of DOIs and metadata records, enhance research workflows with service integration, and enable the discovery and reuse of research outputs and resources. Our advanced tools leverage the metadata provided to enable discovery, analytics, and reporting capabilities, ensuring that research impact is visible and measurable through our DataCite Commons platform.

For these reasons, we understand both the benefits and challenges in incentivizing open science and sharing high value datasets. We are pleased to support your team's exciting plans to promote data sharing and data reuse to further drive a culture of openness, transparency, and explainability in science.

DataCite brings deep expertise and a strong track record in supporting global research infrastructure, and may be well positioned to contribute across several shared areas of interest—offering opportunities to strengthen and align with your initiatives.

- **DOI and metadata management:** With years of experience as a trusted provider of DOI registration services, DataCite ensures that datasets and other digital objects are persistently identified, citable, and discoverable in accordance with FAIR principles. Our robust APIs—including the DataCite REST API, GraphQL API, and associated services—are widely adopted and can be integrated into your systems to support automated DOI creation, enrich metadata quality, and improve interoperability with existing research

repositories.

- **Analytics and reporting:** DataCite Commons and our advanced analytics tools provide insights into the reach and use of research outputs. These tools can support your efforts to track link-outs and citations, assess usage patterns, and demonstrate the scientific impact of your resources.
- **DataCite Metadata Schema:** As a leader in metadata standards development, DataCite has shaped community-wide practices around metadata quality—spanning accuracy, completeness, consistency, and context. We welcome the opportunity to share this experience and explore how our approaches can inform your efforts to assess and improve metadata quality, including the impact of AI models that account for connectivity, context, and broader impact across disciplines.

DataCite is committed to supporting our shared mission to democratize data discovery and advance biomedical research through innovative metadata collection and management. Our team at DataCite looks forward to contributing to your stakeholder workshops where possible and providing our guidance and expertise in this regard. We are confident that our collaboration on this effort will significantly enhance the functionality and reach of this effort for biomedical researchers worldwide.

We are excited about the opportunity to collaborate on this transformative initiative. We look forward to working closely with you and the stakeholder community to realize the full potential of this opportunity and to contribute to the advancement of human health through enhanced data discoverability and reuse.

Yours sincerely,

Matt Buys
Executive Director

Arjun Krishnan, University of Colorado Anschutz Medical Campus
Steinn Sigurdsson, arXiv
Griffin Weber, Harvard

Dear Colleagues,

On behalf of the NIH-sponsored Generalist Repository Ecosystem Initiative (GREI), we are pleased to offer our support for your submission to the NIH S-Index Challenge, and express our interest in collaborating with you on this important effort to improve the recognition and reward of data sharing in biomedical research.

GREI is a collaborative effort among seven NIH-recognized generalist repositories (Dataverse, Dryad, Figshare, OSF, Mendeley Data, Vivli, and Zenodo) working to enhance the discoverability, interoperability, and reusability of research data. We share a common commitment to building interoperable data infrastructure, promoting FAIR data principles, and advancing a research culture that values data as a first-class scholarly output. The goals of the S-Index Challenge align closely with GREI's mission to support researchers in sharing high-quality, well-documented data across disciplines and platforms.

GREI is well-positioned to contribute to this effort by participating in your proposed stakeholder workshops where we can contribute our gained perspectives from working

GREI is made possible by support from the NIH Office of Data Science Strategy/Office of the NIH Director pursuant to OTA-21-009, "Generalist Repository Ecosystem Initiative (GREI)" through Other Transactions Agreement (OTA) Numbers OT2DB000001, OT2DB000002, OT2DB000003, OT2DB000004, OT2DB000005, OT2DB000006, and OT2DB000013.

together as a “coopetition” to support the advancement of the NIH data sharing ecosystem. We can also provide technical guidance on data deposit practices, metadata standards, and persistent identifiers across generalist repositories. We can further contribute insights into cross-repository usage metrics, discoverability, and data citation practices, helping to ensure the proposed metric is grounded in real-world data sharing behaviors.

We believe the NIH Data Sharing S-Index Challenge will contribute meaningfully to advancing a more FAIR and sustainable data-sharing ecosystem and we look forward to supporting your team in these efforts.

Best wishes,

Julie Wood
Co-chair GREI Collaboration, 2025 and 2022

Ana Van Gulick, PhD
Co-Chair GREI Collaboration, 2025 and 2023
Digital Science Head of Customer Engagement for Government, Funders, and Nonprofits

GREI is made possible by support from the NIH Office of Data Science Strategy/Office of the NIH Director pursuant to OTA-21-009, “Generalist Repository Ecosystem Initiative (GREI)” through Other Transactions Agreement (OTA) Numbers OT2DB000001, OT2DB000002, OT2DB000003, OT2DB000004, OT2DB000005, OT2DB000006, and OT2DB000013.

Invest in Open Infrastructure

Dear Katy Börner, Amy Brand, Kristi Holmes, Daniel Hook, John Inglis, Jones, Arjun Krishnan, Steinn Sigurdsson, Griffin Weber,

I am writing in support of your proposal to the NIH Data Sharing Index Challenge titled "Engaging key stakeholder communities to promote data sharing with an S-Index".

A key objective of Invest in Open Infrastructure (IOI) is to increase the visibility of open infrastructure providers and their value to the ecosystem through targeted research on the benefits, opportunities, and challenges associated with adoption. We work to expand our discovery tools and our mapping of infrastructure providers and needs to new disciplines and communities, including data storage, research data management, data analysis, and digital preservation.

For these reasons, we understand both the benefits and challenges in incentivizing open science and sharing high value datasets. We are pleased to support your team's exciting plans to promote data sharing and data reuse to further drive a culture of openness, transparency, and explainability in science.

I am looking forward to participating in your stakeholder workshops and providing my guidance and expertise.

Best wishes,
Kaitlin

Kaitlin Thaney
Executive Director
Invest in Open Infrastructure

27 May 2025

Dear Kristi,

On behalf of Make Data Count, I express our support for your participation in the NIH Data Sharing S-Index Challenge and offer our advice and guidance on your proposal, "Engaging key stakeholder communities to promote data sharing with an S-Index".

Make Data Count is a community-driven initiative focused on building the infrastructure, standards, and cultural change necessary to make research data a primary scholarly output. Our work is anchored on open infrastructure, community ownership, and the development of meaningful data metrics that go beyond traditional publication volume or citation counts to reflect a broader range of dimensions of impact and reuse. We advocate for indicators and metrics that recognize and reward data sharing and data use, aligning with our commitment to transforming the way data is valued in scholarly research.

We see synergy between your work and Make Data Count's goals to establish open, transparent, and community-governed metrics for data reuse and impact. We believe this work can meaningfully contribute to the broader goals of NIH's S-Index Challenge by developing practical, scalable methods to track and incentivize data sharing and reuse in responsible ways.

Make Data Count is open to collaboration with your team on areas of shared interest, including:

- Advising on the development of robust and transparent data metrics
- Sharing insights from our projects on infrastructure for data-usage tracking, and our collaborations with meta-research on data citation practices
- Providing guidance on the use and application of data-usage information collected via Make Data Count workflows
- Contributing to community engagement and alignment on the practices and principles for responsible data metrics
- Participation in your stakeholder workshops and providing our guidance and expertise

Kristi, in addition to serving as an advisor to Make Data Count, you also co-chair the Make Data Count/HELIOS Open Working Group, 'Implementing Data Evaluation in Academia'. This collaborative initiative focuses on developing practical resources to support the implementation of data metrics and data evaluation in institutional processes, particularly in hiring, review, promotion, and tenure decisions. This Working Group can offer another opportunity for collaboration and guidance, given its active work developing frameworks that recognize and reward data sharing and data use, supporting inclusion and recognition of data outputs in academic evaluation processes.

We look forward to exploring how we can work together to advance the recognition of datasets as critical scientific contributions, and as catalysts of research progress.

Best wishes,

Iratxe Puebla

Dear Kristi and colleagues,

On behalf of Zenodo, I am pleased to provide this letter of support and confirm our collaboration in your application to the NIH Data Sharing S-Index Challenge. Your team's efforts to develop meaningful, responsible metrics for data sharing and reuse work in harmony with Zenodo's mission to support FAIR, open, and impactful science across disciplines.

Zenodo, developed under the European OpenAIRE program and operated by CERN, is a trusted generalist repository that provides long-term, open access to research outputs of any type or size. Our underlying platform, InvenioRDM, is a modular, scalable infrastructure that supports customizable metadata, persistent identifiers (e.g., DOIs, ORCIDs, RORs), and integration with services such as GitHub. These capabilities make Zenodo well-suited to serve as a foundation for assessing and enhancing data sharing practices. Through our collaboration with the NIH Generalist Repository Ecosystem Initiative (GREI), Zenodo is actively collaborating with other repositories to improve metrics, metadata standards, interoperability, and user-centered services that support NIH-funded researchers. We are also working on ways to highlight NIH-funded science in Zenodo.

Zenodo is pleased to support your project through active participation in the stakeholder workshop series to co-develop best practices and community-informed strategies for measuring data impact. We bring direct experience as an early implementer of the Make Data Count (MDC) standard, which enables transparent, standardized tracking of dataset views, downloads, and citations, essential information for building a robust S-Index. Our continued collaboration through the Generalist Repository Ecosystem Initiative (GREI) further supports the advancement of shared infrastructure, metric standards, and cross-repository interoperability to improve the discoverability and reuse of NIH-funded data. Additionally, Zenodo's REST API, OAI-PMH capabilities, and open licensing model enable efficient programmatic access and reuse. We also share your interest in applying AI and machine learning to enhance metadata quality and discovery, all areas where the modular architecture of our underlying platform, InvenioRDM, is already driving innovation.

We're excited about your community-centered approach. Please don't hesitate to reach out as your project moves forward.

Yours sincerely,

Jose Benito

Dear Dr Katy Börner (Indiana U), Dr Amy Brand (MIT Press), Dr Kristi Holmes (Northwestern), Dr Daniel Hook (Digital Science), Dr John Inglis (bioRxiv/medRxiv), Dr Chonnettia Jones (Addgene), Dr Arjun Krishnan (U Colorado), Dr Steinn Sigurdsson (arXiv), and Dr Griffin Weber (Harvard),

I am writing in support of your proposal to the NIH Data Sharing Index Challenge titled "Engaging key stakeholder communities to promote data sharing with an S-Index".

DataDotOrg, is a US-based non-profit organisation leading extensive global programs in the data for good and academic data space, particularly in areas of Public Health and Climate and Health. We are long standing supporters of open science, open data and open software. In our data work we partner with key universities, like Harvard University, University of Chicago in the US, Oxford University, London School of Hygiene and Tropical Medicine in the UK, University of Lagos, University of Pretoria in Africa, IIIT Delhi, Ashoka University, National University of Singapore in Asia, Javeriana University, Los Andes University in South America, as well as social impact organisations, governments and intergovernmental organisations from around the world.

For these reasons, we understand both the benefits and challenges in incentivizing open science and sharing high value datasets. We are pleased to support your team's exciting plans to promote data sharing and data reuse to further drive a culture of openness, transparency, and explainability in science.

I am looking forward to participating in your stakeholder workshops and providing my guidance and expertise.

Best wishes,

Danil Mikhailov, PhD

President and CEO

May 27, 2025

Dear Dr. Jones and Team:

We are writing in support of your proposal to the NIH Data Sharing Index Challenge titled "Engaging key stakeholder communities to promote data sharing with an S-Index".

Janelia Research Campus has been a leader in promoting open science through comprehensive data sharing initiatives that span both large-scale collaborative projects and individual research efforts. We have established institutional guidelines and infrastructure supporting researchers in sharing data according to FAIR principles, recognizing that meaningful data sharing requires both technical excellence and community engagement. Our track record includes disseminating transformative datasets such as the complete Drosophila connectome (Scheffer *et al.* PMID: 32880371) and the comprehensive Mouselight Neuron Browser (Winnubst *et al.* PMID: 31495573), alongside hundreds of smaller datasets through Figshare and specialized repositories. Through this experience, we have identified critical gaps in current data sharing metrics and standards, particularly the need for measures that capture both the quality of shared data and its actual impact on scientific discovery. We believe robust indexing systems like your proposed S-Index are essential for creating sustainable incentives that reward researchers for the substantial effort required to prepare and maintain high-quality, reusable datasets.

For these reasons, we understand the benefits and challenges of incentivizing open science and sharing high-value datasets. We are pleased to express our support for your team's exciting plans to promote data sharing and reuse to further drive a culture of openness, transparency, and explainability in science.

Although the Howard Hughes Medical Institute, Janelia Research Campus does not apply for or accept grant funding and is not participating in the grant application “Engaging key stakeholder communities to promote data sharing with an S-Index*”,* we would be pleased to participate in your stakeholder workshops on an unfunded basis, and are strongly supportive of the effort to develop a robust, meaningful data sharing index.

Best wishes,

Mike Perham, PhD
Director, Janelia Innovations and Open Science

Dear Kristi and team,

As a researcher and advocate in the fields of research integrity, ethics, and open science, I am pleased to offer my full support for your team's submission to the NIH Data Sharing S-Index Challenge, and to express my strong interest in collaborating on this timely and important initiative.

Ethical research requires more than transparency in methods and findings; it demands responsible stewardship of data, clear attribution of contributions, and inclusive practices that foster public trust in scientific research. Your team's proposal to develop a robust metric for recognizing and incentivizing data sharing addresses a longstanding gap in the research ecosystem. I'm especially encouraged by your focus on open infrastructure and transparency in metric design. These principles are not only foundational to open science, but also to the development of trustworthy artificial intelligence (AI) systems and responsible research governance.

My work lies at the intersection of research ethics, AI, and open scholarship. I lead and contribute to ethics-focused projects within national and international organizations such as the Association of Professional and Practical Ethics, the National Information Standards Organization (NISO), the National Academy of Sciences, and the Global Young Academy. This work is further grounded in my teaching on research ethics and the responsible conduct of research at Northwestern University and other institutions globally. I also serve as associate editor of *Accountability in Research* and as the editor of the *Research Ethics Forum* book series.

Contributor roles and attribution have been central to my scholarship since my PhD dissertation, and I've been fortunate to continue this work in collaboration with you and others since joining Northwestern. Together, we serve on the CRediT Standing Committee at NISO, where we help steward the Contributor Roles Taxonomy (CRediT), a framework that supports proper attribution and accountability and is critical to building incentives for data sharing.

I'm particularly excited by your plan to include stakeholder workshops as part of the project. These workshops are essential from an ethics and integrity standpoint, ensuring that diverse voices such as researchers, infrastructure providers, funders, scholarly organizations and the public can work together to shape a fair, transparent, and accountable metric for recognizing and incentivizing data sharing. Such engagement helps illuminate ethical risks and foster trust in both the qualitative and quantitative components of any metric.

In addition to participating in the workshops, I would be eager to contribute in the following ways:

- Advising on the integration of ethical considerations into the design and implementation of data sharing metrics
- Supporting the alignment of metrics with best practices in AI reproducibility and accountability
- Contributing perspectives on openness, fairness, and the recognition of contributions from different researchers and communities
- Ensuring the metric reflects both openness and the ethical robustness of shared data

This challenge represents an important opportunity to recognize and reward the full spectrum of scholarly contributions, and I believe your team is exceptionally well-positioned to offer a thoughtful and impactful solution. I look forward to supporting your work and contributing however I can.

Sincerely,

Mohammad Hosseini, MA, PhD

To whom it may concern:

On behalf of the Federation of American Societies for Experimental Biology (FASEB), we are pleased to offer our strong support for your team's proposal to the NIH Data Sharing (S-Index) Challenge. We also welcome the opportunity to collaborate in this important initiative, which aligns closely with FASEB's mission to advance health and well-being by promoting research and education in the biological and biomedical sciences.

FASEB is a coalition of 22 scientific societies, representing more than 110,000 researchers worldwide across a wide range of disciplines in the biological and biomedical sciences. As a leading voice in the biomedical research community, FASEB advocates for effective policies and practices that support scientific integrity, equitable access to research outputs, and recognition of diverse forms of scholarship—including data sharing and stewardship.

FASEB would be pleased to support your work in several ways, including participating in and helping convene stakeholder workshops to ensure the metric reflects the diverse needs and perspectives of researchers across disciplines and career stages. Additionally, FASEB can contribute to community engagement and communication strategies aimed at building awareness and promoting the adoption of responsible data sharing metrics. Furthermore, FASEB is well-positioned to offer guidance on aligning the proposed metric with broader policy recommendations and infrastructure development priorities within the life sciences.

FASEB looks forward to collaborating with your team to support the development and implementation of a data sharing S-index that truly reflects the values and contributions of the scientific community.

Sincerely,

RE: Letter of Support and Collaboration for NIH Data Sharing Challenge Proposal

To Whom It May Concern,

As a group of academic health science library leaders deeply engaged in supporting biomedical research, data stewardship, and scholarly communication, we write to express our strong support for your team and your submission to the NIH Data Sharing S-Index Challenge. We also welcome the opportunity to collaborate in this vital initiative to advance equitable and responsible data sharing practices across the health research ecosystem.

Academic health sciences libraries play a critical role in facilitating access to research data, advising on data management and sharing practices, and supporting open science across clinical and biomedical disciplines. The development of a meaningful, scalable metric that recognizes and incentivizes data sharing is of significant importance to our community, particularly in an era where reproducibility, transparency, and equitable access to research outputs are central to scientific integrity and public trust.

Your commitment to stakeholder engagement and inclusive metric design aligns closely with the work of health sciences libraries on our campuses where we frequently play a vital role in partnering with university leadership to advance more responsible approaches to research assessment and reward. Leveraging library expertise in metadata, persistent identifiers, and open infrastructure, libraries contribute to the technical and data foundations necessary for responsible evaluation. At the same time, we support the social and cultural dimensions of change by promoting transparency and recognition of the range of research outputs produced by researchers, such as data, software, and community engagement. Through their expertise and close working relationships with campus researchers, libraries can (and do!) help shape institutional policies and practices that better align with the values of open science and integrity.

We look forward to participating in the stakeholder workshops and can also offer your team insights and guidance across several key areas. Our expertise includes data management, metadata standards, and the use of persistent identifiers within biomedical research. We can inform outreach and engagement efforts with researchers and clinicians to ensure the resulting

metric is appropriate and relevant across domains. Additionally, we are prepared to share insights from institutional data repositories and data literacy initiatives, as well as contribute strategies for integrating the metric into academic research assessment and compliance processes.

We are happy to support this effort.

208. Center for Open Science

I am responding: On behalf of an organization

Name: Maryam Zaringhalam

Name of Organization: Center for Open Science

Type of Organization: Non-Profit Research Organization

Role: Organizational Official

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: The Center for Open Science (COS) is a nonprofit organization with a mission to increase the openness, integrity, and trustworthiness of research. Since our founding, we have led several high-profile metascience efforts investigating the reproducibility and replicability of research, including the Reproducibility Project: Psychology, the Reproducibility Project: Cancer Biology, and the Systematizing Confidence in Open Research and Evidence (SCORE) initiative. Across these efforts, we have found that establishing reproducibility and replicability is difficult even under ideal conditions. A failure to reproduce or replicate a finding is not synonymous with misconduct or failure; rather, it is part of how science self-corrects through ongoing inquiry, debate, and refinement. NIH should underscore this nuance in its messaging around rigor and reproducibility, as fears that a lack of repeatability will trigger punitive rather than constructive responses work against the culture change NIH seeks. Nevertheless, NIH has several opportunities to pilot or strengthen programs, policies, and investments to promote rigor and reproducibility.

Reproducibility refers to investigating the same question as a prior study with the same data using the same analysis (https://doi.org/10.31222/osf.io/mqfp4_v1). Reproducibility is a "baseline" form of repeatability — verifying that reported results are repeatable using the same data and analysis. Increasing access to the data, materials, protocols, and analysis underlying a finding is therefore critical to NIH's goals for reproducibility, as we discuss further in our response to "Data, Software, and Model Sharing." Indeed, our SCORE initiative found that papers published in journals with strong data and code sharing policies were more readily reproducible (https://doi.org/10.1038/s41586-026-10251-x). NIH's Data Management and Sharing Policy is a strong step, but NIH has an opportunity to go further by requiring that other elements necessary to reproduce findings are made openly accessible in an appropriate repository and linked to resulting outcomes. These linkages trace findings back to the raw materials and analytic choices that produced discoveries. NIH should invest in infrastructures that enable these linkages across the research lifecycle. For example, COS hosts the Open Science Framework (OSF), an open-source infrastructure that enables researchers to register their study plans and link them to associated data, materials, code, and outcomes in the form of preprints and peer-reviewed articles. OSF thus provides a lifecycle view of a research project, surfacing elements needed to support reproduction, and potentially provide trust markers for findings demonstrated to be reproducible.

Replicability refers to investigating the same question as a prior study with new data. Replicability is a more challenging form of repeatability because one must minimally understand what are the sufficient

conditions to observe a prior finding. Also, it is possible that the prior finding was observed spuriously. As for reproducibility, open sharing of materials, protocols, analyses, and other components of the prior research helps establish replicability by making it easier to scrutinize and reuse the prior research to inform replication efforts. Also, when outcomes differ between original discoveries and replications, transparency of the methods underlying the research supports identification of possible causes. Finally, preregistration of designs and analysis plans supports calibrating confidence in original claims by making transparent actions that may reduce replicability such as selective reporting and p-hacking.

Infrastructures and policies that promote access to research plans and outputs underlying discoveries should also be paired with NIH investments in capacity building for the research community. This can include direct support for training programs that teach skills needed to conduct reproducible and replicable research — including preregistration where appropriate, data and code sharing, and transparent reporting — or incorporating open science practices in required Responsible Conduct of Research training. Critically, reproducibility or replication should not be treated as some boring, rote, or ancillary research activity, but part of the ordinary process by which scientific claims are tested, refined, and generalized (https://doi.org/10.1371/journal.pbio.3000691). Every study extends findings to conditions that differ from those originally examined, so testing whether they hold is foundational to any work that builds on them. Outside of training programs, NIH can further incentivize reproducibility and replication efforts by supporting dedicated replication funding mechanisms and by recognizing replication and reproduction efforts in how it evaluates researchers and research programs.

NIH can also incentivize Registered Reports, a publishing format in which study plans undergo peer review before data are collected, and in-principle acceptance is granted based on the rigor of the question and methods rather than the results. By separating the evaluation of research design from its outcomes, Registered Reports directly reduce publication bias and questionable research practices, such as selective reporting and post hoc hypothesizing, while ensuring that rigorous studies enter the literature regardless of outcome. Uptake of Registered Reports and preregistration offers NIH a concrete, measurable indicator of rigor tied to the quality of the research design rather than the volume or citation count of resulting publications. NIH could pilot Registered Report funding mechanisms, in which peer review of a proposal's design is coupled to a commitment to fund and publish the resulting work, aligning the funding, execution, and publication of research around methodological rigor. Such pilots are useful for building awareness and engagement in scholarly communities that are unfamiliar with the approach — and test the adaptability of the model to new methods and research domains. For example, the Registered Reports model was introduced in a special issue of the journal Social Psychology in 2014 that fostered substantial engagement, refined the model, and promoted adoption by other journals and funders (https://doi.org/10.1027/1864-9335/a000192).

On the question of defining causal research, we note that regardless of how causal claims are categorized, their credibility depends heavily on research design and transparency. Practices such as preregistration and Registered Reports strengthen causal inference by committing researchers to analytic specifications before outcomes are observed, reducing the flexibility that can produce spurious or overstated claims, causal or otherwise.

Any investments NIH makes in reproducibility and rigor should be paired with metascience research to

evaluate the effectiveness of interventions to improve reproducibility and replicability — and to evaluate the costs and benefits of such practices across different disciplines, methodologies, and research contexts. Further, NIH can invest in consistent, sustained replication efforts using a standardized sampling protocol so that replicability can be systematically measured and improvements tracked over time. This ongoing replicability effort should use a standardized sampling method that is determined ahead of time so that the findings are generalizable to the defined population, no single community or methodology receives any more or less scrutiny than deserved, and so that consistent measures can inform the research community with the least amount of bias possible.

2. Data, Software, and Model Sharing: As discussed in our response to "Rigor and Reproducibility," data, software, and model sharing are critical to validating research results and enabling reuse. COS recommends that NIH extend this goal beyond data, software, and models to the protocols, analysis plans, and materials used to generate a research claim — the elements needed to verify how a finding was produced and to build on it (https://doi.org/10.7554/eLife.67995). These outputs are captured in the Transparency and Openness Promotion (TOP) Guidelines, a policy framework led by COS and the TOP Advisory Board that provides recommendations for journals, research institutions, and funders to increase the verifiability of empirical research claims (https://doi.org/10.1186/s41073-026-00223-0). TOP offers a tiered and modular structure for implementing open science policies at three levels of stringency: (1) disclosure that the practice occurred, (2) sharing and citing the open research output, and (3) certification by an independent third party that best practices were followed. COS is continuing to develop implementation guidance for the TOP Guidelines aimed at various communities, including funders, and welcomes engagement on translating this framework into practice.

TOP's broad applicability creates a structured framework for conversations around policies and incentives across research-performing institutions, publishers, and funders — enabling alignment across these sectors so researchers can focus on advancing robust research sharing practices. In addition, policymakers can leverage TOP's modularity to adopt the level of stringency most appropriate to a given field, practice, and the community's readiness to implement it. This flexibility lets NIH recognize and implement policies around sharing in a way that reflects disciplinary differences rather than applying a uniform requirement across all research it funds. COS recommends NIH leverage TOP as a convening tool to align policies and incentives across the disciplinary communities it supports, including by engaging scientific societies and leveraging NIH's own intramural research program as a testbed to pilot incentives and research assessment reform.

This practice-based approach to assessment is increasingly shared across the research system. A recent multi-interest-holder consensus effort, which included COS, identified six core practices that research-performing organizations can monitor and reward — including TOP practices of data, code, and material sharing — as a means of realigning incentives away from publication counts and journal prestige toward research credibility and transparency. As a funder and a research-performing organization, NIH is well positioned to reinforce this movement by aligning its own assessment and reporting expectations with these practices, sending a consistent signal across the institutions and researchers it supports.

NIH should also increase engagement with additional community-driven efforts aimed at incentivizing and rewarding open science and research sharing activities, including the Declaration on Research Assessment, the Coalition for Advancing Research Assessment, Make Data Count, and the Roundtable on

Aligning Incentives for Open Scholarship. These long-standing efforts have a wealth of experiences NIH can draw upon as it develops its own policy and rewards programs. NIH can also draw on examples of funding programs within the government that have made efforts to incentivize meaningful research assessment reform within institutions. For example, the National Science Foundation's Accelerating Research Translation (ART) program, though focused on research translation, conditions its awards on recipient institutions revising their promotion and tenure criteria to reward a broader range of scholarly contributions on par with traditional research outputs. NIH could adapt this model — using funding conditions or incentives to encourage the institutions it supports to recognize and reward rigorous, open, and repeatable research practices in how they assess researchers.

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: Research that is open, verifiable, and subject to correction is a key contributor for earning and maintaining public trust. The comments we have shared on rigor, reproducibility, and sharing of research outputs are thus foundational to that trust. In assessing public impact, NIH should recognize that practices strengthening the credibility of the research record are themselves contributions to public impact. While producing trustworthy research is not sufficient on its own to secure public trust, practices to promote the trustworthiness of research are within the research community's control — and well within NIH's ability to incentivize. COS and colleagues have advanced a framework tying trustworthiness to measurable indicators, offering one foundation for NIH (https://doi.org/10.1073/pnas.2536736123).

At the same time, NIH should be cautious of overly simplistic measures of public impact — or impact more broadly. Just as publication counts and journal prestige are gameable proxies that can offer the appearance of quality in place of genuinely rigorous research, indicators that reward attention rather than substance, including media mentions, altmetrics, or other measures of visibility, risk rewarding researchers who promote their work effectively over those who do the most rigorous work. NIH should instead prioritize indicators that reflect verifiable contribution and demonstrable use. These indicators should be: driven and tested by the community; transparent and auditable so they are understandable by the community and broader audiences; open, non-commercial, and non-proprietary; contextualized and complemented with narrative descriptions where needed; and iterative and subject to evaluation and change over time.

Description: COS Response to NIH RFI on Measuring and Rewarding Scientific Impact with citations

The Center for Open Science's Response to NIH Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Submitted on behalf of the Center for Open Science (COS) by Maryam Zaringhalam, Senior Director of Policy, David Mellor, Senior Policy Analyst, and Brian Nosek, Executive Director.

We are writing today on behalf of the Center for Open Science (COS), a non-profit organization working to increase openness, integrity, and reproducibility of research. To meet that objective, COS employs a systems strategy involving technology to make open practices possible and easy, community building to make open practices normative, and stakeholder engagement to make open practices rewarding and required. COS enacts this Theory of Change with mutually reinforcing activities: providing infrastructure through the Open Science Framework (OSF), enabling researchers to register study plans, publish preprints through community-run services, and link externally to related data, materials, code, publications, and other results; conducting research on research (also known as metascience) to understand contributors to repeatability, efficiency, and integrity; and advocating for policies to support open science practices and culture change. COS appreciates the opportunity to draw from this work to provide comments on NIH's approach to measuring and rewarding scientific impact.

Rigor and Reproducibility

> *Reproducible and replicable biomedical approaches are foundational to rigorous research. New strategies are needed to identify areas ripe for replication and reproducibility efforts, as well as incentives and infrastructure to support the reproduction and replication of existing findings. NIH also seeks comment on rigor, including with regard to defining causal research.*

The Center for Open Science (COS) is a nonprofit organization with a mission to increase the openness, integrity, and trustworthiness of research. Since our founding, we have led several high-profile metascience efforts investigating the reproducibility and replicability of research, including the Reproducibility Project: Psychology, the Reproducibility Project: Cancer Biology, and the Systematizing Confidence in Open Research and Evidence (SCORE) initiative. Across these efforts, we have found that establishing reproducibility and replicability is difficult even under ideal conditions. A failure to reproduce or replicate a finding is not synonymous with misconduct or failure; rather, it is part of how science

self-corrects through ongoing inquiry, debate, and refinement. NIH should underscore this nuance in its messaging around rigor and reproducibility, as fears that a lack of repeatability will trigger punitive rather than constructive responses work against the culture change NIH seeks. Nevertheless, NIH has several opportunities to pilot or strengthen programs, policies, and investments to promote rigor and reproducibility.

Reproducibility refers to investigating the same question as a prior study with the same data using the same analysis.[1] Reproducibility is a "baseline" form of repeatability — verifying that reported results are repeatable using the same data and analysis. Increasing access to the data, materials, protocols, and analysis underlying a finding is therefore critical to NIH's goals for reproducibility, as we discuss further in our response to "Data, Software, and Model Sharing." Indeed, our SCORE initiative found that papers published in journals with strong data and code sharing policies were more readily reproducible.[2] NIH's Data Management and Sharing Policy is a strong step, but NIH has an opportunity to go further by requiring that other elements necessary to reproduce findings are made openly accessible in an appropriate repository and linked to resulting outcomes. These linkages trace findings back to the raw materials and analytic choices that produced discoveries. NIH should invest in infrastructures that enable these linkages across the research lifecycle. For example, COS hosts the Open Science Framework (OSF), an open-source infrastructure that enables researchers to register their study plans and link them to associated data, materials, code, and outcomes in the form of preprints and peer-reviewed articles. OSF thus provides a lifecycle view of a research project, surfacing elements needed to support reproduction, and potentially provide trust markers for findings demonstrated to be reproducible.

Replicability refers to investigating the same question as a prior study with new data. Replicability is a more challenging form of repeatability because one must minimally understand what are the sufficient conditions to observe a prior finding. Also, it is possible that the prior finding was observed spuriously. As for reproducibility, open sharing of materials, protocols, analyses, and other components of the prior research helps establish

finding was produced and to build on it.[5] These outputs are captured in the Transparency and Openness Promotion (TOP) Guidelines, a policy framework led by COS and the TOP Advisory Board that provides recommendations for journals, research institutions, and funders to increase the verifiability of empirical research claims.[6] TOP offers a tiered and modular structure for implementing open science policies at three levels of stringency: (1) disclosure that the practice occurred, (2) sharing and citing the open research output, and (3) certification by an independent third party that best practices were followed. COS is continuing to develop implementation guidance for the TOP Guidelines aimed at various communities, including funders, and welcomes engagement on translating this framework into practice.

TOP's broad applicability creates a structured framework for conversations around policies and incentives across research-performing institutions, publishers, and funders — enabling alignment across these sectors so researchers can focus on advancing robust research sharing practices. In addition, policymakers can leverage TOP's modularity to adopt the level of stringency most appropriate to a given field, practice, and the community's readiness to implement it. This flexibility lets NIH recognize and implement policies around sharing in a way that reflects disciplinary differences rather than applying a uniform requirement across all research it funds. COS recommends NIH leverage TOP as a convening tool to align policies and incentives across the disciplinary communities it supports, including by engaging scientific societies and leveraging NIH's own intramural research program as a testbed to pilot incentives and research assessment reform.

This practice-based approach to assessment is increasingly shared across the research system. A recent multi-interest-holder consensus effort, which included COS, identified six core practices that research-performing organizations can monitor and reward — including TOP practices of data, code, and material sharing — as a means of realigning incentives away from publication counts and journal prestige toward research credibility and transparency.[7] As a funder and a research-performing organization, NIH is well positioned

to reinforce this movement by aligning its own assessment and reporting expectations with these practices, sending a consistent signal across the institutions and researchers it supports.

NIH should also increase engagement with additional community-driven efforts aimed at incentivizing and rewarding open science and research sharing activities, including the Declaration on Research Assessment, the Coalition for Advancing Research Assessment, Make Data Count, and the Roundtable on Aligning Incentives for Open Scholarship. These long-standing efforts have a wealth of experiences NIH can draw upon as it develops its own policy and rewards programs. NIH can also draw on examples of funding programs within the government that have made efforts to incentivize meaningful research assessment reform within institutions. For example, the National Science Foundation's Accelerating Research Translation (ART) program, though focused on research translation, conditions its awards on recipient institutions revising their promotion and tenure criteria to reward a broader range of scholarly contributions on par with traditional research outputs. NIH could adapt this model — using funding conditions or incentives to encourage the institutions it supports to recognize and reward rigorous, open, and repeatable research practices in how they assess researchers.

Public Impact

> *NIH seeks approaches for assessing and recognizing the broader public impact of biomedical research, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit.*

Research that is open, verifiable, and subject to correction is a key contributor for earning and maintaining public trust. The comments we have shared on rigor, reproducibility, and sharing of research outputs are thus foundational to that trust. In assessing public impact, NIH should recognize that practices strengthening the credibility of the research record are themselves contributions to public impact. While producing trustworthy research is not sufficient on its own to secure public trust, practices to promote the trustworthiness of research are within the research community's control — and well within NIH's ability to incentivize. COS and colleagues have advanced a framework tying trustworthiness to measurable indicators, offering one foundation for NIH.[8]

Faculty: Maximizing quality, transparency, and trustworthiness of scientific research in Research-Performing Organizations. MetaArXiv. https://doi.org/10.31222/osf.io/4qmua_v2

[8] Nosek, B. A., Allison, D. B., Jamieson, K. H., McNutt, M., Nielsen, A. B., & Wolf, S. M. (2026). A framework for assessing the trustworthiness of scientific research findings. *Proceedings of the National Academy of Sciences*, *123*(6), e2536736123. https://doi.org/10.1073/pnas.2536736123

At the same time, NIH should be cautious of overly simplistic measures of public impact — or impact more broadly. Just as publication counts and journal prestige are gameable proxies that can offer the appearance of quality in place of genuinely rigorous research, indicators that reward attention rather than substance, including media mentions, altmetrics, or other measures of visibility, risk rewarding researchers who promote their work effectively over those who do the most rigorous work. NIH should instead prioritize indicators that reflect verifiable contribution and demonstrable use. These indicators should be: driven and tested by the community; transparent and auditable so they are understandable by the community and broader audiences; open, non-commercial, and non-proprietary; contextualized and complemented with narrative descriptions where needed; and iterative and subject to evaluation and change over time.

1. Rigor and Reproducibility: While I agree that reproducibility and replicability are important aspects of scientific rigor, these aspect should not become prohibitive. By this I mean that some studies, especially those involving human cognition/behavior/physiology, etc., can be difficult to replicate because people are heterogeneous. One way to overcome this is by using extremely large sample sizes, but due to financial constraints, this is not always possible. A requirement of/emphasis on the replication of such studies, and even more so in patient-oriented studies, may disincentivize researchers from attempting to take the first step in this line of research (i.e., by deciding not to submit such proposals at all). Instead, a special RGP category could be useful that acknowledges the difficulty in replication for such human patient studies when a first step in a new direction is desired. Early results could be useful once published, with other investigators able to draw upon those findings to attempt reproducibility, replication, and extension of the original report.

2. Data, Software, and Model Sharing: The best way to uphold scientific integrity is through transparency, especially transparency of methods. Having a clear understanding of how a study was conducted allows independent researchers to assess the validity of the scientific approach. It may be the case that a small aspect of the protocol can make a big difference in results. Thus, in addition to sharing datasets and tools, researchers could be incentivized to share details of the methods (the process) as well. Typically, this information is glossed over in reports, especially when there are word limits. However, researchers could be encouraged to include method details in a repository with the data and tools. For example, such information could include the screening form used to determine patient eligibility, locally developed questionnaires, the MRI exam card, or the even a study visit protocol checklist. When this level of information is shared openly, it allows other researchers to critique the design and attempt to replicate the process in the most accurate way.

Description: Narrative response from the ORFG addressing rigor and reproducibility, data and code sharing, and colalboration.

To: National Institutes of Health

From: Open Research Funders Group (ORFG)

RE: Response to RFI on Measuring and Rewarding Scientific Impact [NOT-OD-26-087]

Date: 19 August 2026

Please consider the attached as a formal response to the NIH RFI on Measuring and Rewarding Scientific Impact from the Open Research Funders Group.

Open Research Funders Group (ORFG) is a coalition of private philanthropic funders committed to the open sharing of research outputs. Collectively, ORFG members hold assets in excess of $152 billion, with total annual grantmaking in the $11 billion range. We believe openness is better for the American public, better for research, better for global society, and better for philanthropy. Open research accelerates the pace of discovery, reduces information-sharing gaps, encourages innovation, and promotes reproducibility.

As members of the private philanthropic community, we strive to support the rapid and wide dissemination of scientific outputs that serve our society. This community uses a variety of strategies and approaches to increase scientific discovery and continuously works to improve the scientific ecosystem. We have knowledge and expertise in funding scientific outputs – such as preprints, datasets, code, and tangible materials – as well as assessing their impacts.

Much like the NIH, we care deeply about rewarding and incentivizing rigorous research, and we share the view that current metrics do not work as intended.[1]

Current incentive structures fundamentally misalign with the agency's core mission. Researchers are generally rewarded for publication volume, journal prestige, and citation counts rather than for rigorous, reproducible, and collaborative science. This misalignment is the central barrier to the knowledge generation that enhances health and reduces illness. To serve the American public, we encourage the NIH to revise its funding mechanisms and review processes to enhance its evaluation processes by measuring and

[1] Declaration on Research Assessment (DORA), *Guidance on the Responsible Use of Quantitative Indicators in Research Assessment*, September 26, 2024, https://doi.org/10.5281/zenodo.13844873.

rewarding behaviors that strengthen the scientific knowledge base: transparency, open sharing, and investment in research infrastructure.

There are three main areas listed in this RFI that are of utmost importance to ORFG:

1. Rigor and reproducibility
2. Data, software, and model sharing; and
3. Collaboration.

The most effective way to ensure that NIH can better align its measures of research quality with its core mission, and generate knowledge that enhances health, lengthens life, and reduces illness and disability, is to **institute open sharing practices and behaviors, and reward and incentivize these behaviors in new and meaningful ways.** This can and should be achieved using a mix of several levers: policy, rules, workflows, and experimentation with new and innovative assessment and evaluation methods, including qualitative research assessments of individual contributions, and granular outputs.

However, not all approaches to open sharing and incentivization are as impactful and effective as they need to be, and are executed in ways that create unintended and deleterious consequences.

The remainder of this memo outlines ORFG's perspective on how open output sharing and incentivization will best serve the NIH and its mission to serve the American public, and minimize unintended consequences.

Rigor and Reproducibility

Reproducibility at scale requires shared standards and infrastructure, not just individual transparency. Openly sharing research outputs such as preprints, datasets, registered protocols, and code enables the transparent, collaborative peer review and validation necessary for rigorous science. However, this sharing must be supported by community-governed infrastructure (preprint servers, data repositories, registries) and standardized metadata that allows for discovery, interoperability, and reuse. A recent study points to open peer review as a useful research quality indicator; those authors choosing open peer review are more likely to also choose open science practices.[2] While openly sharing alone does not indicate rigor or reproducibility, it enables an environment where rigor and reproducibility can be examined by a large community or researchers. This is why the publish, review, curate model of research sharing is gaining traction in researcher communities.

[2] Adrian Barnett and Matt Spick, "Who Chooses Open Peer Review and Is It an Indicator of Article Quality? An Observational Study of PLOS Journals.," 2b7z5_v1, preprint, MetaArXiv, April 10, 2026, https://osf.io/preprints/metaarxiv/2b7z5_v1/.

Openness coupled with robust infrastructure yields quality reuse and increases/amplifies researcher efforts. Shared outputs must include robust, standardized metadata that enables provenance tracking, machine interoperability, and discovery. This is especially critical as machine learning increasingly drives biomedical research: metadata quality directly enables validation of computational models and responsible AI development.

This metadata is becoming increasingly important as researchers adopt incremental sharing practices known as continuous or modular science. Instead of sharing all results (including data, narrative, code, models, and tangible materials) at the *conclusion* of a study, researchers are sharing these incremental outputs as soon as they are practicably usable by others. One schema that supports this approach is Open Exchange Architecture (OXA). Investment in infrastructures such as schema as well as servers and discovery systems, are critical to the ability for research to be disseminated and reproduced.

Current quantitative incentive structures such as impact factor, h-index, and publication counts are both simplistic and misaligned with the NIH's mission. They measure reputation and citation volume rather than scientific rigor, reuse, or real-world impact. Worse, they perpetuate dependence on for-profit publishers and commercial entities, penalizing researchers for transparent, open work. To align incentives with mission, NIH should adopt non-proprietary, community-governed indicators that measure and reward: (1) preprint and open data publication timelines, (2) participation in open peer review platforms (PREreview, Review Commons), (3) adoption of appropriate transparency standards for the research at hand (OSF registration, registered reports), and (4) replication and replication-focused infrastructure contributions. These shifts should be embedded in grant review rubrics and funding decisions, not merely encouraged.

To reiterate, these behaviors alone do not assure rigor and reproducibility. However, enabling and incentivizing open behaviors creates the condition for the community to be able to evaluate rigor and reproducibility of studies. (It would be very difficult to reproduce a study, where methods, data, and the like are not openly available.) Public peer review of preprints such as those that occur at PREreview, are exemplary of how open enables robust community review and evaluation of rigor.

Data, Software, and Model Sharing

Sharing data, software, and models without infrastructure, standards, or purpose yields limited reuse and creates burden on researchers. Instead, NIH should incentivize and reward sharing that meets community standards: FAIR data principles, robust metadata, open licensing, and demonstrated downstream use. As computational models increasingly drive biomedical research, open licensing of trained models—enabling external validation and collaborative refinement—is essential to reproducibility and scientific integrity.

ORFG recently released a report on *ORFG Funder Policy Landscape Report and Recommendations,* which includes an analysis of data, software, and model sharing practices of private research funders.[3] Among its recommendations is the expansion of data management plan requirements and the need for funders to support existing data principles and practices. Included in this is the use of FAIR data practices and principles that ensure shared data is findable, accessible, interoperable, and reusable.[4]

As an example, Aligning Science Across Parkinson's, discusses FAIR data principles in its open science handbook[5]:

> "Data must be deposited in their rawest reasonable form (e.g., the data have not been cleaned or preprocessed) in a discipline-specific, community-recognized repository that follows FAIR principles. We acknowledge that, depending on the type of data and the repository used, some level of preprocessing or curation may be required before sharing."[6]

Additionally, all shared computational models and software should be openly licensed (e.g., MIT, Apache 2.0) to enable validation, reuse, and adaptation. As researchers increasingly use machine learning models in biomedical discovery, proprietary or closed models limit reproducibility and scientific accountability. NIH should require that funded computational models and ML-derived predictions include: (a) training data specifications, (b) licensing terms that permit validation and derivative use, and (c) metadata documenting model assumptions and limitations. Recognizing data and software contributions equally with publications—through CV sections, grant reviewer rubrics, and annual report metrics—will incentivize quality sharing practices.

Software sharing should follow similar principles: deposit on trusted, community-governed platforms (e.g. Zenodo); use standard open licenses (MIT, Apache 2.0); include documentation of dependencies and computational requirements; and track download/reuse statistics. NIH should measure impact by active reuse such as downloads, forks, and adaptations as one indicator of scientific impact.

In short: data, software, and model sharing should be incentivized based on adherence to community standards (FAIR, open licensing, etc.) and measurable downstream reuse is one indicator of impact. NIH funding mechanisms should track and reward both data reuse and software adoption, recognizing these as primary research contributions alongside publications.

---

[3] Open Research Funders Group, *ORFG Funder Policy Landscape Report and Recommendations: 2026* (Zenodo, 2026), https://doi.org/10.5281/zenodo.20451484.

[6] Aligning Science Across Parkinson's, "ASAP Open Science Policy Handbook."

Some funders, such as The Michael J. Fox Foundation for Parkinson's Research and the Wellcome Trust have implemented similar policies requiring open licensing and deposit of data and software in trusted repositories. Moreover, national funders in the UK, Netherlands, and the EU all support robust data sharing practices. NIH should align with and amplify these efforts.

Collaboration

Team-based science requires new approaches to measure individual contribution. Current publication-based metrics obscure who did what and penalize researchers (statisticians, bioinformaticians, data stewards) whose contributions are essential to rigor but invisible in authorship. Modular outputs—preprints, datasets, code repositories, registered protocols—help make individual contributions transparent and enable earlier visibility into contributor roles. NIH should incentivize collaboration in its awardee assessment and evaluation by recognizing infrastructure contributions (maintaining repositories, creating standards, curating datasets) as primary research contributions in grant review and CV assessment.

Moreover, when considering approaches for assessing and recognizing contributions to team-based science, looking to the open science and open research communities will be key. For example, the Declaration on Research Assessment (DORA) recently released A Practical Guide to Implementing Responsible Research Assessment at Research Funding Organizations stresses the need for research funders themselves to engage in alignment and collaboration in their research assessment approaches and incentives structures. Implementing these changes requires concrete workflow modifications. NIH should: (1) expand SciENcv to allow narrative descriptions of collaboration and team contributions alongside traditional CV sections; (2) allow grant applicants to list modular outputs (datasets, code, protocols, etc.) separately from bundled "publications" as indicators of their scientific contributions; and (3) train grant reviewers to utilize team-based contributions as one indicator of scientific impact.

Narrative CVs—already adopted by funders in the Netherlands, Ireland, Canada, and New Zealand—allow researchers to explain their approach to collaboration, team contributions, and research philosophy rather than relying on publication counts. The NIH has similarly adopted the narrative CV. An additional step to incorporate narrative CVs at NIH would be to modify the SciENcv to support this format at the grant application stage, enabling researchers to highlight modular contributions and collaborative roles before final publication.

As with the other areas addressed by this RFI response, community governed and created metadata and infrastructures enable team science. The CRediT taxonomy allows for

contributor roles on research outputs to be more transparent. The Open Exchange Architecture (OXA) enables transparent attribution across modular outputs, allowing team contributions to be visible before final publication. Combined with the CRediT taxonomy for role specification, OXA creates accountability and visibility into team science at every stage of research, not just at publication.

Finally, NIH should align its assessment and incentive policies with other governmental funders advancing research reform. Initiatives such as the Coalition for Advancing Research Assessment (CoARA,) the Research on Research Institute (RoRI), Declaration on Research Assessment (DORA), and the Global Research Council (GRC) provide templates for policy coordination. This alignment strengthens the collective signal to researchers that hiring, promotion, and grant decisions across funders now reward open, collaborative, team-based science—making individual institutions' adoption easier and more consequential.

Conclusion

To conclude: ORFG urges NIH to align its funding mechanisms, review processes, and workforce policies with a science of rigor, not reputation. This requires three coordinated shifts:

1. Infrastructure Investment. Support community-governed, non-proprietary infrastructure including but not limited to repositories, preprint servers, registries, and schema that enable open standards and shared metadata across the research enterprise.
2. Responsible Indicators. Adopt the use of qualitative research indicators and assessments. Incentivize open science behaviors that enable scientific rigor and reproducibility. Some of these indicators may replace journal-based metrics. Indicators to consider for inclusion are: open peer review participation, FAIR data practices, and the ability to communicate individual and modular contributions to research.
3. Incentive Alignment. Embed these indicators in grant review rubrics, proposal templates (SciENcv), and annual reporting. Recognize and assess individual contributions to teams, considering their modular outputs, infrastructure contributions, and team roles equally with journal publications.

These changes reflect modern science's collaborative, transparency-dependent nature. They better align research assessment with the NIH's core mission: advancing knowledge that enhances health.

211. Elsevier

I am responding: On behalf of an organization

Name: Abi Hilditch

Name of Organization: Elsevier

Type of Organization: Publisher

Role: Other

Role - Other: Policy and Industry Relations Manager

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: Elsevier strongly supports NIH's goal to strengthen replication and reproducibility of biomedical research, a key tenet of Gold Standard Science and the foundation of rigorous research. We believe that stakeholders including funders, institutions, publishers, and researchers must collaborate to build a research system that rewards and integrates reproducibility practices.

Prerequisites for reproducibility are full transparency in how studies and experiments were undertaken, the methods and protocols involved, and the results obtained. Publishers play an important role by making continuous and substantial investments in infrastructure, processes and tooling to support transparency across these areas. For example, Elsevier prompts authors to share data, report openly on methods, and experimentation with approaches to disseminate research findings including negative and null results. Publishers, including Elsevier, additionally operationalize trust and transparency in the publishing process by supporting authors to consistently report funding sources, conflicts of interest, and ethics approvals; linking research articles to related data, code, and metadata that place the research in context; and maintaining the trusted version of record along with a clear, public trail of any subsequent corrections or updates.

NIH and publisher investments in fraud prevention and detection are needed alongside replicability and reproducibility to truly guarantee rigor in research. Publishers aim to prevent fraudulent articles from being published by using sophisticated, data-driven technology at all stages of the submission, editorial, and peer review processes to screen for integrity and ethics issues.

These investments are made possible by sustainable publishing models which enable publishers to recoup their costs. Sustainable models mean that publishers can invest in services which ensure the quality, integrity, discoverability, and accessibility of research in perpetuity. We encourage NIH to consider the need for sustainability in the scholarly communication system that underpins reproducibility and rigor in research, when developing its approach to impact measurement.

Building on this knowledge and experience, we propose the following potential indicators to measure rigor and reproducibility : preregistration, published protocols, transparent methods, materials

availability, statistical/code review, correction/versioning practices, replication-enabling outputs such as data and replication studies. Stakeholders from across the research ecosystem, including publishers, will need to collaborate to develop measures and align on successful indicators and incentives, which should avoid unintended consequences, such as those arising from penalising researchers for corrections.

We encourage NIH to see publishers as expert partners in these areas, and to recognize the importance of supporting existing research communication, research measurement, and research documentation systems that enable replication and reproducibility.

2. Data, Software, and Model Sharing: Elsevier agrees that sharing research outputs such as data, methods, and models is an integral part of the research process and extends (re)use of research, driving efficiencies, boosting the potential impact of research, and fostering innovation within academia and industry. We encourage NIH to explore the following examples of best practices when developing incentives for data sharing:

• The Force 11 FAIR principles for data sharing: supporting Findable, Accessible, Interoperable, Reusable data. These principles help optimize the use of data and methods across stakeholders.
• Researchers and institutions should be encouraged to store, share, discover and effectively (re)use data, following the principle "as open as possible, as closed as necessary." Federal agencies already have requirements in place to encourage this. Publishers provide further support by building prompts into the workflows for article submissions for authors to share links to datasets and include information in a repository of their choice.
• At Elsevier, we additionally make available Mendeley Data, an NIH Generalist Repository Ecosystem Initiative (GREI)-supported open and free generalist repository. We strongly support this initiative and would like to continue to partner with NIH on this effort.
• The Center for Open Science (COS) Transparency and Openness Promotion (TOP) developed community based guidelines to promote transparency, open sharing, and reproducibility.
• The Data Sharing Index (S-index) Challenge, led by the National Eye Institute (NEI) and NIH, which aims to incentivize the creation, development, and validation of a quantitative data sharing index.

Based on our experience of supporting and promoting data sharing, potential indicators for measuring data, software and model sharing include: availability of FAIR deposits in generalist and specialised repositories with DOIs, downloads, reuse signals, documentation quality, steps-to-reproduce fields, and citations in articles which provide vital contextual information to aid reproducibility. When considering policies and incentives, NIH should recognize the need to protect sensitive data, acknowledge domain-specific differences, and avoid rewarding volume of deposits over quality and usability.

Elsevier would welcome the opportunity to partner with NIH to maximize the value of research investments, catalyze collaborations, and accelerate scientific impact.

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: Demonstrating the public impact of federally funded research is key to strengthening public trust in science. Below, we provide examples of how Elsevier is supporting federal agencies to assess public impact:

• NSF Technology, Innovation and Partnerships (TIP) Investment Explorer is an interactive research intelligence portal and map developed by Elsevier in collaboration with the U.S. National Science Foundation's TIP Directorate. It visualizes NSF TIP awards across institutions, states, and technology domains, using Elsevier's Pure and InsightGraph platforms to integrate award data with broader research information. By linking grants to organizations, research outputs, and innovation areas, the TIP Investment Explorer helps stakeholders track where federally funded research investments are being made and how they contribute to national priorities such as AI, quantum science, biotechnology, and advanced manufacturing. This tool supports monitoring benefits and impacts by showing not just the distribution of funding, but also downstream outcomes, such as creation of jobs and start-ups, and follow-on funding. This provides funders, policymakers, and institutions with evidence of how public research dollars drive innovation, collaboration, economic development, and societal progress.
• Elsevier has also developed the US research and innovation portal, which explores the latest trends in US research excellence, highlighting data on high-quality outputs in five key critical and emerging technology areas identified by the US federal government, including biotechnology. This analysis shows how publication data can be used beyond citations to support analysis of research collaboration networks as well as identification of talented individuals and new potential partnerships, which further aligns with NIH's intention to assess and recognise contributions to team-based science.

Building on our extensive experience in this area, we believe NIH should consider measuring the following specific indicators for public impact: clinical guideline influence, policy mentions, media and podcast attention, public engagement, accessibility, patient/community benefit, partner-attested impact, economic activity, job and start-up creation, and evidence of trust-building or adoption. Given the sensitive nature of public impact of research, we recommend that NIH set-up appropriate safeguards to avoid overstating causality of research outcomes and use contribution analysis and confidence levels when health or societal outcomes involve many actors.

Finally, we encourage NIH to consider the infrastructure which allows research to have public impact. To achieve impact, research must be disseminated and accessible, with processes in place to ensure quality, integrity, discoverability and preservation of the version of record in perpetuity. Publishers make significant investments to support a trusted scholarly communications system, which ensures that articles, data and research outputs can continue to have long-term public impact.

NSF Technology, Innovation and Partnerships (TIP) Investment Explorer: https://nsfmap.services.elsevierpure.com/map
Elsevier US research and innovation portal: https://elsevier.shorthandstories.com/us-research-and-innovation-performance/index.html

8. Other Areas: Elsevier welcomes the opportunity to provide feedback to the National Institutes of Health's request for information on Measuring and Rewarding Scientific Impact. For many years, Elsevier has supported the careful use of metrics and indicators in the evaluation of research and has advocated for a combined qualitative and quantitative approach, including support for initiatives such as the San Francisco Declaration on Reforming Research Assessment (DORA). In line with this, we have endeavoured to share specific indicator suggestions in the areas of Rigor and Reproducibility, Data, Software and Model Sharing, and Public Impact while highlighting how publishers support across these areas.

To ensure an aligned approach to measuring and rewarding scientific impact across priority topics, we further recommend that NIH develops an overarching Impact and Rigor Evidence Framework. This should take a transparent, multidimensional approach that uses a basket of validated indicators, qualitative evidence, expert judgment, and clear guardrails. The framework should be designed for portfolio learning and incentive alignment, not for reductive ranking of individuals or automated funding decisions.

NIH should build the framework around principles that keep metrics useful, interpretable, fair, and reusable. Each indicator should have a documented purpose, definition, data source, update cadence, normalization method, limitations, and intended interpretation. Each output should document where information originated and how it contributed to the indicator to support transparency and enable auditing. No single indicator should be treated as a proxy for scientific quality or public impact.
Finally, any framework should be governed as a reusable evidence asset to support future NIH reporting and evaluation needs, subject to necessary and appropriate review, evolution and updates, rather than a one-time reporting exercise.

We believe NIH's aim to incentivize and reward rigorous research that delivers value to the American public is laudable, and we support the responsible use of indicators of success that reflect the collaborative and mission-driven nature of modern biomedical science. We look forward to collaborating with NIH as it further develops this work.

1. Rigor and Reproducibility: See attached for formatted version of the following:
1.1 The missing instrument: indicators for analytic replicability
We are highly encouraged by NIH's renewed focus on transparency, reproducibility, and replication shown in the Request for Information on Measuring and Rewarding Scientific Impact, the Initiative to promote Strengthening Replication and Reproducibility of NIH-funded Research, the Gold Standard implementation plan, and the recent Highlighted Topic on Enhancing Scientific Rigor, Transparency and Replicability. These documents name reproducibility and replicability as distinct goals, correctly, and the Initiative has instruments aimed at each: for the former, longstanding investments in data sharing, standardization, and public access to findings; for the latter, funded replication research through the Common Fund, a Replication Prize, and a stated intent to engage researchers in identifying areas ripe for replication.
These are steps in the right direction. However, we have yet to observe incentives targeting the gap between reproducibility and replicability: whether the reported inference is valid given how the analysis proceeded. Statisticians and biostatisticians have a useful and unusual vantage point on this gap: we are often among the first to recognize why a finding may not replicate, while not always having the standing or involvement needed to address the problem.
This matters because replication studies detect errors, but do not prevent them. They measure the failure rate after the fact, one finding at a time, at a high cost per finding. A study can be perfectly reproducible — fully containerized, one-click re-runnable — and still report inference that is unlikely to replicate, and the replication study will discover this several years and several hundred thousand dollars later.
A common route to this is inference on a model that was chosen using the same data used for inference: unadjusted post-selection inference (UPSI). It is one instance of what Simmons, Nelson, and Simonsohn (2011) termed researcher degrees of freedom: undisclosed flexibility in analytic choices, sufficient on its own to produce significant findings without any intent to deceive. In a satirical blog post, Perry Hackman used simulations with pure-noise outcomes and a modest set of candidate subgroup interactions to show that an ostensibly rigorous method, forward stepwise selection with information criteria followed by standard statistical inference (dubbed UPSI), can produce at least one "significant" effect in 90+% of simulated trials (Peterson, 2025b). Nothing in that pipeline is clearly fraudulent; the analysis plan reads as rigorous, and the resulting code can be shared, containerized, and re-run perfectly.
Recommendation: The Initiative's replication instruments would return more per dollar if paired with a cheap upstream instrument that flags the findings most likely to need them. In analysis plans, progress

reports, and publication reporting, a short structured statement answering the following could be incentivized:

Was the reported model, subgroup, outcome scale, or covariate set chosen using the same data used to compute the reported inference?

If so, how were the inferences adjusted for selection? (sample splitting; selective or conditional inference; bootstrap or model-averaged uncertainty; explicit relabeling as exploratory). If not, where was the full analysis specification verifiably pre-registered?

How many candidate specifications were considered, including those examined and discarded?

Based on the above, results should be taken as on a spectrum between confirmatory (to provide stronger evidence for prespecified claims) and exploratory (to identify patterns and generate hypotheses).

Another recommendation is to commission periodic targeted statistical review of a random sample of supported publications, scored by trained statistical reviewers, reporting the proportion that (a) report selection-conditional inference without adjustment, (b) report subgroup findings without pre-specified subgroup structure, and (c) contain code that does not execute. Tracking that proportion over time measures whether the Initiative is working.

1.2 Candidate pools and model complexity are growing faster than the standards applied

Beneath many variable-selection procedures is an implicit assumption of covariate equipoise: that every candidate predictor is equally worthy of entering the model. Stepwise procedures, popular information criteria searches, and standard lasso implementations can all behave this way, and the assumption becomes problematic in settings where NIH is investing heavily.

Independent groups have converged on the same principle from different directions. Yu, Bien, and Tibshirani (2019) articulate a reluctant interaction selection principle — prefer a main effect over an interaction if all else is equal — and Tay and Tibshirani (2020) extend this method to a reluctant non-linear selection principle, preferring a linear term over a non-linear one on the same grounds. In his standard reference text, Harrell (2015) advises pre-specifying a small set of plausible interactions rather than testing all of them. Peterson and Cavanaugh (2022) advise that human-understandable "glass-box" models with meaningful features should be preferred to more complex ones precisely because they are easier to interrogate and replicate. Different penalties, different algorithms, same underlying claim: complexity should have to earn its way into a model, and treating every candidate term as equally deserving is what allows spurious complexity through. NIH need not adjudicate among these methods, but it should seek to require the reporting that makes the problem visible.

Transparent modeling methods matter because replication requires something to replicate: a claim specific enough that an independent team can test it on new data and report whether it held. Transparent statistical models often make such claims directly available. Waist circumference is associated with one-year HDL, $\beta = -0.04$ (95% CI -0.07 to -0.01) is a statement another group can go and check in a different dataset, and the check has a clear objective.

On the other hand, black-box predictive models, such as neural networks, XGBoost, random forests, and statistical models with high-order interaction terms, instead primarily yield prediction functions. A second team can apply the deposited model to new data and test whether predictive performance holds up. That is a meaningful form of external validation, but it is different from replicating an interpretable scientific claim. When performance drops, the failure may be difficult to localize: a transparent model can reveal which estimated relationship moved and in which direction, while an opaque model may reveal only that predictive performance deteriorated, and, if subgroup metrics are tracked, for whom.

This has a direct implication for the Initiative. Predictive modeling is an increasingly prominent category of NIH-supported research (e.g., Arshi et al. 2025, Le et al. 2024), and it is precisely the category on which replication instruments have the least purchase. Transparency is therefore not only a matter of trust, fairness, or regulatory compliance, though it is those too. It also determines how specifically a scientific claim can be interrogated and replicated.

As datasets grow larger and contain newer, more high-dimensional modalities, new statistical methodology will be critical. For instance, with only twenty candidate predictors, to capture potential interactions, one would need to sift through 190 pairwise interactions, 1,140 three-way interactions, and over a million candidate models across all orders. Further, when modalities differ in their dimension and overall signal, they quickly run into practical challenges. For example, in a lung adenocarcinoma survival analysis with 7 clinical covariates and 22,283 gene expression measurements, assuming covariate equipoise and penalizing both groups equally encodes a structural disadvantage for clinically well-motivated variables, which get de-selected due to the sheer difference in dimensionality of the two modalities. With NIH's data-integration priorities, as studies become multimodal, consisting of genomics plus clinical plus imaging plus wearable plus environmental and more, the need for novel methods that can accommodate such data is critical; important methodological challenges remain at the scale and complexity of these data.

Recommendations: First, NIH should be wary of accepting post-hoc explanation of an opaque model (such as a locally interpretable model, a SHAP-based variable importance metric, etc.) as a reliable, replicable scientific finding; the explainer is a separate model that may or may not describe what the first one does, and should not be treated as equivalent to a directly interpretable scientific claim. Second, the accuracy cost of transparency is an empirical question that has been studied. A systematic review of 71 studies developing clinical prediction models found no performance benefit of machine learning over logistic regression (Christodoulou et al., 2019). Benchmarking work supports this outside the clinical setting as well: across 110 datasets from the Penn Machine Learning Benchmarks database, a transparent regression approach was within 5% of the best-performing method on 79% of classification and 62% of regression datasets, with random forests and gradient boosting showing no statistically distinguishable advantage (Peterson et al., 2024). Where transparent methods fell short, the reasons were diagnosable and specific and not reflective of a general law that complexity buys accuracy (specific examples can be found in Peterson et al., 2024, Section 3.3.2).

The implication is not that black-box methods should be discouraged, but that the burden of justification runs backward. Investigators are rarely asked to show that their model's opacity bought anything. For NIH-funded models intended to inform clinical decisions, a low-cost expectation is that a transparent baseline be fit and reported alongside the complex one, so the cost of interpretability is measured in that application rather than assumed. Where the gap is negligible, as is often the case, the transparent model is the better scientific product, because it can be interrogated and corrected.

1.3 Adequacy at the design stage: making evidentiary expectations auditable

These analysis-stage safeguards are necessary, but inference is only as strong as the data generated by the study design. The design determines which populations, outcomes, contrasts, and sources of variation are observed and therefore which scientific claims the resulting data can support. One of the earliest places this becomes explicit is the sample-size or design justification, where investigators state what they expect the proposed design to be capable of learning.

This makes the justification useful for more than determining a number. It provides a prospective, auditable statement of what adequate evidence was expected to look like. NIH can then ask whether the

realized study provided that evidence and, if not, whether the departures and their implications were documented. A study need not unfold exactly as anticipated. Recruitment, measurement properties, effect sizes, intraclass correlations, or other design features must often be learned during the course of a study, at which point they become scientific information in their own right. Reporting them allows planning assumptions to be updated across studies rather than repeatedly regenerated from incomplete information.

For studies relying on existing or linked data, realized data quality may also differ from what was assumed at design, with implications for which claims the data can support. Rigor requires making those departures visible and reconsidering the claims they permit, rather than retrospectively treating the original justification as though nothing changed.

Gold Standard Science creates a policy demand for determining and justifying adequate sample sizes, but no common definition of “adequate” accompanies it. Raising conventional thresholds does not settle the problem. A study can have 90% power under poorly supported assumptions, for an effect of little scientific consequence, using an inefficient design, or with an imprecisely measured outcome. Adequacy is instead a fit-for-purpose judgment: whether the design, measurement, data quality, and analysis are sufficient for the claims the study is intended to support.

NIH guidance already reflects this principle. Under the current Parent R01 review framework, reviewers assess whether sample size is sufficient and well justified in relation to the research questions, outcomes, and design (NIH, 2024). NCCIH feasibility trials instead require quantitative feasibility or acceptability benchmarks and justification that the sample is sufficient to evaluate them; testing efficacy or “preliminary efficacy” is explicitly not the purpose (NCCIH, 2024a). By contrast, NCCIH efficacy, effectiveness, and pragmatic trials require power calculations linked to endpoints and hypotheses, at least 90% power for the primary outcome, adjustment for multiple primary outcomes, and a clinically meaningful effect size (NCCIH, 2024b). NIH therefore already treats adequacy as purpose-dependent; the opportunity is to make that principle explicit, consistent, and auditable.

The same principle extends beyond these examples. Exploratory secondary analyses, transportability or triangulation studies, resource construction, and methods development may require adequate precision, population overlap, analytic scope, ability to assess discordance, or support for future studies rather than power against a single alternative. Requiring a power calculation regardless can produce the calculation without the justification. This is not a lower bar for exploratory work but a different one: identify the intended claim, the criterion of adequacy it requires, and the corresponding limits on inference.

Design information also interacts with the candidate analysis space. Limited information combined with broad analytic flexibility can generate apparently strong but unstable findings, while each source of risk is largely invisible to instruments aimed only at the other.

Declaring intended claims and criteria of adequacy at the design stage gives the disclosure in §1.1 something to be checked against. A confirmatory aim that later relies on substantial data-dependent selection, or a secondary outcome later presented as a primary claim, has changed evidentiary status during execution. That is not necessarily a scientific failure, provided that its path from "design" to "discussion" is visible and reflected in the claims made.

Recommendations:

First, require fit-for-purpose definitions of adequacy. Applications should identify the claims or objectives the study is intended to support, and the criterion for an adequate sample size or design should reflect that purpose. When an effect size is used to justify adequacy, its magnitude should be grounded where

possible in empirical evidence and interpreted on a scale meaningful to the scientific question. Generic standardized effect-size conventions such as “small,” “medium,” and “large” should not substitute for separately considering the magnitude of effect that would matter and the variability anticipated in the study population. Not every aim of a complex study requires a separate, fully developed power analysis. However, the study should identify the minimum set of claims or objectives it is designed to support with strong evidentiary justification and demonstrate that the proposed design is adequate for those purposes.

Second, treat sample-size justification as an integral part of study design rather than a calculation performed after the design is largely fixed. The amount of information a study can provide depends not only on the number of observations but on interdependent choices about the population recruited, comparisons made, measurements collected, timing and intensity of follow-up, analytic strategy, and other features that can affect the credibility of conclusions. Those choices must also be made within constraints on participant burden, operational feasibility, time, and budget. Improving one dimension may worsen another. Sample-size justification should therefore be an iterative, collaborative process in which statistical, substantive, operational, and other relevant experts identify the major threats to the study’s success, examine how alternative design choices redistribute those threats, and determine how limited resources can be used to produce the strongest evidence for the study’s purpose. This provides a concrete, early example of collaboration that NIH could recognize and measure: integrating statistical, scientific, operational, and other relevant expertise into consequential study-design decisions.

Third, make sample-size and design justification transparent, auditable, and cumulative. Power analyses and other sample-size calculations should be reproducible from the statistical analysis plan, with the method, inputs, assumptions, and software or tools documented sufficiently for an independent reviewer to recreate and vary the calculation. Studies should subsequently compare planning assumptions with what was realized, including recruitment and retention, variability, clustering, measurement performance, and other design quantities. Meaningful departures should be reported along with their implications for the evidence the study can support, rather than treated only as implementation failures. Recording what was expected, what occurred, and how those differences affected the study would allow empirical knowledge about design assumptions to accumulate across studies, so that future investigators can ground their assumptions in better evidence. NIH could track the proportion of funded studies that make their design justifications reproducible and subsequently report comparisons between key planning assumptions and realized study conditions.

1.4 Identifying findings ripe for replication

The Initiative states that NIH will engage researchers in selecting research areas ripe for replication and reproducibility studies. The indicators proposed above provide a practical way to do so.

Statistical fragility can triage more effectively than citation count alone. A tractable prioritization score could combine downstream influence (citations, guideline adoption, use as the basis for subsequent trials) with fragility markers extractable from the published record: limited effective information relative to analytic complexity; post-hoc subgroup findings; adaptive analytic choices; estimates where the magnitude just passes a significance threshold; single-site designs; and material departures from the design assumptions or adequacy criteria established at the outset. Findings that are both highly influential and structurally fragile are where replication dollars buy the most information.

The proposed indicators make these markers much easier to identify prospectively. Section 1.1 records whether inference was conditioned on data-driven selection; §1.3 records what the design was expected to support and whether realized information or study objectives materially changed. Issues like a lower-

than-anticipated effective sample size, unexpectedly high or low intraclass correlation, or a claim that moved from exploratory to confirmatory status are not themselves a scientific failure. But when such changes materially affect the strength of a consequential finding, they provide a rational signal for replication priority.

1.5 Learning from discordance: reconciliation and transportability

Discordance in the existing evidence is itself informative. Studies that appear to address the same question may differ in estimand, population, measurement, design, or analytic assumptions. Triangulation uses this principle: agreement across approaches with different sources of bias can strengthen causal inference, while disagreement can reveal which assumptions or design features matter (Lawlor et al., 2016). Rather than defaulting to another de novo study, NIH could support structured reconciliation of discordant evidence, harmonizing these dimensions where possible and identifying the likely sources of remaining disagreement.

The same idea is more powerful when planned prospectively. Where transportability matters, a second cohort, site, health system, or data source can apply the same estimand, outcome definition, and prespecified analysis. This narrows the dimensions that vary and provides direct evidence about whether a result transports across populations or settings. Methods for generalizability and transportability already formalize this problem as extending causal inferences from a study population to a defined target population (Dahabreh et al., 2021).

One element of a definition of causal research is explicit definitions of the theoretical and empirical estimands and assumptions under which the design and analysis identify that quantity. Randomization alone does not remove this requirement: PCORI-funded work on post-randomization selection in cluster trials shows how treatment-dependent identification, recruitment, or noncompliance can change the population represented by the observed data and the causal effect that can be identified (Li et al., 2024). Recent causal frameworks similarly emphasize the target estimand, target population, target trial, and target validity (Lu et al., 2024). Multiple data sources do not establish causality by themselves, but they can show whether a causal conclusion depends on the population, measurement, or contextual factors from which it was obtained.

Recommendations: Fund reconciliation of consequential discordant evidence as a scientific activity, with harmonized comparisons and identified sources of disagreement as deliverables rather than another narrative review. Where claims are intended to extend beyond a single source population, allow and incentivize budgets for harmonization and prespecified analysis in a second data source. The work required to make those sources comparable should itself be recognized as part of the scientific contribution.

1.6 A model that already works

NIH need not build a reproducibility review from scratch. Since 2016, the Journal of the American Statistical Association (JASA) has operated a reproducibility initiative establishing minimum criteria for code, data, and workflow, and created the Associate Editor of Reproducibility role to implement them; it has since expanded from Applications and Case Studies to all original research (Wrobel et al., 2024). Public materials include a reviewer and author guide, a pre-submission checklist, a standardized artifact declaration form, and a template repository.

Directly transferable elements:

A standardized artifact declaration, submitted with progress reports or at closeout, stating what is reproducible, by which script, from which data, and where scope is limited and why.

A designated, credited reproducibility reviewer role. The single most important design feature of the

JASA program is that this is a named position with real editorial standing, not volunteer labor. NIH could support analogous roles in biostatistics cores as an allowable and expected budget line.
A recognition mechanism. JASA gives an award for materials exceeding the minimum. NIH's Replication Prize already establishes the model; the same logic could extend to reproducibility artifacts, recognized in award reporting and citable in biosketches.
Master-script executability: relative paths only, a wrapper script that reproduces results without modification, transparent run order, seeds set where exact reproduction is expected, versioned software documented and cited. Low-burden if adopted at project start rather than retrofitted.

2. Data, Software, and Model Sharing: Extend sharing from data to analytic artifacts. A dataset without the analysis is insufficient for validation. Deposited artifacts should include the executable pipeline, the computational environment (container or lockfile), seeds, and the selection procedure itself, assuming the model choice was data-dependent, not merely the final chosen model. Reporting only the winning specification discards what is needed to evaluate the inference.

Adopt synthetic facsimile data as the standard answer to restricted access. Where real data cannot be shared, JASA (for instance) requires a synthetic or facsimile dataset in the same format so code can at least be executed and inspected. This is a tested solution to NIH's hardest sharing problem and could be made an explicit, fundable expectation rather than an ad hoc accommodation.

Measure executed reproductions, not availability statements. The proportion of awards with a data availability statement is helpful but less meaningful as a quality signal. The meaningful metric is the proportion of deposited artifacts a qualified third party can execute end-to-end in a clean environment. NIH could seed this by funding a small number of institutional or consortium reproduction services and reporting aggregate success rates.

Fund data resources, not just data access. Valuable clinical and administrative data often require substantial legal, technical, and scientific work before they are usable beyond the institution that generated them. Curation, linkage, harmonization, missing-data assessment, and measurement-quality evaluation are part of evidence production, not background plumbing. NIH should fund and recognize this work, including contributions from the institutions and personnel that create usable data resources, and expect data quality to be assessed relative to specified use cases rather than treated as an intrinsic property of a dataset. PCORI's Patient-Centered Outcomes Data Repository provides one model: methodological projects can deposit documented, reusable study data expressly to support secondary analysis, reproduction, and further methods research (Li, 2026).

Integrating modalities is a methodological problem requiring renewed investment and awareness to protect the scientific record. Making heterogeneous data available together does not ensure that existing tools will handle them appropriately. Differences in measurement, missingness, dimensionality, and relevance to the scientific question across modalities require methodological development alongside infrastructure investment. As argued in §1.2, funding data integration without funding the methods to analyze integrated data legitimately risks producing a great deal of accessible data and a great many non-replicable findings drawn from it.

Fund software maintenance. Methods software is infrastructure that decays without support.

Statisticians and data scientists maintain packages on CRAN that are used well beyond the projects that produced them, with no funding attached to that maintenance — which is the ordinary arrangement rather than an unusual one. NIH should permit and expect maintenance budgets, count software citations as scholarly output, and expect critical software to be cited in references alongside papers so its use is traceable.

3. Training and Mentorship: Training impact should be measured as development, not placement alone. Career outcomes remain useful, but they depend on trainees' starting goals, opportunities, and the changing research labor market. NIH could instead pair placement outcomes with brief baseline and follow-up measures of trainees' skills, confidence, research responsibilities, and career plans. Useful indicators include the number of trainees supported; gains in competencies such as study design, data analysis, communication, collaboration, and reproducible practice; and whether trainees gained responsibilities or opportunities they did not have at entry.

Access to appropriate mentorship is itself measurable. Trainees on non-methodological projects should have documented access to statistical and other relevant quantitative mentorship with protected effort, and training plans should treat reproducible workflows, including version control, environment management, and executable analysis as basic research competencies rather than specialty skills.

Suggested indicators: baseline and follow-up assessments of trainee competencies and career plans; trainee placement interpreted relative to stated goals at entry; access to appropriate methodological mentorship; and inclusion of reproducible-research competencies in training plans.

4. Collaboration: See attached for formatted version of the following:

Recognize methodological and reproducibility service as a scored contribution. Reproducibility review, cross-lab statistical mentoring, maintenance of shared analytic infrastructure, and other methodological service are largely invisible in conventional productivity metrics. Making these contributions visible in biosketches and review criteria is a low-cost way to recognize work that directly supports team science and research rigor. Independent methodological service, including statistical service on DSMBs and other monitoring bodies, should likewise be recognized as a substantive contribution even when it does not result in co-authorship.
Collaborative statistical contribution is otherwise typically recorded as either co-authorship or an acknowledgment. Better indicators would capture both the role and structure of the collaboration, including the following:
Named quantitative collaborators with meaningful, specified effort, ideally distinguishable from nominal statistical support at token (e.g., supervisory or consulting) levels.
Contribution taxonomy (e.g., CRediT) at publication, naming methodology, software, formal analysis, and data curation roles.
Collaborative products beyond publications, including jointly submitted grants, workshops or meetings developed, shared data or software resources, and trainees taught or mentored across disciplines.
Whether the analysis plan was authored or co-authored by, and final analytic decisions authorized by, a named quantitative scientist with substantive responsibility for the analysis.
Collaboration should reflect more than the number of people a scientist has worked with, disciplines spanned, or projects contributed to. A quantitative scientist who develops a deep, sustained

collaboration in one scientific area may contribute as much as one working across many fields. At the program or institutional level, NIH could instead characterize the reach and durability of collaborative networks, including repeated collaboration across projects and connections among otherwise separate scientific groups.

Analytic independence should be an explicit expectation. Individually reasonable analysis decisions, such as which covariates to adjust for, how to restrict a population, which subgroups to consider, how to handle outliers, etc., can cumulatively add up to an undocumented selection procedure, especially if there is pressure on such decisions in the direction of increased significance. Gelman and Loken (2014) call this the garden of forking paths: multiplicity exists even when only one analysis was ever run, because the path taken depended on the data. A quantitative collaborator supported only at token effort may lack the standing to resist result-driven analytic choices or to advocate independently for the ethical and judicious analysis.

Such independence should be supported by expecting named quantitative experts to participate meaningfully on research teams with substantive, not token, effort. Further, such independence is potentially measurable: whether the quantitative scientist holds authorship rather than acknowledgment, giving them standing to insist on a caveat or decline; whether their effort is protected on the award rather than discretionary; and, for high-stakes observational analyses, whether independent statistical review occurred, on the model of the independence already expected of trial statisticians.

5. Entrepreneurship and Translation: Translation measured through patents, licenses, and company formation systematically undercounts methodological translation. A method that moves from paper to open-source implementation to routine use in NIH-funded studies, clinical guidelines, regulatory submissions, or policy analysis is translated in the sense NIH cares about, and the process is measurable: downstream software citation, dependency counts in other NIH-supported analyses, adoption in guidelines and regulatory review.

NIH should include methods-to-practice pathways in translation indicators and support the unglamorous middle step between invention and adoption: testing, documentation, maintenance, training, and integration of methods into usable software and workflows. These activities currently fall through the cracks between methodological and translational funding.

6. Foundational Scientific Exploration: Valid inference after data-dependent selection is, at best, only partially solved. General solutions face fundamental limits; partial solutions exist but remain underused, in part because accounting honestly for selection often produces wider uncertainty, and wider uncertainty can be harder to publish.

Adjacent problems are similarly open and consequential: quantifying uncertainty for models produced by regularized selection; setting evidentiary thresholds that scale with the size and structure of a candidate space; establishing theoretical guarantees when covariate groups grow at different rates; and building transparent methods that remain competitive for outcome distributions where they currently underperform, such as zero-inflated and heavily skewed clinical endpoints.

This is precisely the foundational work the Initiative should fund: methodological, high-risk, without necessarily having an immediate clinical output, and directly relevant to whether findings across the rest

of the portfolio replicate. As biomedical data and analytic choice expand, investment in replication alone addresses failures downstream; foundational statistical research can prevent some of them upstream.

7. Public Impact: Public impact should be evaluated along an impact pathway rather than inferred from citation counts alone. Evaluation frameworks distinguish intermediate outcomes such as reach, adoption, and sustained use from downstream changes in population health (Glasgow et al., 1999). NIH could similarly assess whether research produces trustworthy findings that reach intended populations, enter practice or policy, and are sustained over time.

Population outcomes are harder to attribute because the population is ultimately uncontrolled. Before asking whether research changed health outcomes, NIH often needs to know whether the resulting intervention, diagnostic, screening strategy, or clinical practice actually reached the population. NIH should incentivize studies linking changes in disease profiles and outcomes to changes in management and uptake, supported by data on where and among whom products and practices are used. This may require linking surveillance and health-system data with commercial, claims, registry, or other sources that capture diffusion beyond traditional research datasets.

Trustworthy evidence is a prerequisite for meaningful public impact. The replication rate of influential NIH-supported findings, tracked over time, would therefore provide an expensive but unusually direct indicator of whether the knowledge being propagated into research, practice, and policy remains supported when tested again.
Two additional indicators worth developing are the estimated resources committed downstream to findings that later failed to replicate, which NIH is uniquely positioned to assess; and the inspectability of clinical decision tools derived from NIH-funded research, including whether clinicians and patients can understand and contest the basis of the model’s outputs.

Finally, not all public impact should be reduced to a count. Periodic expert evaluation of influential NIH-supported bodies of work could assess whether and how they changed scientific understanding, practice, policy, or population health over time.

8. Other Areas: See attached for formatted version of the attached

8. Other Area: Generative AI, Agents, & Accountability
Generative AI and modern agentic analytic tools interact with every other category, and current trajectories run against the goals of this initiative.
AI-assisted analysis can quickly become an unrecorded selection procedure. An agent that iterates through dozens or hundreds of specifications and surfaces the one that "works best" is performing model selection at a scale exceeding what any analysis plan can reasonably specify in advance. The path taken by an LLM agent is rarely, if ever, reproducible from the prompt alone. If human-led data analysis represents Gelman's "garden of forking paths," an AI agent turns that garden into a random forest. Mandating a complete audit trail of this search process is technically possible. However, with modern "chain of thought" LLMs, the massive volume of intermediate and erratic "thinking" steps renders any such record highly convoluted. An AI-assisted scientist must then decide among several alternatives. One option is to diligently store a large, complex record of these AI-dictated choices, and to publish this record alongside their research. Another option is to narratively summarize the AI-enabled search, which

asks readers and funders alike to trust that whatever decisions were made, justified or not, were appropriate. Yet another option is to proceed as though the selected path was the "right" one all along. Every incentive pushes the scientist toward this final path of least resistance, which also carries the worst consequences for replicability. Consequently, as AI-assisted analysis becomes normalized, rejected specifications and the rationale for moving among them will disappear — not because scientists intend to conceal them, but because we lack both the norms of analytic accountability and the practical, rigorous tools to support them. This is multiplicity at machine speed, and it is poised to undermine replicability if left unchecked.

Recommendation: prevent multiplicity at the used for analytic work should make this information exportable rather than requiring investigators to reconstruct it after the fact. NIH could support development of provenance-capture tooling as research infrastructure.

Recommendation: retain locatable human accountability. A named individual should be able to explain and defend every analytic choice. NIH could require an attestation, parallel to existing authorship and conflict attestations, that a responsible analyst reviewed and understood AI-generated analytic code and decisions. AI may propose analytic choices, but a named human must adopt them and be able to state why each was selected over considered alternatives. This shifts analytic authority from AI dictation, which cannot be held to account for its mistakes, back to human judgment.

Recommendation: promote team science through shared analytic artifacts. Collaboration requires a shared, inspectable artifact to collaborate on. If each member works in a private AI-assisted workflow producing unshared code and unlogged decisions, team science becomes several parallel solo efforts with a joint author list (or worse, reverts to solo work with an AI). Shared repositories, executable master scripts, versioned environments, and declared selection procedures are the practical antidote, and NIH should fund and expect them at the team level.

9. Other Area: Unintended Consequences and Feasibility

Checklist theater. Any requirement can become a compliance artifact if checked for existence rather than content; data-availability statements are a cautionary example of the limitations of existence-based metrics. Mitigation: sample-based audits by qualified reviewers, and metrics based on execution rather than deposit.

Chilling exploration. Pre-specification requirements can be misread as prohibiting exploration. The requirement is labeling, not prohibition. Selection disclosure should let exploratory work proceed freely and be reported honestly as exploratory rather than presented as confirmatory.

Over-rewarding confirmation. If replication success becomes a scored metric for individual investigators, the rational response is to study safe questions. This ultimately risks stifled innovation and hinders research exploration. Replication incentives should attach to the enterprise and to replication teams, not to the original investigator's record.

Regressive burden. Container registries, reproducibility reviewers, and synthetic data generation are easier to absorb at well-resourced institutions than at small ones. Mitigation: fund shared infrastructure, allow these costs explicitly in budgets, and scale expectations to award size and complexity rather than applying a uniform standard.

Career-stage asymmetry. Compliance and service expectations impose different burdens across career stages, with early-career investigators often least able to absorb them. Reproducibility service and exemplary artifacts should count concretely in review.

Metric capture generally. The indicators emphasized here, including executed reproductions, audited selection disclosure, candidate-space reporting, and downstream enablement, are relatively resistant to

gaming because satisfying them requires producing much of the underlying scientific behavior they are intended to measure.
Feasibility across contexts: selection disclosure, candidate-space reporting, and artifact declaration are relatively low burden when incorporated prospectively into the workflow, because they record decisions as they occur rather than reconstructing them later. Executable-artifact standards carry moderate costs and scale with award size. Independent reproduction services are more resource-intensive and should be centrally or consortium-funded rather than mandated institution by institution.

Description: The attached file has the American Statistical Association's entire set of comments, which are also pasted into the text boxes above but without the formatting (e.g., section titles, bullets).

ASA Response to NIH Request for Information: Measuring and Rewarding Scientific Impact

August 19, 2026

Developed with scientific and technical input from Ryan A. Peterson, PhD, University of Iowa; Elizabeth W. Eisenhauer, PhD; Theresa Kim, PhD, MS; and other ASA members.

Claude Opus 5 (Anthropic) and GPT-5.6 Sol (OpenAI) were used to assist with drafting and editing these comments.

Contributor disclaimer: The views do not necessarily represent the views of contributors' employers or affiliated institutions. Theresa Kim provided scientific and technical input during off-duty hours and without use of government-furnished equipment; her participation does not represent the views of NIH, HHS, or the U.S. Government.

---

1. Rigor and Reproducibility

1.1 The missing instrument: indicators for analytic replicability

We are highly encouraged by NIH's renewed focus on transparency, reproducibility, and replication shown in the Request for Information on Measuring and Rewarding Scientific Impact, the Initiative to promote Strengthening Replication and Reproducibility of NIH-funded Research, the Gold Standard implementation plan, and the recent Highlighted Topic on Enhancing Scientific Rigor, Transparency and Replicability. These documents name reproducibility and replicability as distinct goals, correctly, and the

Initiative has instruments aimed at each: for the former, longstanding investments in data sharing, standardization, and public access to findings; for the latter, funded replication research through the Common Fund, a Replication Prize, and a stated intent to engage researchers in identifying areas ripe for replication.

These are steps in the right direction. However, we have yet to observe incentives targeting the gap between reproducibility and replicability: whether the reported inference is valid given how the analysis proceeded. Statisticians and biostatisticians have a useful and unusual vantage point on this gap: we are often among the first to recognize why a finding may not replicate, while not always having the standing or involvement needed to address the problem.

This matters because replication studies *detect* errors, but do not *prevent* them. They measure the failure rate after the fact, one finding at a time, at a high cost per finding. A study can be perfectly reproducible — fully containerized, one-click re-runnable — and still report inference that is unlikely to replicate, and the replication study will discover this several years and several hundred thousand dollars later.

A common route to this is inference on a model that was chosen using the same data used for inference: **unadjusted post-selection inference (UPSI)**. It is one instance of what Simmons, Nelson, and Simonsohn (2011) termed researcher degrees of freedom: undisclosed flexibility in analytic choices, sufficient on its own to produce significant findings without any intent to deceive. In a satirical blog post, Perry Hackman used simulations with pure-noise outcomes and a modest set of candidate subgroup interactions to show that an ostensibly rigorous method, forward stepwise selection with information criteria followed by standard statistical inference (dubbed UPSI), can produce at least one "significant" effect in 90+% of simulated trials (Peterson, 2025b). Nothing in that pipeline is clearly fraudulent; the analysis plan reads as rigorous, and the resulting code can be shared, containerized, and re-run perfectly.

Recommendation: The Initiative's replication instruments would return more per dollar if paired with a cheap upstream instrument that flags the findings most likely to need them. In analysis plans, progress reports, and publication reporting, a short structured statement answering the following could be incentivized:

- Was the reported model, subgroup, outcome scale, or covariate set chosen using the same data used to compute the reported inference?
- If so, how were the inferences adjusted for selection? (sample splitting; selective or conditional inference; bootstrap or model-averaged uncertainty; explicit relabeling as exploratory). If not, where was the full analysis specification verifiably pre-registered?
- How many candidate specifications were considered, including those examined and discarded?

Based on the above, results should be taken as on a spectrum between confirmatory (to provide stronger evidence for prespecified claims) and exploratory (to identify patterns and generate hypotheses).

Another recommendation is to commission periodic targeted statistical review of a random sample of supported publications, scored by trained statistical reviewers, reporting the proportion that (a) report selection-conditional inference without adjustment, (b) report subgroup findings without pre-specified subgroup structure, and (c) contain code that does not execute. Tracking that proportion over time measures whether the Initiative is working.

1.2 Candidate pools and model complexity are growing faster than the standards applied

Beneath many variable-selection procedures is an implicit assumption of covariate equipoise: that every candidate predictor is equally worthy of entering the model. Stepwise procedures, popular information criteria searches, and standard lasso implementations can all behave this way, and the assumption becomes problematic in settings where NIH is investing heavily.

Independent groups have converged on the same principle from different directions. Yu, Bien, and Tibshirani (2019) articulate a *reluctant interaction selection principle* — prefer a main effect over an interaction if all else is equal — and Tay and Tibshirani (2020) extend this method to a *reluctant non-linear selection principle*, preferring a linear term over a non-linear one on the same grounds. In his standard reference text, Harrell (2015) advises pre-specifying a small set of plausible interactions rather than testing all of them. Peterson and Cavanaugh (2022) advise that human-understandable "glass-box" models with meaningful features should be preferred to more complex ones precisely because they are easier to interrogate and replicate. Different penalties, different algorithms, same underlying claim: complexity should have to earn its way into a model, and treating every candidate term as equally deserving is what allows spurious complexity through. NIH need not adjudicate among these methods, but it should seek to require the reporting that makes the problem visible.

Transparent modeling methods matter because **replication requires something to replicate**: a claim specific enough that an independent team can test it on new data and report whether it held. Transparent statistical models often make such claims directly available. *Waist circumference is associated with one-year HDL, $\beta = -0.04$ (95% CI −0.07 to −0.01)* is a statement another group can go and check in a different dataset, and the check has a clear objective.

On the other hand, black-box predictive models, such as neural networks, XGBoost, random forests, and statistical models with high-order interaction terms, instead primarily yield prediction functions. A second team can apply the deposited model to new data and test whether predictive performance holds up. That is a meaningful form of external validation, but it is different from replicating an interpretable scientific claim. When performance drops, the failure may be difficult to localize: a transparent model can reveal which estimated relationship moved and in which direction, while an opaque model may reveal only that predictive performance deteriorated, and, if subgroup metrics are tracked, for whom.

This has a direct implication for the Initiative. Predictive modeling is an increasingly prominent category of NIH-supported research (e.g., Arshi et al. 2025, Le et al. 2024), and it is precisely the category on

which replication instruments have the least purchase. Transparency is therefore not only a matter of trust, fairness, or regulatory compliance, though it is those too. It also determines how specifically a scientific claim can be interrogated and replicated.

As datasets grow larger and contain newer, more high-dimensional modalities, new statistical methodology will be critical. For instance, with only twenty candidate predictors, to capture potential interactions, one would need to sift through 190 pairwise interactions, 1,140 three-way interactions, and over a million candidate models across all orders. Further, when modalities differ in their dimension and overall signal, they quickly run into practical challenges. For example, in a lung adenocarcinoma survival analysis with 7 clinical covariates and 22,283 gene expression measurements, assuming covariate equipoise and penalizing both groups equally encodes a structural disadvantage for clinically well-motivated variables, which get de-selected due to the sheer difference in dimensionality of the two modalities. With NIH's data-integration priorities, as studies become multimodal, consisting of genomics plus clinical plus imaging plus wearable plus environmental and more, the need for novel methods that can accommodate such data is critical; important methodological challenges remain at the scale and complexity of these data.

Recommendations: First, NIH should be wary of accepting post-hoc explanation of an opaque model (such as a locally interpretable model, a SHAP-based variable importance metric, etc.) as a reliable, replicable scientific finding; the explainer is a separate model that may or may not describe what the first one does, and should not be treated as equivalent to a directly interpretable scientific claim. Second, the accuracy cost of transparency is an empirical question that has been studied. A systematic review of 71 studies developing clinical prediction models found no performance benefit of machine learning over logistic regression (Christodoulou et al., 2019). Benchmarking work supports this outside the clinical setting as well: across 110 datasets from the Penn Machine Learning Benchmarks database, a transparent regression approach was within 5% of the best-performing method on 79% of classification and 62% of regression datasets, with random forests and gradient boosting showing no statistically distinguishable advantage (Peterson et al., 2024). Where transparent methods fell short, the reasons were diagnosable and specific and not reflective of a general law that complexity buys accuracy (specific examples can be found in Peterson et al., 2024, Section 3.3.2).

The implication is not that black-box methods should be discouraged, but that the burden of justification runs backward. **Investigators are rarely asked to show that their model's opacity bought anything**. For NIH-funded models intended to inform clinical decisions, a low-cost expectation is that a transparent baseline be fit and reported alongside the complex one, so the cost of interpretability is measured in that application rather than assumed. Where the gap is negligible, as is often the case, the transparent model is the better scientific product, because it can be interrogated and corrected.

1.3 Adequacy at the design stage: making evidentiary expectations auditable

These analysis-stage safeguards are necessary, but inference is only as strong as the data generated by the study design. The design determines which populations, outcomes, contrasts, and sources of variation are observed and therefore which scientific claims the resulting data can support. One of the earliest places this becomes explicit is the sample-size or design justification, where investigators state what they expect the proposed design to be capable of learning.

This makes the justification useful for more than determining a number. It provides a prospective, auditable statement of what adequate evidence was expected to look like. NIH can then ask whether the realized study provided that evidence and, if not, whether the departures and their implications were documented. A study need not unfold exactly as anticipated. Recruitment, measurement properties, effect sizes, intraclass correlations, or other design features must often be learned during the course of a study, at which point they become scientific information in their own right. Reporting them allows planning assumptions to be updated across studies rather than repeatedly regenerated from incomplete information.

For studies relying on existing or linked data, realized data quality may also differ from what was assumed at design, with implications for which claims the data can support. Rigor requires making those departures visible and reconsidering the claims they permit, rather than retrospectively treating the original justification as though nothing changed.

Gold Standard Science creates a policy demand for determining and justifying adequate sample sizes, but no common definition of “adequate” accompanies it. Raising conventional thresholds does not settle the problem. A study can have 90% power under poorly supported assumptions, for an effect of little scientific consequence, using an inefficient design, or with an imprecisely measured outcome. Adequacy is instead a fit-for-purpose judgment: whether the design, measurement, data quality, and analysis are sufficient for the claims the study is intended to support.

NIH guidance already reflects this principle. Under the current Parent R01 review framework, reviewers assess whether sample size is sufficient and well justified in relation to the research questions, outcomes, and design (NIH, 2024). NCCIH feasibility trials instead require quantitative feasibility or acceptability benchmarks and justification that the sample is sufficient to evaluate them; testing efficacy or “preliminary efficacy” is explicitly not the purpose (NCCIH, 2024a). By contrast, NCCIH efficacy, effectiveness, and pragmatic trials require power calculations linked to endpoints and hypotheses, at least 90% power for the primary outcome, adjustment for multiple primary outcomes, and a clinically meaningful effect size (NCCIH, 2024b). NIH therefore already treats adequacy as purpose-dependent; the opportunity is to make that principle explicit, consistent, and auditable.

The same principle extends beyond these examples. Exploratory secondary analyses, transportability or triangulation studies, resource construction, and methods development may require adequate precision, population overlap, analytic scope, ability to assess discordance, or support for future studies rather

than power against a single alternative. Requiring a power calculation regardless can produce the calculation without the justification. This is not a lower bar for exploratory work but a different one: identify the intended claim, the criterion of adequacy it requires, and the corresponding limits on inference.

Design information also interacts with the candidate analysis space. Limited information combined with broad analytic flexibility can generate apparently strong but unstable findings, while each source of risk is largely invisible to instruments aimed only at the other.

Declaring intended claims and criteria of adequacy at the design stage gives the disclosure in §1.1 something to be checked against. A confirmatory aim that later relies on substantial data-dependent selection, or a secondary outcome later presented as a primary claim, has changed evidentiary status during execution. That is not necessarily a scientific failure, provided that its path from "design" to "discussion" is visible and reflected in the claims made.

Recommendations:

First, require fit-for-purpose definitions of adequacy. Applications should identify the claims or objectives the study is intended to support, and the criterion for an adequate sample size or design should reflect that purpose. When an effect size is used to justify adequacy, its magnitude should be grounded where possible in empirical evidence and interpreted on a scale meaningful to the scientific question. Generic standardized effect-size conventions such as “small,” “medium,” and “large” should not substitute for separately considering the magnitude of effect that would matter and the variability anticipated in the study population. Not every aim of a complex study requires a separate, fully developed power analysis. However, the study should identify the minimum set of claims or objectives it is designed to support with strong evidentiary justification and demonstrate that the proposed design is adequate for those purposes.

Second, treat sample-size justification as an integral part of study design rather than a calculation performed after the design is largely fixed. The amount of information a study can provide depends not only on the number of observations but on interdependent choices about the population recruited, comparisons made, measurements collected, timing and intensity of follow-up, analytic strategy, and other features that can affect the credibility of conclusions. Those choices must also be made within constraints on participant burden, operational feasibility, time, and budget. Improving one dimension may worsen another. Sample-size justification should therefore be an iterative, collaborative process in which statistical, substantive, operational, and other relevant experts identify the major threats to the study’s success, examine how alternative design choices redistribute those threats, and determine how limited resources can be used to produce the strongest evidence for the study’s purpose. This provides a concrete, early example of collaboration that NIH could recognize and measure: integrating statistical, scientific, operational, and other relevant expertise into consequential study-design decisions.

Third, make sample-size and design justification transparent, auditable, and cumulative. Power analyses and other sample-size calculations should be reproducible from the statistical analysis plan, with the

method, inputs, assumptions, and software or tools documented sufficiently for an independent reviewer to recreate and vary the calculation. Studies should subsequently compare planning assumptions with what was realized, including recruitment and retention, variability, clustering, measurement performance, and other design quantities. Meaningful departures should be reported along with their implications for the evidence the study can support, rather than treated only as implementation failures. Recording what was expected, what occurred, and how those differences affected the study would allow empirical knowledge about design assumptions to accumulate across studies, so that future investigators can ground their assumptions in better evidence. NIH could track the proportion of funded studies that make their design justifications reproducible and subsequently report comparisons between key planning assumptions and realized study conditions.

1.4 Identifying findings ripe for replication

The Initiative states that NIH will engage researchers in selecting research areas ripe for replication and reproducibility studies. The indicators proposed above provide a practical way to do so.

Statistical fragility can triage more effectively than citation count alone. A tractable prioritization score could combine downstream influence (citations, guideline adoption, use as the basis for subsequent trials) with fragility markers extractable from the published record: limited effective information relative to analytic complexity; post-hoc subgroup findings; adaptive analytic choices; estimates where the magnitude just passes a significance threshold; single-site designs; and material departures from the design assumptions or adequacy criteria established at the outset. Findings that are both highly influential and structurally fragile are where replication dollars buy the most information.

The proposed indicators make these markers much easier to identify prospectively. Section 1.1 records whether inference was conditioned on data-driven selection; §1.3 records what the design was expected to support and whether realized information or study objectives materially changed. Issues like a lower-than-anticipated effective sample size, unexpectedly high or low intraclass correlation, or a claim that moved from exploratory to confirmatory status are not themselves a scientific failure. But when such changes materially affect the strength of a consequential finding, they provide a rational signal for replication priority.

1.5 Learning from discordance: reconciliation and transportability

Discordance in the existing evidence is itself informative. Studies that appear to address the same question may differ in estimand, population, measurement, design, or analytic assumptions. Triangulation uses this principle: agreement across approaches with different sources of bias can strengthen causal inference, while disagreement can reveal which assumptions or design features matter (Lawlor et al., 2016). Rather than defaulting to another *de novo* study, NIH could support structured reconciliation of discordant evidence, harmonizing these dimensions where possible and identifying the likely sources of remaining disagreement.

The same idea is more powerful when planned prospectively. Where transportability matters, a second cohort, site, health system, or data source can apply the same estimand, outcome definition, and prespecified analysis. This narrows the dimensions that vary and provides direct evidence about whether a result transports across populations or settings. Methods for generalizability and transportability already formalize this problem as extending causal inferences from a study population to a defined target population (Dahabreh et al., 2021).

One element of a definition of causal research is explicit definitions of the theoretical and empirical estimands and assumptions under which the design and analysis identify that quantity. Randomization alone does not remove this requirement: PCORI-funded work on post-randomization selection in cluster trials shows how treatment-dependent identification, recruitment, or noncompliance can change the population represented by the observed data and the causal effect that can be identified (Li et al., 2024).

Recent causal frameworks similarly emphasize the target estimand, target population, target trial, and target validity (Lu et al., 2024). Multiple data sources do not establish causality by themselves, but they can show whether a causal conclusion depends on the population, measurement, or contextual factors from which it was obtained.

Recommendations: Fund reconciliation of consequential discordant evidence as a scientific activity, with harmonized comparisons and identified sources of disagreement as deliverables rather than another narrative review. Where claims are intended to extend beyond a single source population, allow and incentivize budgets for harmonization and prespecified analysis in a second data source. The work required to make those sources comparable should itself be recognized as part of the scientific contribution.

1.6 A model that already works

NIH need not build a reproducibility review from scratch. Since 2016, the Journal of the American Statistical Association (JASA) has operated a reproducibility initiative establishing minimum criteria for code, data, and workflow, and created the Associate Editor of Reproducibility role to implement them; it has since expanded from Applications and Case Studies to all original research (Wrobel et al., 2024). Public materials include a reviewer and author guide, a pre-submission checklist, a standardized artifact declaration form, and a template repository.

Directly transferable elements:

- **A standardized artifact declaration**, submitted with progress reports or at closeout, stating what is reproducible, by which script, from which data, and where scope is limited and why.
- **A designated, credited reproducibility reviewer role.** The single most important design feature of the JASA program is that this is a named position with real editorial standing, not volunteer labor. NIH could support analogous roles in biostatistics cores as an allowable and expected budget line.

- **A recognition mechanism.** JASA gives an award for materials exceeding the minimum. NIH's Replication Prize already establishes the model; the same logic could extend to reproducibility artifacts, recognized in award reporting and citable in biosketches.
- **Master-script executability**: relative paths only, a wrapper script that reproduces results without modification, transparent run order, seeds set where exact reproduction is expected, versioned software documented and cited. Low-burden if adopted at project start rather than retrofitted.

---

2. Data, Software, and Model Sharing

Extend sharing from data to analytic artifacts. A dataset without the analysis is insufficient for validation. Deposited artifacts should include the executable pipeline, the computational environment (container or lockfile), seeds, and the *selection procedure itself,* assuming the model choice was data-dependent, not merely the final chosen model. Reporting only the winning specification discards what is needed to evaluate the inference.

Adopt synthetic facsimile data as the standard answer to restricted access. Where real data cannot be shared, JASA (for instance) requires a synthetic or facsimile dataset in the same format so code can at least be executed and inspected. This is a tested solution to NIH's hardest sharing problem and could be made an explicit, fundable expectation rather than an *ad hoc* accommodation.

Measure executed reproductions, not availability statements. The proportion of awards with a data availability statement is helpful but less meaningful as a quality signal. The meaningful metric is the proportion of deposited artifacts a qualified third party can execute end-to-end in a clean environment. NIH could seed this by funding a small number of institutional or consortium reproduction services and reporting aggregate success rates.

Fund data resources, not just data access. Valuable clinical and administrative data often require substantial legal, technical, and scientific work before they are usable beyond the institution that generated them. Curation, linkage, harmonization, missing-data assessment, and measurement-quality evaluation are part of evidence production, not background plumbing. NIH should fund and recognize this work, including contributions from the institutions and personnel that create usable data resources, and expect data quality to be assessed relative to specified use cases rather than treated as an intrinsic property of a dataset. PCORI's Patient-Centered Outcomes Data Repository provides one model: methodological projects can deposit documented, reusable study data expressly to support secondary analysis, reproduction, and further methods research (Li, 2026).

Integrating modalities is a methodological problem requiring renewed investment and awareness to protect the scientific record. Making heterogeneous data available together does not ensure that existing tools will handle them appropriately. Differences in measurement, missingness, dimensionality, and relevance to the scientific question across modalities require methodological development alongside

infrastructure investment. As argued in §1.2, funding data integration without funding the methods to analyze integrated data legitimately risks producing a great deal of accessible data and a great many non-replicable findings drawn from it.

Fund software maintenance. Methods software is infrastructure that decays without support. Statisticians and data scientists maintain packages on CRAN that are used well beyond the projects that produced them, with no funding attached to that maintenance — which is the ordinary arrangement rather than an unusual one. NIH should permit and expect maintenance budgets, count software citations as scholarly output, and expect critical software to be cited in references alongside papers so its use is traceable.

---

3. Training and Mentorship

Training impact should be measured as development, not placement alone. Career outcomes remain useful, but they depend on trainees' starting goals, opportunities, and the changing research labor market. NIH could instead pair placement outcomes with brief baseline and follow-up measures of trainees' skills, confidence, research responsibilities, and career plans. Useful indicators include the number of trainees supported; gains in competencies such as study design, data analysis, communication, collaboration, and reproducible practice; and whether trainees gained responsibilities or opportunities they did not have at entry.

Access to appropriate mentorship is itself measurable. Trainees on non-methodological projects should have documented access to statistical and other relevant quantitative mentorship with protected effort, and training plans should treat reproducible workflows, including version control, environment management, and executable analysis as basic research competencies rather than specialty skills.

Suggested indicators: baseline and follow-up assessments of trainee competencies and career plans; trainee placement interpreted relative to stated goals at entry; access to appropriate methodological mentorship; and inclusion of reproducible-research competencies in training plans.

---

4. Collaboration

Recognize methodological and reproducibility service as a scored contribution. Reproducibility review, cross-lab statistical mentoring, maintenance of shared analytic infrastructure, and other methodological service are largely invisible in conventional productivity metrics. Making these contributions visible in biosketches and review criteria is a low-cost way to recognize work that directly supports team science and research rigor. Independent methodological service, including statistical service on DSMBs and other

monitoring bodies, should likewise be recognized as a substantive contribution even when it does not result in co-authorship.

Collaborative statistical contribution is otherwise typically recorded as either co-authorship or an acknowledgment. Better indicators would capture both the role and structure of the collaboration, including the following:

- Named quantitative collaborators with **meaningful, specified effort**, ideally distinguishable from nominal statistical support at token (e.g., supervisory or consulting) levels.
- Contribution taxonomy (e.g., CRediT) at publication, naming methodology, software, formal analysis, and data curation roles.
- Collaborative products beyond publications, including jointly submitted grants, workshops or meetings developed, shared data or software resources, and trainees taught or mentored across disciplines.
- Whether the analysis plan was authored or co-authored by, and final analytic decisions authorized by, a named quantitative scientist with substantive responsibility for the analysis.

Collaboration should reflect more than the number of people a scientist has worked with, disciplines spanned, or projects contributed to. A quantitative scientist who develops a deep, sustained collaboration in one scientific area may contribute as much as one working across many fields. At the program or institutional level, NIH could instead characterize the reach and durability of collaborative networks, including repeated collaboration across projects and connections among otherwise separate scientific groups.

Analytic independence should be an explicit expectation. Individually reasonable analysis decisions, such as which covariates to adjust for, how to restrict a population, which subgroups to consider, how to handle outliers, etc., can cumulatively add up to an undocumented selection procedure, especially if there is pressure on such decisions in the direction of increased significance. Gelman and Loken (2014) call this the garden of forking paths: multiplicity exists even when only one analysis was ever run, because the path taken depended on the data. A quantitative collaborator supported only at token effort may lack the standing to resist result-driven analytic choices or to advocate independently for the ethical and judicious analysis.

Such independence should be supported by expecting named quantitative experts to participate meaningfully on research teams with substantive, not token, effort. Further, such independence is potentially measurable: whether the quantitative scientist holds authorship rather than acknowledgment, giving them standing to insist on a caveat or decline; whether their effort is protected on the award rather than discretionary; and, for high-stakes observational analyses, whether independent statistical review occurred, on the model of the independence already expected of trial statisticians.

5. Entrepreneurship and Translation

Translation measured through patents, licenses, and company formation systematically undercounts methodological translation. A method that moves from paper to open-source implementation to routine use in NIH-funded studies, clinical guidelines, regulatory submissions, or policy analysis is translated in the sense NIH cares about, and the process is measurable: downstream software citation, dependency counts in other NIH-supported analyses, adoption in guidelines and regulatory review.

NIH should include **methods-to-practice pathways** in translation indicators and support the unglamorous middle step between invention and adoption: testing, documentation, maintenance, training, and integration of methods into usable software and workflows. These activities currently fall through the cracks between methodological and translational funding.

---

6. Foundational Scientific Exploration

Valid inference after data-dependent selection is, at best, only partially solved. General solutions face fundamental limits; partial solutions exist but remain underused, in part because accounting honestly for selection often produces wider uncertainty, and wider uncertainty can be harder to publish.

Adjacent problems are similarly open and consequential: quantifying uncertainty for models produced by regularized selection; setting evidentiary thresholds that scale with the size and structure of a candidate space; establishing theoretical guarantees when covariate groups grow at different rates; and building transparent methods that remain competitive for outcome distributions where they currently underperform, such as zero-inflated and heavily skewed clinical endpoints.

This is precisely the foundational work the Initiative should fund: methodological, high-risk, without necessarily having an immediate clinical output, and directly relevant to whether findings across the rest of the portfolio replicate. As biomedical data and analytic choice expand, investment in replication alone addresses failures downstream; foundational statistical research can prevent some of them upstream.

---

7. Public Impact

Public impact should be evaluated along an impact pathway rather than inferred from citation counts alone. Evaluation frameworks distinguish intermediate outcomes such as reach, adoption, and sustained use from downstream changes in population health (Glasgow et al., 1999). NIH could similarly assess whether research produces trustworthy findings that reach intended populations, enter practice or policy, and are sustained over time.

Population outcomes are harder to attribute because the population is ultimately uncontrolled. Before asking whether research changed health outcomes, NIH often needs to know whether the resulting intervention, diagnostic, screening strategy, or clinical practice actually reached the population. NIH should incentivize studies linking changes in disease profiles and outcomes to changes in management and uptake, supported by data on where and among whom products and practices are used. This may require linking surveillance and health-system data with commercial, claims, registry, or other sources that capture diffusion beyond traditional research datasets.

Trustworthy evidence is a prerequisite for meaningful public impact. The replication rate of influential NIH-supported findings, tracked over time, would therefore provide an expensive but unusually direct indicator of whether the knowledge being propagated into research, practice, and policy remains supported when tested again.

Two additional indicators worth developing are the estimated resources committed downstream to findings that later failed to replicate, which NIH is uniquely positioned to assess; and the inspectability of clinical decision tools derived from NIH-funded research, including whether clinicians and patients can understand and contest the basis of the model's outputs.

Finally, not all public impact should be reduced to a count. Periodic expert evaluation of influential NIH-supported bodies of work could assess whether and how they changed scientific understanding, practice, policy, or population health over time.

---

8. Other Area: Generative AI, Agents, & Accountability

Generative AI and modern agentic analytic tools interact with every other category, and current trajectories run against the goals of this initiative.

AI-assisted analysis can quickly become an unrecorded selection procedure. An agent that iterates through dozens or hundreds of specifications and surfaces the one that "works best" is performing model selection at a scale exceeding what any analysis plan can reasonably specify in advance. The path taken by an LLM agent is rarely, if ever, reproducible from the prompt alone. If human-led data analysis represents Gelman's "garden of forking paths," an AI agent turns that garden into a random forest.

Mandating a complete audit trail of this search process is technically possible. However, with modern "chain of thought" LLMs, the massive volume of intermediate and erratic "thinking" steps renders any such record highly convoluted. An AI-assisted scientist must then decide among several alternatives. One option is to diligently store a large, complex record of these AI-dictated choices, and to publish this record alongside their research. Another option is to narratively summarize the AI-enabled search, which asks readers and funders alike to trust that whatever decisions were made, justified or not, were appropriate. Yet another option is to proceed as though the selected path was the "right" one all along.

Every incentive pushes the scientist toward this final path of least resistance, which also carries the worst consequences for replicability. Consequently, as AI-assisted analysis becomes normalized, rejected specifications and the rationale for moving among them will disappear — not because scientists intend to conceal them, but because we lack both the norms of analytic accountability and the practical, rigorous tools to support them. This is multiplicity at machine speed, and it is poised to undermine replicability if left unchecked.

Recommendation: prevent multiplicity at the design stage through methodological collaboration. Methodological input on study design should be a fundable, expected component of research, not an unbudgeted courtesy. It has always been true that a specification chosen *a priori* on a firm statistical foundation generates no search to document. Until recently, the effort required to explore many specifications served as an informal check on doing so. AI agents remove that friction, making design-stage input more consequential, yet simultaneously easier to skip. The recommendations that follow address the multiplicity that remains, as it always will, since no analysis plan can anticipate everything a real dataset will demand.

Recommended indicator: an analytic provenance record. Where generative AI materially contributes to analytic code or decisions, require a short log — model and version, date, nature of the contribution, and, where AI was used to generate or compare analytic alternatives, the alternatives considered and the selection process. Systems used for analytic work should make this information exportable rather than requiring investigators to reconstruct it after the fact. NIH could support development of provenance-capture tooling as research infrastructure.

Recommendation: retain locatable human accountability. A named individual should be able to explain and defend every analytic choice. NIH could require an attestation, parallel to existing authorship and conflict attestations, that a responsible analyst reviewed and understood AI-generated analytic code and decisions. AI may propose analytic choices, but a named human must adopt them and be able to state why each was selected over considered alternatives. This shifts analytic authority from AI dictation, which cannot be held to account for its mistakes, back to human judgment.

Recommendation: promote team science through shared analytic artifacts. Collaboration requires a shared, inspectable artifact to collaborate on. If each member works in a private AI-assisted workflow producing unshared code and unlogged decisions, team science becomes several parallel solo efforts with a joint author list (or worse, reverts to solo work with an AI). Shared repositories, executable master scripts, versioned environments, and declared selection procedures are the practical antidote, and NIH should fund and expect them at the team level.

9. Other Area: Unintended Consequences and Feasibility

- **Checklist theater.** Any requirement can become a compliance artifact if checked for existence rather than content; data-availability statements are a cautionary example of the limitations of

existence-based metrics. Mitigation: sample-based audits by qualified reviewers, and metrics based on execution rather than deposit.

- **Chilling exploration.** Pre-specification requirements can be misread as prohibiting exploration. The requirement is *labeling*, not prohibition. Selection disclosure should let exploratory work proceed freely and be reported honestly as exploratory rather than presented as confirmatory.
- **Over-rewarding confirmation.** If replication success becomes a scored metric for individual investigators, the rational response is to study safe questions. This ultimately risks stifled innovation and hinders research exploration. Replication incentives should attach to the enterprise and to replication teams, not to the original investigator's record.
- **Regressive burden.** Container registries, reproducibility reviewers, and synthetic data generation are easier to absorb at well-resourced institutions than at small ones. Mitigation: fund shared infrastructure, allow these costs explicitly in budgets, and scale expectations to award size and complexity rather than applying a uniform standard.
- **Career-stage asymmetry.** Compliance and service expectations impose different burdens across career stages, with early-career investigators often least able to absorb them. Reproducibility service and exemplary artifacts should count concretely in review.
- **Metric capture generally.** The indicators emphasized here, including executed reproductions, audited selection disclosure, candidate-space reporting, and downstream enablement, are relatively resistant to gaming because satisfying them requires producing much of the underlying scientific behavior they are intended to measure.

Feasibility across contexts: selection disclosure, candidate-space reporting, and artifact declaration are relatively low burden when incorporated prospectively into the workflow, because they record decisions as they occur rather than reconstructing them later. Executable-artifact standards carry moderate costs and scale with award size. Independent reproduction services are more resource-intensive and should be centrally or consortium-funded rather than mandated institution by institution.

Closing

Statisticians and biostatisticians have an unusual vantage point on this RFI: we are often among the first to recognize why a finding may not replicate, while not always having the standing or involvement needed to address the problem. The interventions most likely to succeed make analytic choices visible and attributable, because visibility is what allows a collaborator, reviewer, or reader to catch the problem, and because the alternative in an era of AI-accelerated analysis is a scientific record that is easy to re-run and impossible to interrogate.

The American Statistical Association appreciates the opportunity to comment on the Request for Information on Measuring and Rewarding Scientific Impact. Questions or comments may be directed to ASA Director of Science Policy Steve Pierson: spierson@amstat.org.

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: Americans for Medical Progress (AMP) appreciates the opportunity to provide input on approaches for measuring and rewarding scientific impact. As a national nonprofit dedicated to promoting and protecting responsible research, AMP supports NIH's efforts to strengthen rigor, reproducibility, transparency, and reliable scientific findings.

AMP affirms the essential role of animal research in advancing biomedical discovery and furthering NIH's mission to improve human health. We also support NIH's efforts to advance New Approach Methodologies (NAMs) and other human-based research technologies, recognizing that these approaches and animal research are most effective when viewed as complementary tools rather than competing alternatives.

Given AMP's expertise in animal research, we offer recommendations within two of NIH's identified areas:
• Rigor and Reproducibility: recognizing the role of intrinsic and extrinsic variables in research outcomes, reproducibility, and animal welfare.
• Data, Software, and Model Sharing: recognizing model selection, characterization, validation, and scientific appropriateness as necessary foundations for meaningful model sharing.

Rigor and Reproducibility
Reliable, reproducible findings are essential to ensuring that federal research investments generate knowledge that can be trusted, built upon, and translated into meaningful health advances.

NIH has examined these issues extensively in the past, including through its 2021 Advisory Committee to the Director Working Group on Enhancing Rigor, Transparency, and Translatability in Animal Research. AMP encourages NIH to revisit and build upon the recommendations from this committee's final report, particularly those related to identifying, controlling, and reporting extrinsic variables that can influence experimental outcomes. Factors such as genetics, sex, age, diet, microbiome, housing conditions, social environment, handling, acclimation, environmental enrichment, lighting, noise, temperature, transportation, medications, veterinary interventions, and other aspects of animal care can affect physiology, behavior, and how researchers interpret findings.

To account for the conditions that may influence the biological system under investigation, AMP

recommends NIH consider indicators that encourage investigators to identify, manage, justify, and report relevant sources of variability, including those associated with animal care and the research environment. Greater attention to these factors would strengthen reproducibility while also reinforcing the close connection between high-quality animal care and high-quality science.

Potential indicators could include:
• Identification and transparent reporting of intrinsic and extrinsic variables relevant to the research question.
• Scientific justification for which variables are controlled, randomized, stratified, or intentionally varied.
• Incorporation of veterinary, animal-care, behavioral, and comparative-medicine expertise into study design where appropriate.
• Reporting of animal health, housing, husbandry, handling, and environmental conditions that may affect interpretation or reproducibility.
• Use of refinement practices that improve animal welfare while reducing unintended physiological or behavioral variability.

In applying these indicators, AMP advises NIH not to confuse scientific rigor with over-standardization, as excessive standardization may limit the generalizability of findings in many research cases. Depending on the scientific question, investigators may appropriately control certain variables while intentionally incorporating variation in others to determine whether findings remain robust across conditions. The relevant measure of rigor should therefore be whether investigators understand, account for, document, and appropriately interpret the variables that influence their experimental system.

Adopting these indicators also provides an opportunity to recognize more explicitly the scientific contribution of animal care and welfare practices. Appropriate acclimation, handling, enrichment, pain management, housing, training, and veterinary care can influence physiology and behavior and, consequently, the quality and interpretation of experimental data. Recognizing these practices within the context of rigor and reproducibility would reinforce that refinement can contribute directly to both animal welfare and scientific quality.

Taken together, these measures would build on NIH's prior work and support a more complete approach to rigor and reproducibility, one that reflects the biological and environmental context in which animal research is conducted. They would also reinforce the principle that careful attention to animal health, welfare, and experimental conditions is central to responsible biomedical research and supports more reliable and reproducible science.

2. Data, Software, and Model Sharing: AMP supports NIH's goal of increasing the sharing of scientific data, tools, software, and research models. Greater sharing can facilitate independent validation, reduce unnecessary duplication, enable new analyses, and maximize the value of federally funded research.

However, AMP encourages NIH to expand this category to recognize and reward an important component that is not currently captured: model selection, characterization, validation, and scientific appropriateness. Before investigators are incentivized to disseminate a model for broader use, there should be sufficient evidence to define what the model represents, the scientific questions it is suited to address, its known limitations, and the context in which its use is appropriate.

This consideration is especially important in the current policy and communications environment, where animal models and NAMs or other human-based approaches are too often framed as competing alternatives. Modern biomedical research increasingly relies on a diverse range, and often a combination, of experimental systems, each with distinct strengths, limitations, and applications. As a foundational principle, AMP strongly encourages NIH to make clear that no model or methodology should be presumed more rigorous, innovative, predictive, or scientifically valuable solely because it falls within a particular category. These determinations should be based on the scientific question, the evidence supporting the model's use, and its demonstrated fitness for purpose.

Accordingly, NIH should consider indicators that recognize the scientific work required to establish a model's utility and appropriate application before rewarding its dissemination. Potential indicators could include:

- A clear scientific rationale for selection of the model or experimental system.
- Evidence that the model is appropriate for the biological question being studied.
- Characterization of the model's strengths, limitations, and relevant performance expectations.
- Validation or comparative assessment against other relevant approaches, where scientifically appropriate.
- Definition of the model's intended context of use, including circumstances in which its findings may have limited applicability.
- Consideration of whether complementary models or approaches are needed to address the scientific question.
- Availability of sufficient methodological information to support appropriate interpretation and reuse by other investigators.

These considerations are particularly timely as NIH and other federal agencies increase support for NAMs and other human-based research approaches. As these methods are developed and incorporated into biomedical research, it will be important to evaluate them using the same scientific standards applied to any other model, including animal studies. Their value should be demonstrated through evidence of reliability, relevance, and fitness for purpose, rather than inferred from novelty or from reduced animal use alone.

Regarding incentives, AMP recommends NIH be deliberate in defining what it chooses to reward in this area. Incentives should emphasize the evidence needed to determine whether a model is reliable, fit for purpose, and appropriately applied, rather than simply whether it is new, widely adopted, or associated with reduced animal use. Model sharing is most valuable when it rests on a sound scientific foundation and gives other investigators sufficient information to understand not only how a model can be used, but also when, why, and for what purposes its use is appropriate.

By incorporating model selection, characterization, validation, and scientific appropriateness into this category, NIH can ensure that incentives reward the utility, reliability, and appropriate application of shared resources rather than dissemination alone. This approach would also preserve the scientific flexibility necessary for investigators to use animal models, human-based technologies, computational approaches, or combinations of methods according to the needs of the research question.

Conclusion
As NIH considers new ways to recognize and reward scientific impact, AMP urges the agency to preserve the scientific judgment and methodological flexibility that are essential to biomedical progress. Incentives should reward the quality of the science, regardless of the model or methodology used, and should not create a preference for animal models, NAMs, or other human-based approaches simply by virtue of the category into which they fall. Rather, NIH should encourage better model selection and validation, careful attention to intrinsic and extrinsic variables, high standards of animal care and welfare, and transparent reporting.

NIH may also benefit from continued consultation with relevant stakeholder groups, including scientific societies, research institutions, veterinarians, animal care professionals, and organizations such as AMP, as these recommendations move toward implementation. Ongoing engagement can help ensure that any new indicators are scientifically meaningful, practical to apply, and responsive to the realities of research across different settings.

Given the breadth of NIH's research portfolio, flexibility in implementation will also be important. Appropriate indicators may vary by scientific discipline, species, model system, career stage, institution type, and research objective. A framework that establishes clear expectations while allowing for these differences will better support rigor, validation, transparency, and responsible research practices across the diverse programs and institutions NIH supports.

By grounding incentives in scientific appropriateness, rigor, and reliable outcomes, NIH can help ensure that efforts to modernize biomedical research strengthen the scientific foundation needed to advance its mission and improve human and animal health.

Re: Request for Information (RFI) on Measuring and Rewarding Scientific Impact (NOT-OD-26-047)

Submitted electronically via response portal and e-mail: SciencePolicy@od.nih.gov

Dear Dr. Jorgenson,

Americans for Medical Progress (AMP) appreciates the opportunity to provide input on approaches for measuring and rewarding scientific impact. As a national nonprofit dedicated to promoting and protecting responsible research, AMP supports NIH's efforts to strengthen rigor, reproducibility, transparency, and reliable scientific findings.

AMP affirms the essential role of animal research in advancing biomedical discovery and furthering NIH's mission to improve human health. We also support NIH's efforts to advance New Approach Methodologies (NAMs) and other human-based research technologies, recognizing that these approaches and animal research are most effective when viewed as complementary tools rather than competing alternatives.

Given AMP's expertise in animal research, we offer recommendations within two of NIH's identified areas:

- **Rigor and Reproducibility:** recognizing the role of intrinsic and extrinsic variables in research outcomes, reproducibility, and animal welfare.
- **Data, Software, and Model Sharing:** recognizing model selection, characterization, validation, and scientific appropriateness as necessary foundations for meaningful model sharing.

Rigor and Reproducibility

Reliable, reproducible findings are essential to ensuring that federal research investments generate knowledge that can be trusted, built upon, and translated into meaningful health advances.

NIH has examined these issues extensively in the past, including through its 2021 Advisory Committee to the Director Working Group on Enhancing Rigor, Transparency, and Translatability in Animal Research.[1] AMP encourages NIH to revisit and build upon the recommendations from this committee's final report,[2] particularly those related to identifying, controlling, and reporting extrinsic variables that can influence experimental outcomes. Factors such as genetics, sex, age, diet, microbiome, housing conditions, social environment, handling, acclimation, environmental enrichment, lighting, noise, temperature, transportation, medications, veterinary

[2] National Institutes of Health, Advisory Committee to the Director, Working Group on Enhancing Rigor, Transparency, and Translatability in Animal Research. (2021, June 11). *Final report.* *https://acd.od.nih.gov/documents/presentations/06112021_ACD_WorkingGroup_FinalReport.pdf*

interventions, and other aspects of animal care can affect physiology, behavior, and how researchers interpret findings.

To account for the conditions that may influence the biological system under investigation, AMP recommends NIH consider indicators that encourage investigators to identify, manage, justify, and report relevant sources of variability, including those associated with animal care and the research environment. Greater attention to these factors would strengthen reproducibility while also reinforcing the close connection between high-quality animal care and high-quality science.

Potential indicators could include:

- Identification and transparent reporting of intrinsic and extrinsic variables relevant to the research question.
- Scientific justification for which variables are controlled, randomized, stratified, or intentionally varied.
- Incorporation of veterinary, animal-care, behavioral, and comparative-medicine expertise into study design where appropriate.
- Reporting of animal health, housing, husbandry, handling, and environmental conditions that may affect interpretation or reproducibility.
- Use of refinement practices that improve animal welfare while reducing unintended physiological or behavioral variability.

In applying these indicators, AMP advises NIH not to confuse scientific rigor with over-standardization, as excessive standardization may limit the generalizability of findings in many research cases. Depending on the scientific question, investigators may appropriately control certain variables while intentionally incorporating variation in others to determine whether findings remain robust across conditions. The relevant measure of rigor should therefore be whether investigators understand, account for, document, and appropriately interpret the variables that influence their experimental system.

Adopting these indicators also provides an opportunity to recognize more explicitly the scientific contribution of animal care and welfare practices. Appropriate acclimation, handling, enrichment, pain management, housing, training, and veterinary care can influence physiology and behavior and, consequently, the quality and interpretation of experimental data. Recognizing these practices within the context of rigor and reproducibility would reinforce that refinement can contribute directly to both animal welfare and scientific quality.

Taken together, these measures would build on NIH's prior work and support a more complete approach to rigor and reproducibility, one that reflects the biological and environmental context in which animal research is conducted. They would also reinforce the principle that careful attention to animal health, welfare, and experimental conditions is central to responsible biomedical research and supports more reliable and reproducible science.

Data, Software, and Model Sharing

AMP supports NIH's goal of increasing the sharing of scientific data, tools, software, and research models. Greater sharing can facilitate independent validation, reduce unnecessary duplication, enable new analyses, and maximize the value of federally funded research.

However, AMP encourages NIH to expand this category to recognize and reward an important component that is not currently captured: **model selection, characterization, validation, and scientific appropriateness**. Before investigators are incentivized to disseminate a model for broader use, there should be sufficient evidence to define what the model represents, the scientific questions it is suited to address, its known limitations, and the context in which its use is appropriate.

This consideration is especially important in the current policy and communications environment, where animal models and NAMs or other human-based approaches are too often framed as competing alternatives. Modern biomedical research increasingly relies on a diverse range, and often a combination, of experimental systems, each with distinct strengths, limitations, and applications. As a foundational principle, AMP strongly encourages NIH to make clear that no model or methodology should be presumed more rigorous, innovative, predictive, or scientifically valuable solely because it falls within a particular category. These determinations should be based on the scientific question, the evidence supporting the model's use, and its demonstrated fitness for purpose.

Accordingly, NIH should consider indicators that recognize the scientific work required to establish a model's utility and appropriate application before rewarding its dissemination. Potential indicators could include:

- A clear scientific rationale for selection of the model or experimental system.
- Evidence that the model is appropriate for the biological question being studied.
- Characterization of the model's strengths, limitations, and relevant performance expectations.
- Validation or comparative assessment against other relevant approaches, where scientifically appropriate.
- Definition of the model's intended context of use, including circumstances in which its findings may have limited applicability.
- Consideration of whether complementary models or approaches are needed to address the scientific question.
- Availability of sufficient methodological information to support appropriate interpretation and reuse by other investigators.

These considerations are particularly timely as NIH and other federal agencies increase support for NAMs and other human-based research approaches. As these methods are developed and incorporated into biomedical research, it will be important to evaluate them using the same scientific standards applied to any other model, including animal studies. Their value should be demonstrated through evidence of reliability, relevance, and fitness for purpose, rather than inferred from novelty or from reduced animal use alone.

Regarding incentives, AMP recommends NIH be deliberate in defining what it chooses to reward in this area. Incentives should emphasize the evidence needed to determine whether a model is reliable, fit for purpose, and appropriately applied, rather than simply whether it is new, widely adopted, or associated with reduced animal use. Model sharing is most valuable when it rests on a sound scientific foundation and gives other investigators sufficient information to understand not only how a model can be used, but also when, why, and for what purposes its use is appropriate.

By incorporating model selection, characterization, validation, and scientific appropriateness into this category, NIH can ensure that incentives reward the utility, reliability, and appropriate application of shared resources rather than dissemination alone. This approach would also preserve the scientific flexibility necessary for

investigators to use animal models, human-based technologies, computational approaches, or combinations of methods according to the needs of the research question.

Conclusion

As NIH considers new ways to recognize and reward scientific impact, AMP urges the agency to preserve the scientific judgment and methodological flexibility that are essential to biomedical progress. Incentives should reward the quality of the science, regardless of the model or methodology used, and should not create a preference for animal models, NAMs, or other human-based approaches simply by virtue of the category into which they fall. Rather, NIH should encourage better model selection and validation, careful attention to intrinsic and extrinsic variables, high standards of animal care and welfare, and transparent reporting.

NIH may also benefit from continued consultation with relevant stakeholder groups, including scientific societies, research institutions, veterinarians, animal care professionals, and organizations such as AMP, as these recommendations move toward implementation. Ongoing engagement can help ensure that any new indicators are scientifically meaningful, practical to apply, and responsive to the realities of research across different settings.

Given the breadth of NIH's research portfolio, flexibility in implementation will also be important. Appropriate indicators may vary by scientific discipline, species, model system, career stage, institution type, and research objective. A framework that establishes clear expectations while allowing for these differences will better support rigor, validation, transparency, and responsible research practices across the diverse programs and institutions NIH supports.

By grounding incentives in scientific appropriateness, rigor, and reliable outcomes, NIH can help ensure that efforts to modernize biomedical research strengthen the scientific foundation needed to advance its mission and improve human and animal health.

Sincerely,

Paula Clifford, MLA, RLATG, CVT

1. Rigor and Reproducibility: Reproducing a computational finding requires identifying the exact software artifact used, and artifact identification fails when a project's own surfaces disagree about version and identifier: in a recent audit of 117 open-source research software projects (arXiv:2608.17159), version agreement across comparable metadata surface pairs was 0.447. A measurable indicator: publications and data deposits carry a resolvable software identifier whose version matches the project's distribution record. As implementation infrastructure, registered analysis protocols with released verification logs make audits themselves replicable; the study above deposited its sampling protocol with a DOI before measurement and released a complete hand-verification log (98.5% verified instrument precision), a pattern NIH could recognize and reward in methodological work generally.

2. Data, Software, and Model Sharing: Incentivizing software sharing presupposes that shared software can be credited, and crediting presupposes that the software's machine-readable citation metadata is consistent. The audit cited above suggests it is not. Across up to seven self-description surfaces per project (CITATION.cff, codemeta.json, .zenodo.json, resolved DOI records, package registry records, README citation content), 83.9% of projects exposing at least two comparable surfaces conflicted with themselves on at least one citation-critical field (title, authors, version, year, or DOI). Half of hand-verified conflicts traced to surfaces describing the software's paper rather than the software, and among projects whose citation file designates a preferred citation, 28 of 32 route citations to a record that disagrees with the software's own metadata (open data: doi.org/10.5281/zenodo.21969769).

Three measurable indicators follow. First, presence of machine-readable citation metadata (a citation file, exchange-schema record, or archival DOI) on funded software: cheap, automatable, and currently a minority practice (41% of audited projects carry CITATION.cff; 5% codemeta.json). Second, cross-surface metadata consistency as a quality indicator, automatically checkable at release time; an open Apache-2.0 audit pipeline demonstrating feasibility has been released (doi.org/10.5281/zenodo.21969695). Third, an archival DOI whose registered metadata agrees with the repository's own declarations, as a condition for counting software as "shared."

One unintended consequence deserves emphasis: attaching rewards to software citation counts before the metadata substrate is consistent would mismeasure, since inconsistent surfaces split citation counts

across records and route credit to papers rather than software. Fixing the measurement substrate is a precondition for the incentive, not an optional refinement. Feasibility is favorable: the audit above was performed by a single investigator with public APIs; the same checks embed in release workflows at negligible cost, and the method is domain-general, with the paper-proxy pattern independently documented in biomedical corpora (Du et al., JASIST 2021; PeerJ Computer Science 2022).

3. Training and Mentorship: N/A

4. Collaboration: Team-science credit requires persistent person identifiers on the surfaces that tooling actually reads. In the audit cited above, measured ORCID coverage varies from 62% of authors in archive metadata and 54% in citation files to 39% in resolved DOI records and 0% in package registry records and README citation blocks, so the surfaces most consumed by automated tooling carry the least contributor-level attribution. A simple indicator: ORCID coverage on machine-readable software surfaces of funded projects. The benefit is contributor-level credit in team-built software, where repository metadata frequently collapses many contributors into an entity string.

5. Entrepreneurship and Translation: N/A

ABSTRACT

Research software projects describe themselves in many places at once: citation files in the repository, archive deposits, DOI registry records, package registries, and README text. We treat the software as the underlying object and these machine-readable self-descriptions as its surfaces: the points where people and automated systems read what the project declares about the software. Citation guidance, indexing services, and automated agents may read a different subset of these surfaces, so disagreement between them can silently fragment credit and provenance. This paper asks a simple question that has not been measured directly: when a project's own metadata surfaces are compared with each other, how often do they agree? We audited 117 open-source research software projects, comprising an 87-project high-performance computing and quantum computing corpus and a 30-project registered baseline drawn from the JOSS and pyOpenSci accepted-package lists, across up to seven machine-readable surfaces per project. Using a four-level verdict rubric across six metadata fields, with 98.5% hand-verified verdict precision on a 338-row stratified sample, we found that 52 of the 62 projects exposing at least two comparable surfaces (83.9%) contain at least one core-field conflict, a result that is insensitive to the fuzzy-matching threshold. Half of hand-adjudicated cross-surface conflicts trace to a single mechanism: surfaces describing the software's paper rather than the software itself. Among projects whose CITATION.cff includes a preferred citation, 28 of 32 route citations to a record that disagrees with the software's own metadata. The author lists and titles disagree the most, and the registry surfaces are the least aligned. We release the audit pipeline as an importable library, the corpus, the registered sampling protocol, all raw snapshots, and the complete verification log.

Keywords software citation · metadata consistency · research software · CITATION.cff · provenance · scholarly infrastructure

1 Introduction

The software citation infrastructure has largely solved the problem of *where* a project can declare its citation metadata. CITATION.cff [1], codemeta.json [2], archived deposits with DOIs [3], package registry metadata, and README citation sections are all established, machine-readable, and widely promoted. What this infrastructure does not guarantee is that these surfaces say the same thing. Each could be written at a different time, by a different process, for a different consumer: a CITATION.cff is edited by software developers or maintainers, a Zenodo record may be minted automatically from a GitHub release, a PyPI record is generated at the packaging time, and a README BibTeX block is often pasted directly from a paper's landing page and never updated.

Consumers of citation metadata, whether human authors following a "how to cite" section, automated indexers resolving a DOI, or Large Language Models (LLMs) assembling citations, each read one surface and trust it. If the surfaces

disagree, which record a citation carries depends on which surface the consumer happened to read. The consequences are familiar from software citation research: split citation counts, misattributed credit, version ambiguity, and paper-software conflation [4–6]. What has been missing is a direct measurement of how often a project's own self-descriptions disagree, across surfaces, at scale, with verified instrument precision.

This paper contributes that measurement. We framed the problem as a *supply-side* audit: we frame what projects declare across multiple machine-readable surfaces they expose, and score pairwise consistency. Our contributions:

- **An audit instrument.** An open pipeline (harvest, normalize, compare, report) covering seven surfaces: CITATION.cff (root and preferred-citation), codemeta.json, .zenodo.json, the resolved DOI record, PyPI and npm registry records, and README citation content. The comparison rubric has four verdict levels over six fields, with all thresholds documented and released.
- **A measured corpus with a registered baseline.** 87 HPC and quantum computing projects from a prior, DOI-anchored corpus [7], plus a 30-project baseline drawn from the accepted-package lists of JOSS and pyOpenSci under a sampling protocol fixed and timestamped before candidate acceptance.
- **Verified findings.** 83.9% of projects with at least two comparable surfaces disagree with themselves on at least one core field, with verdict precision hand-verified at 98.5% over a stratified 338-row sample and results insensitive to the matching threshold.
- **A mechanism taxonomy.** Half of adjudicated cross-surface conflicts trace to paper-versus-software conflation, and the remainder cluster into archive staleness, registry ghost metadata, and identity ambiguities, each illustrated with named, snapshot-dated examples.

2 Related Work

The FORCE11 software citation principles established software as a citable research product and specified what a citation must identify: the artifact actually used, through its authors, title, version, date, and a unique persistent identifier [4]. The FAIR principles for research software carry the same position into metadata practice, tying findability and reuse to rich, machine-readable description of the software itself [8]. Reviewing the implementation two years after the principles, Katz and Chue Hong reported that the infrastructure had arrived, with over 50,000 DOIs issued for software at the time, while challenges remained in developer practice and in publisher systems retaining the required metadata [6]. Five of the six fields our rubric compares (title, authors, version, year, and DOI) are the fields this line of work designates as citation-critical; the sixth, license, is carried by every machine-readable surface we audit. Our question is not whether projects declare these fields but whether the surfaces declaring them agree.

Declaration infrastructure followed the principles. The Citation File Format gives maintainers a plain-text citation file in the repository root [1], and GitHub renders that file as the "cite this repository" widget on the repository landing page, so a single YAML file now reaches every visitor. CodeMeta provides a JSON-LD exchange schema with crosswalks between registry and archive vocabularies [2], and archive DOI records are registered against the DataCite metadata schema [3]. Adoption of this infrastructure is measured at registry scale: El Hounsri and Garijo analyzed research software metadata adoption across the software registries of five European Open Science clusters and a multi-disciplinary registry and found recommended practice unevenly followed [9]. Adoption studies of this kind have established whether a surface is present and well-formed, but none has asked whether the surfaces a project has adopted describe the same object in the same way, which is the measurement this paper adds.

Where metadata quality is studied, it is studied one surface at a time. On the paper side, Howison and Bullard examined how software is mentioned in the biology literature and found mentions that were informal and incomplete, lacking the version and identifier information needed to find the artifact used [5]. On the registry side, Bommarito and Bommarito characterized package metadata across 178,592 PyPI packages [10], and Gao et al. measured that existing tools can recover source-repository information for at most 70.5% of PyPI releases because release metadata omits the repository or names the wrong one, and built PyRadar to retrieve and validate those links [11]. The newest large-scale datasets aggregate in the same direction: OpenDORS compiles license, version, and language metadata for over 120,000 openly referenced research software repositories, one record per project [12]. Each of these efforts measures the presence or quality of a single surface across many projects, or merges a project's surfaces into one record. To our knowledge, no prior study compares a project's own self-description surfaces against each other, so the rate at which research software disagrees with itself has not been measured. That distinction also separates this audit from adoption analyses such as [9] as counting surfaces and cross-checking them are different measurements, and only the first exists in the literature.

A separate line of work documents the paper standing in for the software. The Journal of Open Source Software aims to create a peer-reviewed, citable paper, so that software work can be credited through existing publication infrastructure [13]; which citation carries is left to authors and citing practice. Corpus studies show how the proxy pattern emerges

in that practice. The Softcite dataset, built from expert annotation of 4,971 biomedical and economics publications, found that software is mentioned informally far more often than it is formally cited [14], and a follow-up study of the CORD-19 corpus found that even where projects request a specific citation, identifying the canonical record among a project's several candidate sources is difficult [15]. These studies measure conflation where it lands in the citing literature. Our mechanism analysis in Section 4.4 measures it one step earlier: in the machine-readable metadata projects themselves publish, where half of verified cross-surface conflicts trace to a surface describing the paper rather than the software.

Supply-chain security frameworks audit adjacent layers of the same projects. OpenSSF Scorecard scores repository and maintenance practices automatically [16]; SLSA defines graded levels of build provenance, and since the specification is community-maintained without a peer-reviewed primary description, we reference the qualitative study of its deployment challenges by Tamanna et al. [17]; Sigstore provides signing infrastructure for released artifacts [18]. These frameworks address whether code and artifacts are what they claim to be. None checks whether a project's self-descriptions agree with each other, so the audit reported here is complementary to them and overlaps none of their controls.

3 Methods

3.1 Corpus

The corpus contains 117 projects in three strata. The **supercomputing stratum** (labeled `sc26` in the released data files; 87 projects; 44 HPC, 43 quantum computing) is exported verbatim from the tagged v1.0.0 release of our prior provenance-audit corpus [7], where the derivation from the tagged release keeps the corpus identity claim checkable. The **baseline strata** (15 JOSS, 15 pyOpenSci) exist to test whether findings from infrastructure-heavy HPC/Quantum software generalize to community-reviewed research software, and were drawn as follows.

Sampling frames were retrieved on 2026-08-12 from the JOSS published-papers API (3,662 records after retrieval) and the pyOpenSci packages registry (70 records). Corresponding software repositories were required to be GitHub-hosted, since all six eligibility surfaces are probed through the GitHub API. Non-GitHub candidates were excluded at sampling under rule R5 (JOSS: 185, pyOpenSci: 4, hosts reported in the exclusion log). Four further pre-registered rules applied in order: R1 corpus overlap with the 87 (7 exclusions), R2 dual-listing resolved to the pyOpenSci stratum (32), R3 JOSS version papers deduplicated to the most recent (22), R4 missing repository URL (0). Domain bins were assigned from a committed keyword map (first match wins; disciplinary keywords precede generic ones). Candidates with no keyword matched were retained in an explicit "unmapped" bin that participates in the stratified draw rather than being excluded, so the draw does not depend on the coverage of a hand-written map. The registered unmapped share was 33% (JOSS) and 2% (pyOpenSci). One design correction was made before the protocol was registered: an earlier rule that refused to finalize while unmapped candidates appeared in the draw window was unsatisfiable under round-robin interleaving, since the unmapped bin is guaranteed window slots by construction, and it was replaced by unmapped-bin participation plus a 50% frame-level ceiling.

A seeded, domain-stratified draw (seed 202608121338, round-robin over domain bins, oversample 30 per stratum) produced ranked candidate windows. The sampling protocol, ranked candidate lists, and exclusion log were committed (baseline-sampler v0.1.0) and deposited under restricted access with a DOI before any eligibility probing (10.5281/zenodo.21909720; the deposit timestamp precedes the acceptance log timestamp). Eligibility required at least 2 of six machine-readable surfaces, probed per candidate: CITATION.cff, codemeta.json, .zenodo.json in the repository root, a README citation surface (citation section or BibTeX block; the registered rule), a discoverable DOI (from CFF or the README citation section, not resolved at probe time) and a verified registry listing (a PyPI or npm package matching the repository name and linking back to the repository). Acceptance proceeded strictly in rank order to 15 per stratum: JOSS accepted ranks 2-18 (3 skips for insufficient surfaces), pyOpenSci ranks 1-19 (4 skips). One drawn candidate's declared repository did not resolve at probe time and was never reached by acceptance. 15 of the 30 pyOpenSci window candidates are dual-listed with JOSS and therefore carry a JOSS paper DOI, so the DOI-by-construction confound noted below extends partially into that stratum.

Hand-curated concept DOIs were filled for the supercomputing stratum only (20 projects), drawn from the prior corpus's distribution-metadata records; both baseline strata rely entirely on automatic discovery from project surfaces, keeping the baseline availability numbers free of curation effects. Registry package names were detected uniformly for all 117 projects by name-part lookup verified by repository back-link and were hand-reviewed. Two detections were removed as packages not controlled by the project.

3.2 Surfaces

For each project we harvest up to seven surfaces: `cff` (CITATION.cff root), `cff_preferred` (its preferred-citation block, extracted as a pseudo-surface so intra-file disagreement is measurable), `codemeta` (codemeta.json), `zenodo_json` (.zenodo.json), `doi_record` (the DOI's registered metadata, resolved via DataCite [3] with Crossref fallback; DOI priority order: corpus-curated concept DOI, then CFF-declared, then README citation section, with provenance recorded), `pypi` and `npm` (registry records), and `readme` (a heuristic parse of the README's citation section, BibTeX block, and DOIs). GitHub's "cite this repository" widget is generated from CITATION.cff and is covered by the `cff` surface. The README surface is defined as a README file in the repository root; GitHub additionally renders docs/ and .github/ READMEs on the landing page, which this audit does not credit (one corpus project is affected). Every API response is snapshotted with a retrieval timestamp; all snapshots were retrieved on 2026-08-14 and are released in the data deposit.

3.3 Normalization

Each surface is normalized into one record shape: title, authors (family, given, ORCID), version, year, DOI, license. Extraction rules are released with the pipeline, where three deserve note: BibTeX in READMEs is extracted with brace-matching rather than regular expressions, after live testing showed regex extraction silently dropping fields across common forms; DOI strings are sanitized (resolver-URL prefixes, badge-image suffixes, trailing punctuation) and validated against the DOI pattern before resolution; DataCite creator records frequently carry the full name in familyName with no givenName so the normalizer uses record-supplied name parts as-is and falls back to name-splitting only when the record supplies neither part.

3.4 Comparison rubric

For every pair of surfaces present, each of the six fields receives one of four verdicts. **exact**: normalized values identical. **minor**: clearly the same referent with superficial variation (title token-sort fuzzy >= 90; the same author set reordered or fuzzy-matched; year differing by exactly 1; version differing only by a v prefix). **conflict**: both present and materially different. **missing**: at least one side absent. Zenodo concept-versus-version DOI pairs are flagged for hand adjudication rather than auto-resolved. All thresholds live in one released module.

Headline results are insensitive to the fuzzy-match threshold: at 85 and 95 the share of projects whose surfaces contain at least one core-field conflict is unchanged (83.9%, with identical per-stratum rates), while field-level agreement shifts modestly (authors 0.459-0.511 around the reported 0.481; title 0.436-0.442; median per-project pairwise agreement 0.50-0.55). Threshold-sensitivity outputs are released alongside the results.

3.5 Verification protocol and instrument disclosure

We hand-verified the instrument's verdicts against the harvested snapshots rather than the live web, since precision measures whether the pipeline judged correctly given the evidence it retrieved. The verification set comprised every conflict verdict, every minor verdict, every intra-file conflict between CFF root and preferred-citation metadata, and a seeded random sample of 30 exact verdicts. For each judgment, we re-derived the verdict by hand from the recorded value pair; identical value pairs recurring across surface pairs within a project were adjudicated once and the judgment propagated to each covered comparison row. Raw snapshots were consulted where a recorded value appeared anomalous. Rows flagged as possible Zenodo concept-versus-version identifier pairs were additionally adjudicated by resolving both identifiers.

Verified precision was 98.5% over 338 comparison rows (275 deduplicated judgments): conflict 276/281 (98.2%), minor 26/26, exact 31/31. The five disagreeing rows classify into two mechanisms, both documented heuristic limits: threshold boundary (2 rows; an author-entity name variant scoring just below the fuzzy threshold) and parse limitations (3 rows; an organizational author split at an embedded "and", and a LaTeX-escaped accented character blocking one name match). The complete verification log is released.

Instrument defects found and corrected before the reported measurements, in the honest-reporting style this protocol requires: two normalization defect classes were identified in pre-run live testing (YAML date serialization in CITATION.cff snapshots; .zenodo.json license objects producing spurious license conflicts); three DOI-string hygiene classes were identified in first-run review (resolver-URL prefixes, badge-image suffixes, non-DOI identifier values); and hand verification identified one systematic defect (DataCite creator records carrying full names in familyName caused token duplication and depressed author matching), which was corrected and the affected comparisons re-scored and re-verified. The instrument's stage history (v0.2.0 pre-run; v0.2.1 first-run corrections; v0.2.2 verification-corrected

Table 1: Availability of self-description surfaces across the corpus (n = 117; all projects resolvable at snapshot time).

Surface	Availability
README (root-level)[a]	116/117 (99%)
Stable releases	111/117 (95%)
CITATION.cff[b]	48/117 (41%)
Registry listing (PyPI or npm)[c]	46/117 (39%)
Archival DOI (doi_record)	20/117 (17%)
SECURITY.md	16/117 (14%)
.zenodo.json[d]	10/117 (9%)
codemeta.json	6/117 (5%)

[a] One project (preCICE) keeps its README under docs/; under the root-only rule it is counted absent (see Section 3.2). [b] By stratum: 26/87 supercomputing, 10/15 JOSS, 12/15 pyOpenSci. [c] One project is npm-listed; it is also PyPI-listed. [d] By stratum: 3/87 supercomputing, 1/15 JOSS, 6/15 pyOpenSci.

Table 2: Pairwise agreement by field across comparable surface pairs, with and without registry-involved pairs. Registry exclusion is shown only for the two fields where registry pairs change the rate materially.

	All comparable pairs		Excluding registry pairs	
Field	n	Agreement	n	Agreement
Year	50	.780		
DOI	61	.770		
License	47	.766		
Authors	135	.481	98	.612
Version	47	.447		
Title	165	.436	90	.644

Of 93 title conflicts, 61 involve a registry surface.

final) is documented above and in the repository README; the public repository history was flattened for release, and v0.2.2 produced every number reported here.

4 Results

4.1 Surface availability

All 117 repositories resolved at snapshot time. Table 1 reports surface availability. The human-facing substrate is near-universal: README in 116 of 117 projects and stable releases in 95%. The machine-readable citation surfaces are minority practice, led by CITATION.cff at 41% and thinning to codemeta.json at 5%. 62 of 117 projects (53%) expose at least two comparable surfaces; the consistency results below concern those 62. That only half the corpus can be cross-checked at all is itself a finding: for the other half, whatever the single surface says is uncheckable by construction.

4.2 Pairwise consistency

Across 1,104 field comparisons (505 comparable, 599 with at least one side missing), 52 of 62 projects (83.9%) contain at least one core-field conflict (title, authors, version, year, or DOI), and median per-project pairwise agreement is 0.50. By field, agreement among comparable pairs is: year 0.78, DOI 0.77, license 0.77, authors 0.48, version 0.45, title 0.44. Figure 1 shows the composition behind these rates: of 1,104 field comparisons, 599 could not be made at all because at least one surface omits the field, so the agreement rates in Table 2 describe only the comparable remainder.

The registry surfaces drive much of the title and authors disagreement: 61 of 93 title conflicts involve PyPI or npm, largely the structural gap between a registry's package name and a descriptive title ("mpi4py" versus "MPI for Python"). Excluding registry pairs, title agreement rises from 0.44 to 0.64 and authors from 0.48 to 0.61. Figure 2 locates the disagreement: pairs involving a registry surface concentrate the low agreement values, while the repository-native pairs (cff with codemeta, codemeta with .zenodo.json) agree most. We report both because both are real: a human reader distinguishes a package name from a title, but a metadata consumer joining records across surfaces sees a mismatch.

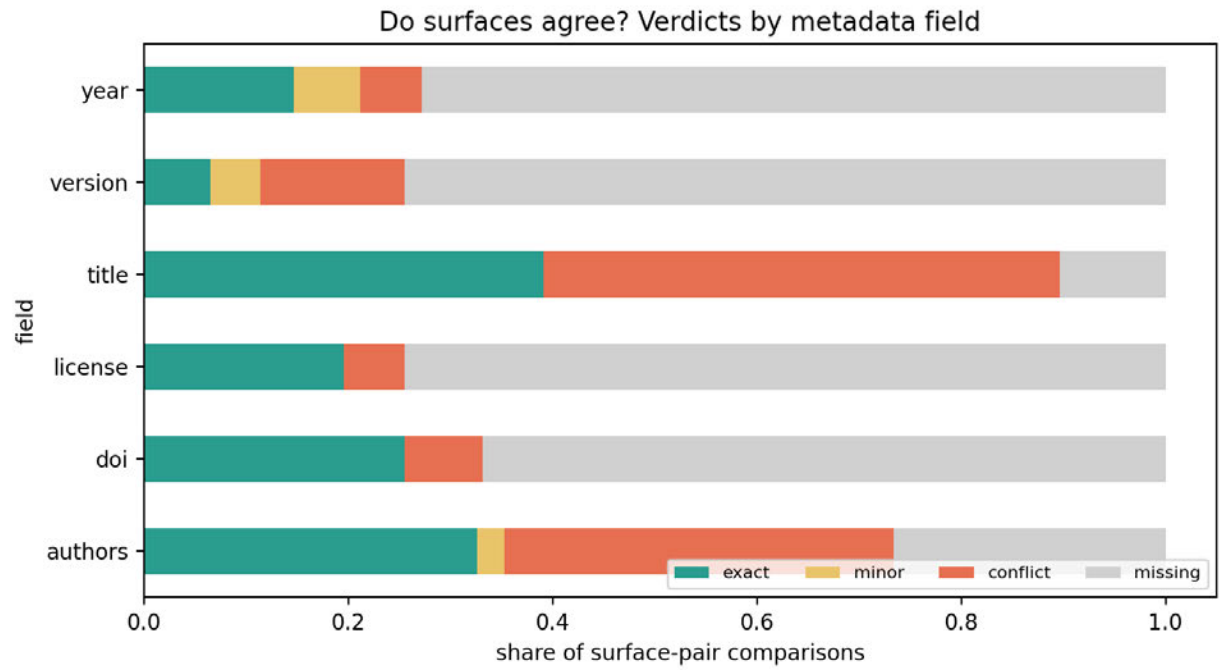

Figure 1: Verdict composition per field across all 1,104 surface-pair field comparisons. Gray indicates the field was not comparable because at least one surface omits it; Table 2 reports agreement among the comparable remainder.

Table 3: Consistency by stratum among projects with at least two comparable surfaces. Agreement is pooled pairwise agreement: exact plus minor verdicts over comparable pairs within the stratum.

Stratum	Projects	Comparable pairs	Agreement	≥1 core-field conflict
supercomputing	36	236	.559	86.1%
JOSS	11	97	.649	63.6%
pyOpenSci	15	172	.494	93.3%
Overall	62	505	.554	83.9%

The median per-project pairwise agreement across the 62 projects is .500.

By stratum, the phenomenon is not an HPC idiosyncrasy: core-field conflict affects 86.1% of supercomputing projects (31/36 with >= 2 surfaces), 63.6% of JOSS projects (7/11), and 93.3% of pyOpenSci projects (14/15). Two cautions attach to the baseline comparison: the JOSS stratum's DOI field is partially DOI-by-construction (every JOSS paper carries a DOI, and 15 of 30 pyOpenSci window candidates are dual-listed), and per-stratum denominators are small (11-36 projects), so we report the direction (community-reviewed packages are not cleaner; pyOpenSci projects expose more surfaces and correspondingly more disagreement) without significance claims. One tautology is excluded from interpretation: when the resolved DOI was discovered from a project's own CFF or README, the DOI-field agreement between the discovering surface and the DOI record is expected; informative DOI comparisons are those between non-source surfaces, including the four adjudicated concept-versus-version pairs.

4.3 The project's own citation file disagrees with itself

32 projects' CITATION.cff files include a preferred-citation block. In 28 of 32 (87.5%), following the preferred-citation yields a record that conflicts with the software's own metadata on at least one field (56 conflicting field comparisons; 39 exact, 1 minor). This is partly the CFF specification working as designed, since preferred-citation exists precisely to route citation to a different object, usually a paper. The measured fact is about the consequence: for seven out of eight such projects, the record a compliant citation tool emits and the record the software's other surfaces describe are different objects, and which one a consumer lands on depends on tooling, not on the project's intent.

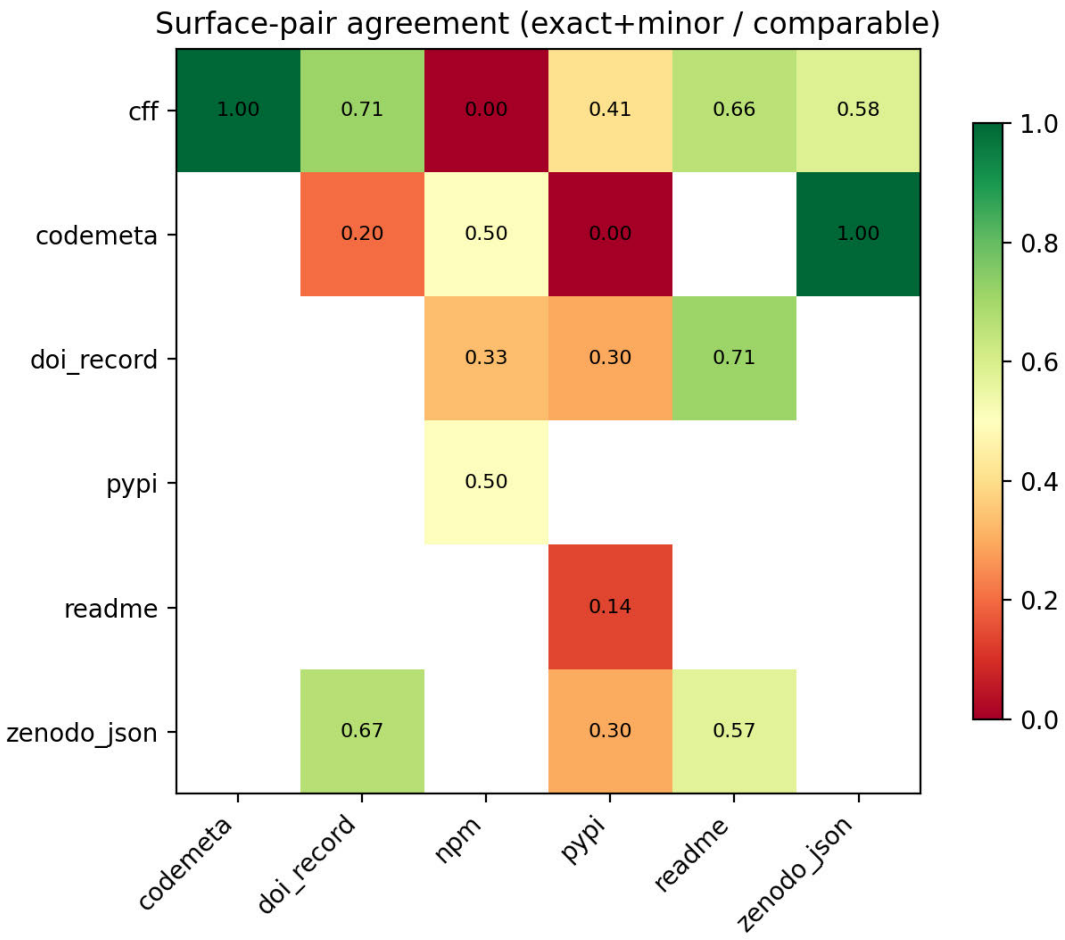

Figure 2: Pairwise agreement (exact plus minor over comparable) by surface pair. Cell denominators vary widely; extreme values, including 0.00 and 1.00, can rest on few comparable pairs, and per-cell counts are in the released results data; the corpus contains a single npm-listed project.

4.4 A mechanism taxonomy of verified conflicts

Hand adjudication of every conflict produced a mechanism classification; the four recurring mechanisms, with named, snapshot-dated examples (retrieved 2026-08-14):

Paper-versus-software conflation (86 of 171 cross-surface conflict judgments, 50%). Surfaces describe the software's paper rather than the software. Two sub-patterns. Divergent: dace's CITATION.cff root titles the software ("DaCe - Data Centric Parallel Programming") while its README BibTeX carries the conference paper's title and its five authors, against 28 in the CFF. *Consistent-but-paper-anchored:* thread-pool's CFF root itself declares the SoftwareX paper's DOI and title, so its surfaces agree with each other while all describing the paper; consistency is not correctness of referent.

Archive staleness. DOI'd archive records lag the distributed release: felupe's Zenodo record says v9.4.0 while PyPI serves 10.1.0; cuda-quantum shows the same mechanism at minimum distance (0.15.0 versus 0.15.1). The rubric counts each non-equal pair once regardless of distance.

Registry ghost metadata. Registry records exist that the project does not control or no longer describes: our review removed two back-link-verified packages (a community npm build and a third-party PyPI wrapper) as not project-controlled; registry author fields are frequently entity strings or empty, and no registry surface in the corpus carries an ORCID (0/25 sampled authors on PyPI).

Identity ambiguity. Entity and person names collide across surfaces: cirq's surfaces disagree only on "Cirq Developers" versus "The Cirq Developers"; mfem's CFF root credits "MFEM Team" while its archive record credits two named individuals and its preferred citation seventeen.

By design, the by-design routing of Section 4.3 (mfem-style preferred-citation) is tabulated separately from cross-surface conflation, since the former is specification-compliant behavior with a fragmenting consequence and the latter is unintended divergence.

4.5 ORCID coverage

Where surfaces carry authors, ORCID coverage varies from 62% of authors in .zenodo.json and 54% in CFF to 39% in resolved DOI records and 0% in registry records and README BibTeX, so the surfaces most likely to be read by packaging tooling carry the least persistent-identifier information.

5 Discussion

Three implications follow from the supply side alone. First, single-surface consumers inherit whichever record their surface carries; at the measured disagreement rates, two compliant consumers reading different surfaces of the same project will disagree about its citation roughly half the time at the field level. Second, the paper-versus-software mechanism dominating verified conflicts (50%) means the fragmentation is not primarily sloppiness: it is the unresolved question of what the citable object is, propagating into machine-readable metadata, consistent with the credit incentives documented in software citation research [4, 6], and it will not be fixed by adoption campaigns for any single format. Third, agreement infrastructure is absent: no existing supply-chain or metadata framework checks cross-surface consistency ([16–18] audit build and release integrity, not self-description coherence), and the near-universal surfaces (README, releases) are precisely the ones with the least structure.

The audit engine is released as an importable library whose per-project primitive (harvest, normalize, compare, report for one repository) is designed for downstream reuse in release-time integrity checks and citation and provenance checker tools; the corpus-scale study reported here is one instantiation. The demand side, how automated consumers weight these surfaces when they disagree, is measurable with the same instrument as ground truth and is deliberately out of scope here.

6 Limitations

The corpus is GitHub-hosted by criterion and skewed toward HPC/QC by design, with small baseline strata. README parsing is heuristic; verified precision (98.5%) bounds but does not eliminate instrument error, and the released log classifies every known disagreement. The registry surface covers PyPI and npm only, so R and Julia packages face a five-surface ceiling, and their registry practice is unmeasured. Registry name-versus-title conflicts are structural and reported both included and excluded. The eligibility filter conditions the baseline on having >= 2 surfaces, so baseline agreement rates describe metadata-active projects, not the registries at large. Snapshots date to a single retrieval window; projects change. Concept-versus-version DOI adjudication covered flagged Zenodo pairs only. Verdict counts weight all conflicts equally regardless of severity.

7 Conclusion

Measured across their own machine-readable surfaces, five of six research software projects that can be cross-checked disagree with themselves on at least one citation-critical field, and the single largest verified mechanism is the paper standing in for the software. The instrument, corpus, registered protocol, snapshots, and verification log are released so the measurement can be repeated, extended to other ecosystems, and used as ground truth for the demand-side question of what metadata consumers do when the surfaces disagree. Extending the corpus beyond GitHub-hosted projects and additional registries, and re-measuring the same projects over time and assessing mitigation in which a single authoritative record generates the other surfaces, is planned future work on the same instrument.

8 Data and Code Availability

Pipeline: https://github.com/pengyin-shan/rda-audit-pipeline (Apache-2.0). Measurements were produced with v0.2.2; the archived release v0.2.3 adds only license, citation, and README files, with measurement code identical

(10.5281/zenodo.21969695). Corpus, raw snapshots (retrieval-timestamped), results, verification log, and sensitivity outputs: *10.5281/zenodo.21969769*, CC-BY-4.0. Sampling protocol, ranked candidate lists, and exclusion log: *10.5281/zenodo.21909720* (restricted until publication; opened on posting); the same files are public in the sampler repository. Sampler: baseline-sampler v0.1.0 (registered draw commit 64b979e), https://github.com/pengyin-shan/baseline-sampler. Prior corpus: *10.5281/zenodo.21443211*.

9 Acknowledgments

The author thanks Daniel S. Katz for comments on a draft. Portions of the manuscript text were drafted with writing assistance from Claude (Anthropic); the author reviewed and verified all content, and all data collection, measurement, and verification were performed by the author. The corpus derives from work conducted during the author's 2025-2026 Trusted CI Fellowship with Trusted CI, the NSF Cybersecurity Center of Excellence; the fellowship provided no financial support for this work. The author thanks the National Center for Supercomputing Applications (NCSA), University of Illinois Urbana-Champaign, for a supportive professional environment; this work was conducted in the author's individual capacity and received no dedicated funding. The author declares no competing interests.

Description: Please see attached comments from UsAgainstAlzheimer's

UsAgainstAlzheimer's

August 19, 2026

Lyric Jorgenson, PhD
Associate Director for Science Policy
Office of Science Policy
National Institutes of Health
Bethesda, MD

Re: Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Dear Dr. Jorgenson:

UsAgainstAlzheimer's is pleased to submit comments in response to the National Institutes of Health (NIH) request for information. UsAgainstAlzheimer's mission is to end Alzheimer's disease (AD). Our strategic priorities are to advance prevention and risk reduction; work to promote early detection and diagnosis; and ensure access to treatments and care. We are guided by the experiences of individuals living with AD and Alzheimer's disease related dementias (ADRDs, which include frontotemporal dementia, Lewy body dementia, vascular contributions to cognitive impairment and dementia, and rare, related dementias, e.g., MAPT-FTD and FTD-GRN), their families, and the communities most at risk.

Preventing and treating AD/ADRDs is an urgent national priority for American families and for the social, economic, and fiscal health of our nation — and it is within reach. Our nation is not prepared for the current toll of Alzheimer's — let alone its projected growth. The scale of this disease already exceeds what our care infrastructure was built for. An estimated 7.4 million Americans age 65 and older are living with AD in 2026, with about 1 in 9 people age 65 and older affected.[1] By 2050, the number of Americans living with AD is projected to rise to nearly 13 million.[2] Many Americans are at uniquely high risk: women are twice as likely to develop AD than men, African Americans are twice as likely and Latinos are 1.5 as likely to develop AD than white older Americans.[3] Rural adults have a higher burden of modifiable dementia risk factors.[4] And individuals with Down syndrome are also at extremely high risk, and often develop the disease at much younger ages.[5] The cost curve is just as alarming: health and long-term care costs for people living with AD and other dementias are projected to reach $409 billion in 2026 — not including the value of unpaid caregiving — and total payments are projected to climb to nearly $1 trillion by 2050.[6]

We commend the NIH for outlining goals for scientific excellence in its report, "Leading in Gold Standard Science." Many aspects of this publication, including the promotion of collaboration, data sharing, public access, and dissemination (among others) are consistent with tenets of reproducibility, transparency, communication, and avoidance of

conflict of interest – which we also endorse. We believe the research reward and impact assessment system must include these goals, but UsAgainstAlzheimer's is extremely concerned that the Gold Standard Science policy is inconsistent with other administration policies, including those advanced in a recent proposed rule from the Office of Management and Budget, "Regulation for Federal Financial Assistance." Ultimately, UsAgainstAlzheimer's urges that science and promise for breakthroughs be what drives investment, not politics.

The RFI states that "NIH seeks to better align its measures of success with its core mission; generating knowledge that enhances health, lengthens life, and reduces illness and disability," and it requests input on potential indicators and incentives in the following areas:

Rigor and Reproducibility

We agree with the NIH assertion that advancing foundational knowledge should explicitly prioritize rigor and generalizability as core scientific principles. Such priorities are particularly urgent for research on AD/ADRD, where gaps in representativeness have limited progress and the generalizability of findings. Several populations that are at increased risk are noted above; ensuring that research considers the variability across different groups (e.g., genetics, exposome, geography, age) from the outset will strengthen the external validity and translational impact of research on AD/ADRD and other conditions.

Similarly, strengthening rigor and reproducibility also requires heightened emphasis on implementation and real-world translation. It is essential to ensure that discoveries from the laboratory are moved into clinical practice and community settings, particularly in very high therapeutic need fields such as AD/ADRD. NIH must continue to expand support for pragmatic trials, community-based research, and public-private partnerships, as well as collaboration with other agencies, e.g., the Centers for Disease Control and Prevention (CDC), to ensure scientific advances translate into meaningful, generalizable improvements in health outcomes for women and men, and in diverse populations.

Along these lines, while AD/ADRD research has a long history of testing and retesting hypotheses (e.g., the amyloid hypothesis) before translation into rigorous clinical trials, some areas of AD/ADRD research – e.g., research on caregiving interventions – do not easily lend themselves to assessment in typical double-blind randomized clinical trials. NIH's sister agency – the Agency for Healthcare Research and Quality (AHRQ) – has assessed how other research approaches, including quasi-experimental designs, might be weighed when considering a body of research evidence for translation, and we would urge NIH leadership to consider working with AHRQ to investigate options for reinforcing rigor across these fields, while also fostering collaborative discussion about where and when specific design and statistical approaches are appropriate to incentivize.

Data, Software, and Model Sharing

NIH must continue to build and modernize research infrastructure, emphasizing data use and protections. Expanding existing platforms to capture longitudinal, harmonized, and interoperable datasets – and ensure that sex differences (noting the higher burden of AD/ADRD on women) are built in at both the design and analysis end – is essential to advancing science; data standards and sharing requirements must be consistently enforced to maximize the value of NIH-funded research and enable collaboration.

Ensuring that clinical trial data are relevant to all Americans should also be an NIH priority. Clinical trial recruitment and monitoring efforts must be prioritized, made more efficient, and adequately funded. NIH has launched hundreds of AD/ADRD clinical trials in the past decade, but clinical trial recruitment remains a challenge across populations, and it's imperative that everyone has access to participation. Several sub-groups have a differential risk to AD, as noted above: women, African Americans, Latinos, individuals living rurally, and individuals living with Down syndrome are all at higher risk. Recruitment and the development and maintenance of related infrastructure that ensures broad inclusion of these groups lead to non-trivial costs, and investments to support these structures and actions must be prioritized.

As just one example, most trials are implemented with traditional cognitive assessment measures that rely on trained human raters to evaluate patients. The availability, retention, training costs and variability of raters all pose challenges – and must be considered when budgets are developed. Monitoring and enforcing recruitment from the federal government is also key to success, and the National Institute on Aging's (NIA's) tracking has only relatively recently been modernized (via its Clinical Research Operations & Management System). The success of this tracking and the enforcement opportunities it provides are key to the inclusion of appropriate gender and population representation in NIH-funded AD/ADRD trials. It is unclear what the status of this effort is, but future success will require an investment both in programs such as CROMS that support data collection on recruitment, and in programmatic staff capable of utilizing the data generated to ensure compliance by investigators.

Lastly, investments in clinical trials are impacted by the overall destabilization of federal research funding that is occurring, in ways that seriously hamper progress in AD/ADRD research: researchers will not be able to secure the funding they need for the trials, including the costs of adequate recruitment efforts, and participants will be apprehensive about joining a trial, at the risk that the trial might be de-funded mid-way through the research.

Disruptions to ongoing studies also have consequences that extend well beyond financial costs. Prematurely interrupting or terminating research may result in the loss of valuable scientific data and waste significant public investments in grant funding and institutional infrastructure. Of utmost importance, such disruptions may also adversely affect study

participants and their care partners, who often rely on research participation not only for access to investigational therapies or non-pharmacological interventions, but also for specialized clinical monitoring, care coordination, cognitive assessments, and other health and support services provided through the study. It is particularly dangerous to the health and safety of patients who may face sudden and unplanned disruption or discontinuation of medical interventions where their medical team has no time and resources, and therefore no ability, to manage a medically prudent transition (e.g., tapering off of a medicine, transitioning to a new provider).

In the case of AD/ADRD research, a number of current drug treatments in clinical trials have potentially serious side effects such as amyloid-related imaging abnormalities (ARIA) that require careful, consistent, and complex safety monitoring. Abruptly suspending or terminating grant funding for such a trial literally risks serious avoidable harm and potential death for study participants – in addition to wasting data and financial resources already invested.

NIH should also invest in emerging technologies that expand research capacity and accelerate discovery. Innovations including but not limited to CRISPR and AI-driven analytics hold significant promise for identifying disease mechanisms and therapeutic targets. Research tools such as digital cognitive assessments offer the potential for earlier, longitudinal, more sensitive, and more efficient measurement of cognitive change in diseases like AD/ADRD, while also reducing trial burden and improving participant experience. As novel therapies move earlier in the disease course, increased sensitivity of clinical measures will be indispensable to demonstrate efficacy. NIH's leadership in funding and coordinating validation of these resources would help resolve a key research bottleneck.

One challenge in the realm of optimizing large datasets that is somewhat unique to the field of AD/ADRD research is the need to study age-related cognitive changes as an add-on or ancillary activity to a clinical trial for which the initial outcomes were not cognitive (e.g., cardiovascular, endocrine). Sustained and reliable funding streams are necessary to ensure that investments made in the “base” trials are not then wasted in the realm of AD/ADRD, if a study is de-funded, or funding is reduced, such that the data collection needed at distal study endpoints to assess cognition (often imaging) is not feasible.

Lastly, but critically, there is a significant need for optimizing data and datasets in the realm of women’s brain health research. Currently, NIH invests only 3% of its AD/ADRD funding on work that is relevant to women’s health (based on FY2024 RePORTER data). Women make up two-thirds of the people living with AD/ADRD, and research over the last decade has highlighted that women experience a range of unique and differential life exposures, as well as sex-based differences in cardiovascular, immune, endocrine systems, etc. – all of these influence AD/ADRD risk and response to interventions.

NIH should prioritize collaborations across women's health and AD/ADRD research teams that enable women's health-related data to be collected in AD/ADRD studies, and should consider incentivizing prospective high value datasets (that would capture life course data following risks and exposures of women, as well as outcomes across a wide range of systems, including endocrine and cognitive). It is only through significant incentivization and investment at the level of the NIH Office of the Director – as well as a sustained commitment to enforce NIH's own 2016 Sex as a Biological Variable (SABV) policy – that we will yield substantive progress in this area.

Training and Mentorship

NIH must prioritize workforce development as a core strategic investment. NIH's shift toward parent awards and multi-year funding models have devastated the training community; greater attention is needed to ensure investigator-focused training mechanisms are not overlooked in future strategic planning efforts.

NIH's commitment to mentorship is vital and should be a formal, valued component of the research enterprise. NIH must ensure adequate salary support and protected time to enable established researchers – including both mid-career and established investigators – to nurture the next generation of researchers. In parallel, small but meaningful investments in training programs (e.g., increasing stipends) improve trainee recruitment and retention, particularly those from underserved backgrounds and in fields facing workforce shortages (e.g., geriatrics). These investments demonstrate the value placed on training and help reduce financial barriers disproportionately affecting individuals entering biomedical research careers.

Emerging scientific challenges require interdisciplinary expertise; accordingly, the strategic plan should also prioritize interdisciplinary training and support career transitions across fields. A strong research workforce requires investing in scientists from underserved and underrepresented backgrounds, whose perspectives and experiences strengthen scientific rigor, innovation, and research relevance to broader populations. To move science toward a precision medicine model, NIH must restore funding mechanisms (e.g., diversity supplements) to support these researchers.

Collaboration

Recognizing contributions to team-based science has been a longstanding problem across biomedical research, and fields like AD/ADRD research demand an increasingly complex array of contributing disciplines – including geneticists, molecular biologists, clinicians, statisticians, data scientists, imaging experts, and much, much more. The contributions of these individuals and their expertise is critical to the progress of science, yet each individual contributor must weigh their interest in and commitment to scientific discovery with their goals for academic stability and advancement within their organization. Progress is already underway at the NIH to provide appropriate incentives to team science, including

but not limited to the multiple-PI option for grant applicants, but it should continue to make novel funding opportunities available to collaborative teams and supporting roles that facilitate team science; essentially, those that would be recognized by traditional academic review committees. It is notable, though, that the many forces at play within the current NIH landscape that are destabilizing research funding are not likely to incentivize research collaborations.

Entrepreneurship and Translation

We agree that innovation and entrepreneurship should be fostered by the NIH, towards preventing and treating conditions like AD/ADRD. The expansion of NIA's small business and technology programs as AD/ADRD funding has increased – as well as the development of challenge prize programs at the NIA – have demonstrated the contributions that are possible with these investments. We urge the NIH to continue to incentivize these programs, and to think more broadly about how more entrepreneurial approaches might be applied to unique and innovative directions of disease research in the future, at the basic, translational, and clinical realms. A specific goal could be the launch of another EUREKA (Ensuring Useful Research Expenditures is Key for Alzheimer's) prize, targeted to AD/ADRD research.

Foundational Scientific Exploration

We agree that both basic and high-risk/high-reward research should be given fair consideration within the overall research realm. For AD/ADRD research, we also encourage continued diversification of the target pipeline, both for treatment and disease prevention, and we hope NIH will closely monitor emerging lines of research that may yield innovative strategies, such as the potential of shingles and other safe and effective vaccines to protect against development of AD/cognitive impairment, as studies designed to validate this possibility would be a meaningful contribution to the field.[7,8] Similarly, one of the challenges in AD/ADRD research is predicting the disease trajectory in different individuals – discovery in this area would be very high reward for both healthcare providers as well as those designing clinical trials. Validating models to predict which patients are likely to progress will be a major support for the field.[9,10]

Many other aspects of AD/ADRD research play a critical role in ensuring that the investments in NIH yield optimal impact – including caregiving research and studies that explore interventions for AD-related neuropsychiatric symptoms (e.g., agitation and psychosis). While outcomes in these areas are incredibly meaningful for disease management, such studies might not be considered "high risk." Nevertheless, the payoff when interventions prove effective, as was the case recently with the NIH-funded LiBBY study, is immense for families, caregivers, and healthcare providers. In addition to addressing agitation and other late-stage symptoms of AD/ADRD, we also encourage the NIH to consider outcomes related to hospice, bereavement, and end of life decision-making as important and relevant in the overall spectrum of disease research.

At the same time, we need better data on how treatment, care planning, and family burden differ when a diagnosis involves mixed etiology or a related dementia – rather than "pure" AD, since these conditions often carry different symptom trajectories, caregiver burden profiles, and treatment eligibility (including for emerging AD-specific therapies), yet families frequently receive the same generic guidance regardless of the underlying pathology.

Public Impact

The RFI lists many contributions to public impact that may be considered, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit.

With respect to ***health outcomes***, NIH AD/ADRD research investments have already borne fruit in the pharmacological sector, with two relatively recent drug approvals having been made by the Food and Drug Administration (FDA) for early-stage disease. Prevention and risk reduction for AD has also advanced (including both pharmacological and non-pharmacological approaches) and the means to achieve it at population scale are either known or in development: proven life-course risk-reduction strategies, active and passive immunotherapies, and other emerging modalities, including vaccines aimed at reducing AD/ADRD risk. Even more effective solutions can emerge from the world class research laboratories across our country. NIH must prioritize prevention in addition to treatment research, and it should expand these studies, including treatments and risk reduction strategies applicable to the preclinical phase of disease and combinations of interventions that include both pharmacological and non-pharmacological approaches.

Patient preferences should also be a high priority for the NIH when considering what constitutes “success” with respect to health outcomes. UsAgainstAlzheimer’s Alzheimer’s Disease Patient and Caregiver Engagement (AD PACE) Initiative is designed to address this need, i.e., to identify the outcomes and care goals that are most meaningful to those living with AD/ADRD and their families, caregivers, and care partners. The focus of the What Matters Most (WMM) Research Program of AD PACE has collected data on over 600 people to improve our understanding and measurement of these outcomes. The next stage of this research is ongoing, and adds in the much-needed focus on aiding FDA and companies to set clinical outcome measures related to WMM to families and on enhancing communication between clinicians and patients about the disease and potential outcomes, to ensure ongoing care is appropriately informed by the outcomes and care goals found to be most meaningful – literally “What Matters Most” – to those affected.

Through the last 15 years, drug development has particularly focused on the earliest stages of disease, when those with the diagnosis can report for themselves about the outcomes and care goals that are most important to them. The connection to the FDA Patient-Focused Drug Development optimizes the investment in both initiatives (FDA Patient-

Focused Drug Development Guidance Series for Enhancing the Incorporation of the Patient's Voice in Medical Product Development and Regulatory Decision Making | FDA).

This Initiative is contributing detailed information about specific areas useful for measuring the impact of treatments as well. As patients and payment-related organizations address the reimbursement challenges created by the growing arsenal of disease treatments, more detailed data about outcomes important to those affected are increasingly needed. These are the data that the AD PACE Initiative generates, and NIH's future planning efforts should address the ongoing need for longitudinal data that focuses on patient and carer perspectives. Connecting patient-centered data to ongoing federally funded initiatives, like the NIH-funded Alzheimer's Disease Neuroimaging Initiative (ADNI), is another fruitful area for emphasis in the coming years. Maintaining funding for these initiatives is therefore even more important as the views of people with lived experience are increasingly incorporated into the work. AD PACE is a model for working directly with people with lived experience to better understand their priorities across the disease spectrum AD PACE is also a model appropriate for other dementias. We would encourage the NIH to utilize our data to ensure the recognition of patient priorities as it incentivizes and prioritizes specific research areas.

Within the ***economic growth*** realm, there continues to be a significant lack of caregiver data — particularly economic data needed to support reimbursement decisions. Caregivers are the backbone of the current system, yet the data needed to value, support, and reimburse their work remain fragmented and inconsistent. More than 12 million family members and other unpaid caregivers provided an estimated 19.6 billion hours of care to people living with AD/ADRD.[11] The most recent AARP analysis found that the average value of one caregiving hour rose from $16.59 to $20.41 in 2024[12]— yet estimates like this vary widely depending on methodology, and there is no standardized, government-collected dataset that payers can rely on consistently. This is not just an academic problem: a peer-reviewed analysis of the indirect costs AD found explicitly that there are currently no publicly available estimates of certain affected populations, and that data gaps and a lack of consensus persist concerning how to value caregiver forgone earnings and disutility.[13] Without consistent, high-quality economic data on caregiving — hours provided, income and career impact, health costs borne by caregivers themselves — payers cannot make sound reimbursement decisions, whether through Medicaid Home- and Community-based Services (HCBS) waivers, paid family leave, tax credits, or emerging CMS models like GUIDE. We are essentially asking decision-makers to build reimbursement decisions on incomplete evidence.

The recent FDA approvals of lecanemab and donanemab have advanced the offerings in ***clinical practice*** for AD/ADRD, but the diagnostic challenges surrounding AD/ADRD have long been highly complex. The NIA contributed a number of years ago to the development of research criteria for AD/ADRD[14], but has since shifted away from those activities as they have morphed into guidance that is increasingly comparable to clinical practice guidelines. Nevertheless, NIA (and the NIH) do have a role in contributing the research that informs practice, and continued investments in understanding the basic science of the disease, as

well as its biomarkers and manifestations that can lead to more accurate diagnoses, will be important, as well contributions to clinical practice in the area of care for those living with advanced AD/ADRD.

Fostering public trust in AD/ADRD research, as well as ***accessibility*** of these findings, is essential – but currently an immense obstacle, as the NIH website (and its institute and center sites) have been trusted public health information resources for decades. Within the AD/ADRD realm, the science is evolving very quickly, and messaging needs to not only reflect advances in drug development but also advances in behavior change and modifiable risk factors (such as blood pressure control and several additional behavior change strategies). NIH must ensure timely, transparent, and scientifically grounded decision-making that supports both the research community and the public. Effective stewardship depends on clear communication channels between NIH leadership and staff with the extramural research community and the public, as well as consistent and efficient funding processes that ensure that federal commitments to research awards are honored.

The reduction and centralization of public-facing functions across ICs, including but not limited to communications, legislative affairs, policy, and evaluation offices is deeply troubling. While central coordination may appear to improve consistency, the elimination and consolidation of these functions compounded by understaffing and loss of expertise has threatened information accuracy, reduced visibility of NIH-supported science, and limited direct engagement with the public and scientific stakeholders. This is particularly consequential given the scale of NIH's mission; no longer are there dedicated channels to the community on specific health conditions such as AD/ADRD, common comorbid conditions, and actionable risk reduction evidence. For example, NIA previously reached more than 125,000 subscribers through weekly e-alerts, and its social media platforms engaged more than 187,000 followers (*HHS National Plan to Address Alzheimer's Disease: 2024 Update*). The absence of NIA communications staff is calamitous for the AD community, as their outreach channels were essential tools for disseminating research advances, particularly at a time when any new intervention must be communicated quickly and accurately with the public. These channels should be strategically reestablished in the near future.

In addition, a lack of transparency has emerged in the last year between program officers and grantees, one of the most essential relationships for NIH. Historically, program officials played a critical role in identifying emerging scientific priorities and rapidly translating them into funding opportunities and were able to share research priorities early with the scientific community. Unfortunately, since 2025, changes to NIH structures and systems have dramatically slowed and undermined scientific opportunities. For example, while some reductions and consolidations in the number of Notices of Funding Opportunities (NOFOs) in redundancy are important, the dramatic decrease has only served to limit the ability of program staff to fill pivotal gaps in highly specialized research fields and disincentivize active communications with prospective applicants and current grantees.

Lastly, ***societal benefit*** should continue to be first and foremost in the minds of NIH leaders as research areas are considered and prioritized. And as such, discovery must benefit women and men equally, as well as diverse, at-risk populations, and NIH should seek to ensure that research portfolios are continually assessed with this goal in mind.

NIH should also prioritize life course considerations with respect to disease research. Within the AD/ADRD research realm, we must better understand the impact of Alzheimer's disease across the lifespan – not just for the person diagnosed, but for the generation(s) caring for them. Emerging research on caregivers for people living with AD/ADRD causes chronic stress, disrupted sleep, and immune dysregulation, and studies increasingly point to a bidirectional relationship in which the strain of caregiving may itself accelerate biological aging and elevate the caregiver's own future dementia risk.[15]

This matters enormously for genetically predisposed adult children and grandchildren – those carrying APOE-e4 or other risk variants –who are simultaneously caring for a parent or grandparent with AD and, some research suggests, may be experiencing years of chronic cortisol exposure and inflammatory stress that could interact with that genetic vulnerability to hasten their own cognitive decline. Much of this evidence is still early and associative rather than causal, but it raises urgent questions about whether we are inadvertently watching the disease propagate across generations through the caregiving experience itself, not just through inherited genes.

Further, societal benefit cannot be fully considered by NIH in a vacuum; collaborations must be fostered with sister agencies under the Department of Health and Human Services (HHS), even when they are not defined in statute. A particular between-agency challenge that NIH leadership could begin to rectify (and which is meaningful to outcomes and "benefit") is related to how agencies under HHS define "evidence," especially in the non-pharmacological realm, that supports broad implementation. For example, within HHS, NIH and the ACL contribute complementary perspectives on what constitutes evidence for improving dementia care. NIH's mission emphasizes generating rigorous, generalizable scientific evidence through clinical trials (particularly randomized clinical trials), observational studies, and systematic evidence reviews to determine whether interventions are effective, for whom they work, and under what conditions. ACL builds on this evidence while also valuing practice-based evidence generated through community programs, service delivery, program evaluation, quality improvement, and the lived experiences of people living with dementia, care partners, and service providers to assess whether interventions are feasible in real-world settings. While these perspectives are complementary, the absence of a shared framework for determining when an intervention has accumulated sufficient evidence to move from research to broad implementation can slow dissemination and implementation, creating uncertainty for researchers, health systems, and community organizations.

In closing, the NIH is well-positioned to continue to make unprecedented progress in AD/ADRD research, but the considerations above are critical to the prioritization and

incentivization of research, and to true “gold standard” science. Thank you for the opportunity to submit these comments. We look forward to working with the NIH to advance our shared priorities and end this disease.

Sincerely,

Catherine Patterson
Acting Chief Operating Officer

Response to NIH RFI NOT-OD-26-087
NIH Office of Science Policy
SciencePolicy@od.nih.gov

Submitted by: National Society for Histotechnology
Date: August 18, 2026

The National Society for Histotechnology (NSH) appreciates the opportunity to provide feedback on NIH's Request for Information regarding the measurement and rewarding of scientific impact. As the leading professional society representing histologists and other tissue-based laboratory professionals, NSH strongly supports NIH's efforts to modernize scientific impact assessment and align incentives with the practices that most effectively advance biomedical discovery and improve public health.

We encourage NIH to expand scientific impact metrics beyond traditional publication and citation measures to more fully recognize contributions that enhance reproducibility, accelerate translation, strengthen collaboration, and improve research quality.

Reproducibility Should Be a Core Measure of Scientific Impact

NSH believes that reproducibility and replicability should be elevated as primary measures of scientific impact. Novel findings have limited long-term value if other investigators cannot evaluate, reproduce, validate, or build upon them. Reproducible research creates a dependable foundation for subsequent discovery, while independent replication tests whether findings remain consistent when examined with new data or in different settings. Both activities strengthen confidence in scientific knowledge and should be recognized as substantive scientific contributions, not treated as secondary quality-control activities.

The importance of methodological transparency is particularly evident in tissue-based biomedical research [1]. In *Guide for collecting and reporting metadata on protocol variables and parameters from slide-based histotechnology assays to enhance reproducibility*, Chiriboga and colleagues identify major categories in which deficiencies can undermine reproducibility. They further note that insufficient reporting of reagents, protocols, and other experimental variables can prevent researchers from replicating or building upon published findings [2]. The recognition of this issue is not limited to the scientific histology community, the lack of rigor and reproducibility has been noted by others and a number of tools to identify materials (https://rrid.site/), laboratories (https://coremarketplace.org/), and researchers (https://orcid.org/) have been successfully implemented in the last several years [3-6]. These tools should play a larger role as metrics of reproducible research practices, with stricter requirements for their use in publications, grant applications, and evaluations of research laboratory performance [7-10].

Real-world histology research illustrates why reproducibility must be evaluated across laboratories rather than assumed from performance at a single site. In *The Impact of Stain Variation and Colour Normalisation on Tissue Stain Intensity and Automated Nuclear Counting: A Multi-Site Study*, investigators found statistically significant differences among laboratories, with greater variation between sites even though intra-laboratory consistency was relatively high [11] . In fact, instrument reproducibility is also subject to significant variation[12]. These examples demonstrate that reproducibility requires attention not only at the analytical steps but real-world performance across

NATIONAL SOCIETY FOR HISTOTECHNOLOGY

Ellicott City, MD 20143
P: 443-535-4060
E: histo@nsh.org

institutions. This variation is a significant barrier to the implementation of computational models [11, 13, 14].

Reproducibility is essential in immunohistochemistry (IHC). In *Immunohistochemistry as an assay*, authors emphasize that IHC is a complex assay requiring analytical standardization and rigorous quality-control standards [15, 16]. This includes implementation of newly developed quantitative standards for statistical process control in immunohistochemistry [17, 18]. Immunohistochemical assay standardization is all the more important in the era of companion diagnostics as lack of rigor can have profound effects on outcomes [19-21]. Establishing best practices with reproducible standards is critical for rigorous scientific investigation [22-24]. Recognizing the scientific contributions of histology scientists would help correct an impact-assessment system that credits the final intellectual interpretation while overlooking the expertise that made a reliable and reproducible test result possible.

In emerging fields such as spatial biology, reproducibility also depends on the development of community standards and best practices [25]. The 2025 article, *Histotechnology at the crossroad of spatial biology bridging legacy and innovation,* observes that spatial-omics currently lacks fully standardized nomenclature, frameworks, and protocols [26]. New technology is vulnerable to artifacts because their effects on outcomes are often unknown. Moreover, when such technology is built on techniques or methodologies with a history of irreproducibility, it poses a significant risk. They and others identify actionable best practices to “standardize workflows, enhance reproducibility, and address logistical challenges [27-29]. Scientific impact evaluation should therefore recognize investigators, technical professionals, societies, and consortia that develop and maintain the shared technological standards underpinning reproducibility, even when those contributions are not fully captured by first-author publications or citation counts.

Investigators and scientists should be recognized and rewarded for following standardized workflows that enhance reproducibility. Likewise, those who develop these workflows should receive clear recognition, including citation, so that existing and emerging tracking tools can capture relevant metrics and help measure scientific reproducibility. NIH should therefore consider rewarding investigators who:

- Develop and publish validated protocols or workflows and participate in replication studies.
- Sharing of well-documented data, code, computational workflows, metadata, and analytical decision rules when ethically and legally permissible.
- Creation of shared reference datasets, control materials, repositories, proficiency-testing resources, and other infrastructure that allows reproducibility to be evaluated across institutions
- Contribute to standards development and demonstrating adherence to best-practice reporting frameworks.

Collaboration as a Measure of Scientific Impact

NSH strongly encourages NIH to recognize and reward scientific collaboration as a meaningful indicator of scientific impact. Many of today's most significant advances in biomedical research are the product of multidisciplinary teams that bring together complementary expertise [30, 31]. This includes the core facilities which exemplify collaborative science [32, 33]

NATIONAL SOCIETY FOR HISTOTECHNOLOGY

Ellicott City, MD 20143
P: 443-535-4060
E: histo@nsh.org

Scientific progress increasingly depends on collaborative models of research. In a multi-industry consortium focused on spatial biology for drug discovery and biomarker development, the authors concluded that: *"Key to the success of these studies is the collaboration among experts from various fields, including molecular biology, pathology, histotechnology, imaging, and data science."* They further noted that *"This multidisciplinary team is essential not only in the design and execution of the experiment but also in the interpretation of the results."* and that *"Early discussions among these experts are vital"* for assessing technical feasibility and ensuring reliable data generation and analysis [27]. Collaboration is a key driver of reproducibility. Scientific teams that include subject matter experts across multiple disciplines are better positioned to identify methodological weaknesses, establish consensus standards, and generate reproducible results.

Professional societies play an important role as infrastructure for collaboration. The spatial biology editorial specifically identifies NSH and its partnerships with organizations such as the College of American Pathologists (CAP), American Society for Clinical Pathology, The Human BioMolecular Atlas Program (HuBMAP), the Human Tumor Atlas Network (HTAN), The Celluar Senescence Network (SenNet), and industry stakeholders as mechanisms for advancing education, workforce development, quality systems, and scientific innovation.

For these reasons, NSH recommends that NIH expand scientific impact assessments beyond traditional publication and citation metrics to recognize meaningful contributions to team science. Activities such as developing consensus standards, participating in scientific consortia, creating shared resources, establishing reproducibility frameworks, mentoring across disciplines, and fostering cross-sector collaborations generate substantial scientific value and accelerate translation fundamentally supporting the biomedical enterprise. As above, recognizing and rewarding these contributions would better align incentives with the collaborative nature of modern biomedical research and ultimately advance the NIH mission

Data, Software, and Model Sharing

Histology scientists manage large volumes of samples that exist in multiple forms, including human, animal, and model organism specimens; fresh, frozen, and archival tissues; images; plus, all the materials required to process these different samples on demand [34]. These specimens contain a wealth of scientific (-omic) information and hold significant research value [35, 36]. Because histologists have deep expertise in how tissue samples are collected, processed, managed, and stored, they are uniquely positioned to guide their use as data resources [36, 37]. Biorepository histology laboratories play an instrumental role in stewarding this powerful source of data [32, 38]. However, many histology biorepositories and core laboratories are understaffed and struggle to meet growing demand because of lack of recognition that stems directly from the lack of quantifiable metrics of the contributions of these facilities to the biomedical research enterprise [39-41].

Training and Mentorship

Core histology laboratories not only support the research enterprise but also provide training to graduate students, residents, fellows, and scientists for all critical steps of tissue processing from preanalytical to post analytical analysis for humans, animals, and model systems, including patient-derived xenografts, xenotransplants, and organoids, all collected for research purposes [42]. This

NATIONAL SOCIETY FOR HISTOTECHNOLOGY

P: 443-535-4060
E: histo@nsh.org

training is essential to ensuring rigor and reproducibility [42]. However, it often goes unnoticed or unrecognized in publications and grant applications because of its informal nature [39, 41].

Public Impact

The lack of recognition for the contributions of histology scientists has significantly contributed to workforce shortages, affecting not only patient-directed clinical histology laboratories but also core laboratories, where this expertise is in high demand [43]. Histologists play a vital role in both basic academic research and clinical practice. Together, these areas represent a substantial economic resource and make important contributions to the biomedical research enterprise. Greater recognition and visibility would help strengthen public trust and support improved health outcomes [44, 45].

Conclusion

Biomedical research is increasingly collaborative, data-intensive, and translational. As NIH modernizes how scientific impact is assessed, it has an important opportunity to reward the behaviors that produce trustworthy science and meaningful improvements in human health.

NSH encourages NIH to place reproducibility and collaboration at the center of scientific impact evaluation. Researchers who establish standards, share resources, validate methods, participate in replication efforts, mentor colleagues, and build collaborative networks contribute substantially to scientific progress.

These activities strengthen public trust, accelerate translation, improve return on federal investment, and ultimately advance the NIH mission of improving health and reducing disease.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: The CRediT taxonomy has advanced the recognition and reward of many kinds of contributions to a research product. However, CRediT does not include contributions to transdisciplinary collaborations, including relationship building and reflective analysis. Transdisciplinary collaborations include patient- and community-engaged research, university/government/industry partnerships, and art-science collaborations, and these are central to translational breakthroughs because they span knowledge groups traditionally kept in siloes. I encourage NIH to sponsor the further development of CRediT-fAIR, an expanded taxonomy of contributorship roles, to the level of a NISO standard so it can be widely adopted like CRediT. CRediT-fAIR has been developed through the art-science journal Ground Works in collaboration with the Alliance for Arts in Research Universities: https://groundworks.io/credit-fair.

I also encourage NIH to review and leverage existing indicators of collaboration and interdisciplinarity in the following open access dataset: Laursen, B. K., Anderson, K. J., & Motzer, N. (2022). Systematic review of the literature assessing interdisciplinarity from 2000 to 2019: A qualitative dataset. https://doi.org/10.7910/dvn/6ucnkw.

The dataset, review papers, and interactive visualizations are listed here: https://aea365.org/blog/reflections-on-practicum-assignments-part-iii-supervisor-perspectives-by-marshall-bailly-assetou-barry-beverly-peters-danuta-dobosz-talatha-kiazolu-reeves-jillian-klarman-michael-petillo-and-2/

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: The Translational Science Benefits Model (TSBM) is an excellent resource. However, it only showcases the ultimate societal benefits of health research and has no place for intermediate indicators of ultimate success. For example, there are no benefits about a "more cohesive research

team". These upstream indicators are essential for tracking progress before societal benefits are realized. Without these intermediate indicators, current practice with the TSBM is to guess at which societal benefits are likely. This guesswork depends on individual judgments of likelihood rather than intersubjective evidence. NIH NCATS explicitly sponsors research and development that targets these upstream impact processes in its quest to understand the science of translation. NIH NCATS could sponsor the development of a corollary TSBM that focuses on features of the translational process itself, and fund research that shows how these are early indicators of the original TSBM outcomes.

8. Other Areas: Regardless of the specific process or outcome being evaluated, I strongly encourage NIH to adopt transparent evaluative reasoning. Such reasoning makes clear what are the criteria and standards being used as thresholds to determine the "worth, merit, and value" of the research being evaluated. If no such thresholds or value determinations are desired, then NIH should be clear that any measurement of the evaluand is simply assessment for ongoing monitoring or exploration, and not for determination of its value. When indicators are tracked but the value we attach to them is not made transparent, then researchers guess and game the system, trying to inflate indicators without understanding the underlying merit they should be pursuing. Laursen et al (2022, attached) explain how this works when it comes to assessing interdisciplinarity.

Description: Laursen, B. K., Motzer, N., & Anderson, K. J. (2022). Pathways for assessing interdisciplinarity: A systematic review. Research Evaluation, 31(3), 326–343. https://doi.org/10.1093/reseval/rvac013

218. Tufts CTSI

I am responding: On behalf of an organization

Name: Hannah M Santos

Name of Organization: Tufts CTSI

Type of Organization: Non-Profit Research Organization

Role: Other

Role - Other: Program Director

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: NIH could support the application of real-world data by funding repositories and funding investigator access and use of the data (similar to the NC3 or All of Us databases).

2. Data, Software, and Model Sharing: Rather than simply denying funding to an investigator unwilling to share data, it would be helpful if grant reviewers rewarded proposals with well-structured data-sharing plans with higher scores.

3. Training and Mentorship: i. Some current NIH policies make it difficult for early-stage investigators to work collaboratively with more senior investigators and thus be mentored by them. For example, NIH disallows early-career status for individual investigators on multi-PI grants. This discourages the inclusion of junior faculty members, effectively blocking a key opportunity for mentoring them.
ii. Also, submitting more than one K award proposal at the same time is not allowed. Given the long turnaround time for the review process, this often leads to gaps in funding for early career researchers. While more than one K can't be funded at the same time, we believe that an investigator should be allowed to apply for an institutional K award while an NIH award is being considered.

4. Collaboration: i. The role of MPI should be exempt from any limit on number of grants on which one can be PI. The MPI role promotes the very goals that the limitation of PI roles intends to achieve. By allowing multiple PIs younger investigators can be included in the MPI role even if they would not yet be eligible for sole PI status. Also, having MPIs promotes team and cross-disciplinary research, which are objectives of NIH.
ii. Include a requirement for broader range of relevant stakeholder groups to provide input on the project. For example, the Army's SBIR Catalyst Program requires partnerships between the small business with a promising technology, Army transition partners, and technology integrators, who work together to speed translation and adoption of the technology research.
iii. Break Through Cancer is a good example of supporting collaboration and data sharing within a disease area. This nonprofit provides a framework for cross-disciplinary collaborations with other researchers working on the same form of cancer. The framework reduces administrative barriers for cross-institutional collaborations through harmonized contracts, a cloud-based data science hub, and 'Team Labs': deeply integrated, multi-institutional research teams working in real-time to solve focused

cancer challenges. Junior faculty are given leadership positions within the 'Team Labs.'
iv. If NIH prioritizes collaborative grants and MPI research, this will encourage universities to prioritize the same in their promotion and tenure decisions.
v. Most research projects are multi-disciplinary and involve multiple investigators. Guidelines on reviewing grants should include recognition of /education on authorship requirements within specific disciplines and the importance of authors who are neither first nor last author.

5. Entrepreneurship and Translation: NCATS or another NIH agency could provide financial support for CTSAs to provide dedicated seed grants for projects seeking commercialization. This would be separate from SBIR/STTR funding mechanisms.

6. Foundational Scientific Exploration: Reinforcing the importance of negative results, providing a searchable online space to record the aims and hypotheses that had negative results, and rewarding investigators for disseminating those results would provide incentives for academic researchers to innovate and take risks.

7. Public Impact: i. Translational Science Benefits Model (TSBM)contains several metrics or benefits under four domains: Clinical, Community, Economic, and Policy
• NIH could require grant applicants to include expected benefits based on this model. For example, does this research improve public health access or improve life expectancy and quality of life?
ii. Grant applicants could be encouraged to use a tool like the TSBM to describe the impact of the proposed research in plain language.
iii. One question that should be part of every grant RFA/RFP is: "What will you do to make sure the general public understands your work?"
iv. To support investigators in communicating results outside of academic venues, grant budgets could include funding for public communication or communication specialists, or providing a service for communicating in plain language could be emphasized in CTSA RFAs.
v. NIH should allocate funds to specifically support engagement with stakeholders, insofar as the applicant demonstrates that engagement can improve public impact.

8. Other Areas: N/A

219. Chronic Pain Research Alliance- an Initiative of The TMJ Association

I am responding: On behalf of an organization

Name: Christin Veasley

Name of Organization: Chronic Pain Research Alliance - an Initiative of The TMJ Association

Type of Organization: Research Participant/Patient Advocacy Organization/Patient Advocate/Caregiver

Role: Research Participant/Patient/Advocate/Caregiver

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: From October 2023 through November 2025, the NIH convened the ENGAGE Working Group to develop a unified vision, framework, roadmap, and recommendations for making meaningful researcher-community partnerships standard practice across NIH-funded clinical research. In December 2025 the NIH Director endorsed the report and committed to implementing the recommendations agency-wide. As NIH moves in this direction, its measures of scientific impact should recognize the education, applied training, and mentorship that enable NIH-funded researchers to partner effectively with people with lived experience (PWLE) and community organizations.

EDUCATION
NIH should recognize and reward researchers who pursue foundational education in PWLE/community-engaged research principles, best practices, and implementation methods. This education should address how meaningful engagement differs from recruitment, research participation, outreach, or one-time consultation; how to assess readiness; establish roles and responsibilities of all partners; identify and connect with appropriate partners; and ensure broad representation. It should teach researchers specific implementation methods to partner with PWLE and communities across the research lifecycle – from developing research questions and designing studies through grant development, study launch and conduct, data interpretation, development and dissemination of knowledge products, and study close-out. Cross-cutting topics should include shared values and decision-making; equitable compensation; bidirectional communication and transparency; accessibility, accommodations, and flexible participation; partner preparation and skills development; recognition and credit; engagement measurement and iterative improvement; and documentation of how partner input changes the research. Whenever possible, educational activities should be co-developed and co-delivered by PWLE and community partners. An exemplar is the research engagement curriculum – Foundations of PWLE Engagement in Clinical Research – which was co-developed and co-taught by PWLE members of the NIH HEAL National K12 Clinical Pain Career Development Program.

Potential metrics:
• Completion of substantive education in PWLE/community-engaged research.
• Demonstrated understanding through knowledge assessments or applied exercises.

• Inclusion of engagement-related learning goals in career-development or research-team plans.
• Documentation of how this education informed the researcher's engagement approach or research decisions.
• Continued education as the researcher assumes responsibility for additional and/or expanded partnerships.

Potential NIH incentives include the following:
• Include engagement education as a review consideration in appropriate career-development, fellowship, institutional training, center, and clinical research awards.
• Allow grant funds and protected time for engagement education.
• Include progress toward educational goals in progress reports and renewals.
• Allow/encourage these activities to be documented in NIH biosketches, NIH RePORTER, and grant products.
• Consider evidence that researchers applied this education in subsequent funding decisions.

NIH should assess what researchers learned and applied - not simply count courses, hours, or certificates.

APPLIED TRAINING AND PWLE MENTORSHIP
NIH should separately recognize and reward researchers who undertake applied, competency-based training in developing, implementing, evaluating, and sustaining meaningful partnerships with PWLE and/or community partners. This training should be co-developed and co-delivered by PWLE and community partners and, where appropriate, include a compensated PWLE or community mentor who contributes to the researcher's career development and research. The NIH HEAL National K12 Clinical Pain Career Development Program provides a promising model: scholars are matched with mentors with lived pain experience, receive training in PWLE and community engagement, develop a PWLE/community engagement plan, and apply what they learn in their own research.

Potential metrics include:
• Completion of applied, competency-based engagement training.
• Development and implementation of study-specific engagement plans, timelines, budgets, partner roles, and evaluation approaches.
• Inclusion of a compensated PWLE and/or community mentors with clearly defined goals and responsibilities.
• Assessments from both the researcher and PWLE mentor regarding the quality and value of the mentorship.
• Documentation of changes made to the research because of the training or mentorship.
• Feedback from PWLE and/or community partners regarding the researcher's engagement practices.
• Continued application of engagement competencies in subsequent research.

Potential NIH incentives include the following:
• Include applied engagement training and PWLE/community mentorship as scored criteria in career-development and training awards.
• Allow dedicated funds and protected time for training and mentorship, including compensation and

administrative support for PWLE mentors.
• Offer administrative supplements for researchers seeking applied training or adding a PWLE/community mentor.
• Include engagement competencies and mentorship outcomes in progress reports and renewal decisions.
• Allow/encourage researchers to document these contributions in NIH biosketches, NIH RePORTER, and grant products.

RESOURCES/REFERENCES
- NIH HEAL K12 Clinical Pain Research Career Development Award (https://www.jpain.org/article/S1526-5900(25)01059-4/abstract, https://www.nih.gov/heal/research/training-workforce)

4. Collaboration: NIH should recognize meaningful partnership with people with lived experience (PWLE) and community members/organizations as a valued form of scientific collaboration and team science. Investigators should be incentivized to involve PWLE and community partners throughout the research lifecycle – from identifying health priorities and developing research questions through study design, grant development, study preparation and conduct, data analysis and interpretation, return of results, and dissemination and implementation. PWLE and community partners should be recognized as contributors of expertise rather than treated only as advisors or recruitment resources.

NIH should not use the number of advisory-panel members or meetings as a measure of success. Recognition should depend on the quality, continuity, and demonstrated influence of the partnership.

Possible metrics include:
1. The point at which PWLE and community partners became involved and the research lifecycle stages in which they participated.
2. The degree of clearly defined roles, responsibilities, bi-directional communication, and decision-making authority.
3. A dedicated engagement budget, including timely and appropriate compensation for individual partners and community organizations.
4. Representation of the populations affected by or expected to use the research, including accommodations needed to support participation.
5. Documentation of specific decisions, materials, methods, outcomes, analyses, or dissemination strategies changed because of partner input.
6. Partner-reported assessments of trust, respect, communication, support, reciprocity, and ability to influence decisions.
7. Evidence that partners received appropriate authorship, contributor credit, presentation opportunities, or other recognition.
8. Continuity of the partnership and efforts to sustain relationships beyond a single grant.

Ways NIH could incentivize and reward these activities include:
1. Ask institutions applying for training, career development, center, and cooperative agreement awards to describe how community-engaged scholarship and team-based contributions are recognized in faculty evaluation, promotion, and tenure.
2. Require a study-specific engagement plan and budget in funding opportunities and make engagement

quality a scored review criterion.
3. Include compensated PWLE and community reviewers on peer-review panels evaluating engagement plans.
4. Provide planning awards or pre-application funding so researchers and communities can develop partnerships before the research question and protocol are developed and finalized.
5. Offer administrative supplements to strengthen or expand engagement during an existing award.
6. Require investigators to report progress against engagement milestones in annual progress reports and consider performance in continuation and renewal decisions.
7. Allow PWLE and community partners to be formally identified and credited as members of the scientific team in applications, NIH RePORTER, biosketches, and grant products.
8. Establish awards recognizing research teams that demonstrate exemplary and sustained research-community partnership.

Resources and Examples include:
- NIH ENGAGE Working Group Report (https://osp.od.nih.gov/wp-content/uploads/2025/12/NExTRACs-ENGAGE-Report_FINAL.pdf): Provides an engagement framework spanning the research lifecycle and recommends NIH requirements, support, measurement, and accountability.
- PCORI Foundational Expectations for Partnerships in Research (https://www.pcori.org/engagement-research/engagement-resources/foundational-expectations): establishes expectations for early and ongoing engagement, partner compensation, shared decision-making, team capacity, and continuous assessment.
- Medical College of Wisconsin (https://www.mcw.edu/-/media/MCW/Departments/Faculty-Affairs/MCW-Faculty-Handbook.pdf): explicitly recognizes Community Engagement as an accomplishment area in faculty promotion, with criteria spanning involvement, achievement, and leadership. Examples include sustained community partnerships, community-engaged scholarship, dissemination to community and academic audiences, and demonstrated impact within both the community and the faculty member's field. Community engagement can also inform tenure through MCW's assessment of contributions to its institutional missions and scholarly and programmatic achievements.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: We applaud NIH's goal of expanding the definition of scientific impact beyond grants, publications, citations, and presentations at scientific meetings. Publicly funded research has greater impact when it addresses questions that are important to affected communities, produces findings that intended users can understand and apply, and contributes to improvements in healthcare, coverage, education, community programs, policy, public trust, and/or health.

Studies should be designed from the outset with dissemination and, where appropriate, implementation in mind. Investigators should identify the intended end users of their findings – such as patients, caregivers, clinicians, insurers and other payers, health systems, community organizations, employers, educators, and policymakers – and partner with representatives of these groups when selecting research questions and outcomes, designing the study, and planning dissemination. This early involvement can help ensure that the study generates findings and outputs that are relevant, accessible, and useful.

NIH should require dissemination and implementation plans in appropriate grant applications and provide sufficient funding to carry them out. Plans should identify relevant end-users of study data, intended audiences, knowledge products, communication channels, partner roles, timelines, accessibility considerations, evaluation methods, and the intended use of the findings. Researchers should work with PWLE, community partners, and other end users to co-develop, test, refine, and disseminate audience-specific products such as plain-language summaries, infographics, webinars, videos, decision tools, clinical resources, payer or policy briefs, toolkits, and community presentations. These activities should be recognized as substantive scientific contributions, not optional outreach.

Metrics NIH could use include:
1. Near-term impact: Early identification and involvement of intended study data end-users; a funded dissemination and implementation plan; relevance of the research questions and outcomes; changes made because of partner input; improvements in study feasibility, acceptability, recruitment, retention, or participant burden; and appropriate compensation and credit for partners.
2. Study outputs: Co-development of audience-specific knowledge products; timely return of aggregate and, when appropriate, individual results; and assessment by intended users of the products' accessibility, clarity, relevance, cultural appropriateness, and usefulness.
3. Intermediate impact: Reach through trusted channels, interpreted in context; use of findings or products by patients, clinicians, payers, health systems, community organizations, educators, or policymakers; adoption in training, programs, guidelines, coverage decisions, or organizational practices; and continuation of partnerships.
4. Longer-term impact: Changes in clinical practice, healthcare access or coverage, policy, public health programs, health outcomes, costs, or public trust when reasonably attributable to the research and measurable within an appropriate timeframe.
5. Public-impact narrative: A concise account of who benefited, what changed, the investigator's contribution, and the evidence supporting the claimed impact.
6. End-user feedback: Input from PWLE, community partners, and other intended users regarding the relevance, usefulness, uptake, and effects of the research and its outputs.

Ways NIH could incentivize and reward these activities include:
- Require a dissemination and implementation plan in appropriate grant applications and make its quality a scored review criterion.
- Require applicants to budget for end-user engagement, partner compensation, development and testing of knowledge products, accessible formats, return of results, and co-dissemination.
- Allow dissemination and implementation planning costs from the beginning of the award rather than limiting support to the study's final stages.
- Provide final-year dissemination supplements and follow-on implementation awards after findings become available.
- Include progress toward dissemination and public-impact goals in annual and final reports, competing renewals, and subsequent funding decisions.
- Allow nontraditional outputs, knowledge products, engagement contributions, and evidence of public impact to be reported in NIH biosketches, NIH RePORTER, and future applications.
- Establish NIH awards or showcases recognizing investigators, community partners, and teams that

demonstrate exemplary co-dissemination or public impact.
- Ask institutions applying for training, center, and cooperative agreement awards how engagement, dissemination, and public impact are recognized in annual review, promotion, and tenure.

NIH should reward evidence that dissemination was planned early, appropriately funded, co-developed with intended users, and resulted in useful and used products, not simply the number of products created, downloads, or social-media impressions. Investigators should not be penalized for null or negative findings or for long-term outcomes beyond their control. They should be recognized for responsible communication, fulfillment of dissemination commitments, and credible evidence of impact within their sphere of influence.

Resources and examples include:
- PCORI Dissemination and Implementation Framework and Toolkit (https://www.pcori.org/implementation-evidence/putting-evidence-work/dissemination-and-implementation-framework-and-toolkit): Integrates early audience identification, partner engagement, dissemination, implementation, and evaluation.
- PCORI Engagement Award: Dissemination Initiative (https://www.pcori.org/funding-opportunities/announcement/engagement-award-dissemination-initiative-spring-2026-cycle): Demonstrates how a funder can provide dedicated support for dissemination through trusted organizations and networks.
- Washington University Translational Science Benefits Model and Translating for Impact Toolkit (https://www.translationalsciencebenefits.wustl.edu/about-the-model/): Provide a framework for planning, tracking, and demonstrating clinical, community, economic, and policy impacts.
- CDC Clear Communication Index (https://www.cdc.gov/ccindex/widget.html): Provides research-based criteria for developing and evaluating public-facing communication products.

1. Rigor and Reproducibility: Frontiers welcomes NIH's Replication and Reproducibility Initiative and its push toward gold standard science, which we see as the premise of good publishing policy rather than its endpoint. As set out in our response to the NIH Request for Information NOT-OD-26-047 (https://grants.nih.gov/grants/guide/notice-files/NOT-OD-26-047.html), the largest gains available to NIH sit in a part of the research system that is currently being significantly changed by the advent of AI: the editorial and integrity workflows that catch error before it enters the record. Frontiers has spent the past eight years engineering that layer, and we would encourage NIH to similarly use integrity in the published scientific records as a clear indicator of rigor. Every indicator NIH is considering depends on accuracy and integrity in practice. A replication study is only informative if the original record is accurate, and preregistration only constrains analysis if deviations are caught at review. Whether NIH is measuring reproducibility, data and software sharing, collaboration, or public impact, accuracy and integrity are essential, and this response draws on Frontiers' operating experience to inform each of those areas below.

The stakes are large and quantified. OSTP's July 2026 report to the President, Science: A New Golden Age (https://www.whitehouse.gov/wp-content/uploads/2026/07/Science-A-New-Golden-Age.pdf), cites published estimates that irreproducible findings in preclinical biomedical research alone misdirect roughly $28 billion a year, and it warns that AI will make plausible results easier to generate than to verify. The same report sets out the Genesis Mission's ambition to unlock federal scientific data and build AI-ready datasets capable of driving discovery at scale. Both goals rest on the same requirement, which is a supply of high quality, structured, reviewed information for AI systems to work from. Peer-reviewed literature and curated, well-determined data are among the most dependable inputs available for that purpose. Frontiers would welcome a conversation with NIH about contributing reviewed content and AI-ready data to this effort.
Every manuscript submitted to Frontiers passes through AIRA, our AI Review Assistant, which runs more than 40 automated integrity and quality checks before a single reviewer sees the paper, covering language quality, image manipulation, plagiarism, conflicts of interest, scope, and potentially fabricated content. That screening blocks or rejects roughly 32% of submissions before peer review begins. Our 66-person research integrity team includes a dedicated auditing division, created in 2022, that proactively investigates paper-mill networks rather than waiting for a report to arrive. Furthermore, Frontiers holds

a COPE Trustee seat, chairs the COPE Papermill Working Group, is a signatory of United2Act, and contributes to the STM Integrity Hub, the shared infrastructure publishers use to flag paper-mill activity, duplicate submissions, and citations to retracted work across the industry before they contaminate someone else's reference list. These are precisely the workflows that must continue to improve as AI generated and hallucinated content reaches the literature in volume, and Frontiers sees real value in iterating and improving these processes with NIH.

None of these pre-review analyses shows up in a citation count, but all of it is what makes a citation trustworthy.

NIH's framework should reward publication of replication studies, null results and confirmatory research; use of registered reports and preregistration; ensuring availability of underlying data, code and protocols; adherence to field-specific reporting standards; and the integrity functions of peer review, editorial assessment, corrections and retractions. Frontiers would add one further indicator: direct recognition of pre-publication screening and post-publication correction activity as evidence of how rigorously the record is being defended, and the quality of each publication validated. Merit review and peer-reviewed publication are already integral to how federal science is evaluated, and Frontiers agrees with the focus of this RFI on broadening the measures of scientific impact. Data, code, protocols, negative results and methodological work deserve to be discoverable and credited too, rather than sitting where neither other researchers nor the public can benefit from them. Team-based science raises a related measurement problem: a paper with dozens of authors does not tell NIH who did which aspects or what percentage of the work. Frontiers adopted the CRediT contributor taxonomy in 2023 (https://www.frontiersin.org/news/2023/07/20/frontiers-adopts-credit-to-enhance-clarity-in-research-authorship/), which disaggregates authorship into 14 defined roles, from conceptualization and methodology to data curation and funding acquisition. That structured record is directly useful for assessing individual contributions to team-based science, and NIH's framework should recognize CRediT style role disclosure as an indicator in its own right and explore how it can be expanded for data, software, and additional research outputs.

Two cautions. First, NIH should not trade one narrow metric, the publication count, for another equally narrow one such as a single reproducibility or deposit indicator. NIH's own Data Sharing Index (S-index) Challenge models the better approach (https://www.nih.gov/challenges/nih-data-sharing-index-s-index-challenge). It scores how effectively a researcher shares data, weighing FAIR adherence, timeliness, completeness of annotation, actual reuse by others, and the publications and patents that follow. That set of data is a measure of overall quality and impact, the logic we would encourage NIH to carry across the rest of the framework. Second, what replication looks like varies by research field. Clinical, laboratory, computational and population-health research each need different reproducibility infrastructure, and a single checklist will fit none of them well.

Frontiers and its industry peers already run, at scale, systems NIH can build this framework on. We would welcome the chance to share our integrity data directly with NIH in the context of any post-submission follow-up, and to explore how these workflows could support the Replication and Reproducibility Initiative in practice.

2. Data, Software, and Model Sharing: Frontiers supports NIH's effort to reward genuine data and code sharing, a standard that we apply to our own authors. Our policies and publication ethics require that the minimum dataset supporting a paper's conclusions be made available, that standardized data be deposited in the relevant community repositories, and that every article carries an explicit data availability statement (https://www.frontiersin.org/guidelines/policies-and-publication-ethics).

Since October 2025, we have gone further with our FAIR² Data Management service. It publishes data itself as a citable, peer-reviewed article type, with an interactive portal offering AI chat, visualization tools and notebooks for reuse, and an AI data steward that helps researchers get metadata right the first time (https://www.frontiersin.org/about/fair-data-management). FAIR² extends the FAIR principles — Findable, Accessible, Interoperable, Reusable — with AI-readiness and governance, and it is aligned with NIH's and NSF's own data-sharing mandates.

That experience tells us where NIH's incentive design will succeed: on quality rather than volume. OSTP's July 2026 report makes the same point about federally funded data, noting that valuable datasets are "routinely abandoned, sometimes due to a lack of stable funding for storage and curation, and other times because there is no signal on the value of the information." A deposit count rewards quantity and does nothing to improve a dataset that is incomplete, undocumented, or disconnected from the paper that produced it. NIH's framework should instead reward deposition in trusted repositories with links back to the literature, persistent identifiers and community metadata standards, documented evidence of reuse or citation, clear versioning and licensing, and appropriate access controls where privacy, security or participant protection genuinely require them. That is the same balance NIH Director Bhattacharya has set for the agency's own Real-World Data Platform, being built "consistent with a deep respect for individual privacy rights" (https://www.nih.gov/about-nih/nih-director/statements/advancing-nihs-mission-through-unified-strategy).

Making any of this measurable depends on metadata. Crossref and DataCite both operate services that connect datasets and software to the articles describing them, through data and software citation deposits (https://www.crossref.org/documentation/schema-library/markup-guide-metadata-segments/data-citation/) and the relationships registered between DOIs (https://www.crossref.org/documentation/retrieve-metadata/data-citations/). The value and longer-term impact of those links depend on publishers supplying complete, accurate metadata at scale. Frontiers integrated with the OA Switchboard in March 2026 to automate metadata exchange with institutions, libraries, and funders (https://www.frontiersin.org/news/2026/03/30/frontiers-integrates-with-oa-switchboard-to-streamline-open-access-workflows). Curated metadata is what makes open science, rigor, and reproducibility monitorable at all.

Publishers are building this infrastructure (i.e., data-article linking, software citation, repository integrations, metadata enhancement) because it is where the field is going. It is also where OSTP's own vision points: Science: A New Golden Age anticipates researchers releasing "shorter outputs more frequently, including datasets, code, preliminary findings, and methodological notes," with "dynamic papers" that "update automatically as underlying data changes." A natural role for a publisher in that future is helping researchers document and link their work so that others can find it, build on it and apply it. Done properly, this is what produces AI-ready data and the richer linked research graphs that

connect papers, datasets, code, methods and people. That is exactly the substrate programs that the Replication and Reproducibility Initiative and the Genesis Mission need, and it is where we think publishers can be most useful to NIH. The incentive framework should accelerate that connectivity of research, data and outputs, rather than creating a parallel compliance regime that counts deposits and cannot see the connections between them.

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: Real translational benefit from biomedical research often takes years to surface, which is the same long horizon the Science: A New Golden Age report gives as the rationale for federal science funding itself. Short-term signals such as news coverage, downloads, views, and social media posts measure attention rather than health outcomes, and the report makes the same point about the incentives around publication: “Journal editors want clear narratives. University press offices demand headlines. Nuance dies, as a result, in the race for attention.”

Nevertheless, the pathway to public benefit runs through publication. What NIH can measure with confidence is whether that pathway is intact: whether findings are peer reviewed, indexed, correctable and openly available. NIH's own Public Access Policy says as much. Increasing access to NIH-funded publications “can accelerate future research, lead to collaboration, and allow interested readers and patients to follow the latest advances more closely,” and reflects NIH's commitment to the “responsible stewardship of the Nation's investment in biomedical research by improving transparency and accessibility of taxpayer-funded research, an essential component of fostering trust in research.” Frontiers has delivered exactly that pathway since 2007. Every article is immediately and permanently free to read under CC-BY 4.0, with no embargo and no paywalled version of record, across more than 759,000 articles in 222 journals. Frontiers delivers this open access model at a comparatively lower cost to researchers, institutions, and funding administrations alike — improving efficiency and enabling highly curated distribution of scientific knowledge, while helping administrators save money relative to prevailing market rates.

Frontiers asks NIH to weigh this RFI against a live financial reality it is also facing. GAO reported in May 2026 that federal agencies spent roughly $295 million on article processing charges in 2024, projected to reach $582 to $937 million by 2030 (https://www.gao.gov/products/gao-26-107738). A separate rulemaking now under consideration at OMB would respond to that pressure with a blanket ban on publication and subscription costs, a step Frontiers has urged OMB to withdraw because it would defund the peer review, integrity screening, indexing and correction functions that make the scholarly record trustworthy in the first place. A framework that rewards trusted dissemination as a component of public impact, while a parallel rule removes the funding that sustains it, sends NIH-funded researchers in two directions at once. We ask NIH to treat reasonable publication costs as impact infrastructure, not overhead.

Publication is also where American research competes globally and NIH's direction can strengthen that

position rather than simply defend it. China published approximately 1.1 million research articles in 2024, compared with 880,000 from the United States, and the Science: A New Golden Age report describes the same shift across the wider enterprise, observing that “America no longer stands alone as the unchallenged leader in science and technology” while China's R&D spending “has surged from a negligible fraction of U.S. levels to full parity on a purchasing-power-adjusted basis.” The answer to that is to broaden what American research shares and how usable it is: open results, reviewed data, documented methods and machine-readable outputs that let computational and AI-driven research move faster on top of them. A framework that treats publication and structured dissemination as central to the mission, and resources them accordingly, is one of the more direct levers NIH has for unlocking U.S. advantage in the quality of our scientific output.

The link between publications and patents merits further attention. Patent citation of the underlying literature is one of the more direct ways to trace research into downstream industrial activity, and it remains comparatively under-tracked next to citation counts. Understanding that connection, and how it varies across fields and institutions, is a natural next step before NIH builds an indicator to assess public impacts. Frontiers’ own publication workflows already build the infrastructure necessary to trace impacts: persistent identifiers, structured metadata and DOI-to-DOI relationships registered through Crossref and DataCite, the same mechanisms that let a patent examiner’s citation be traced back to the paper it drew on. Surfacing those connections for authors and institutions, rather than leaving them buried in citation databases, is work we would welcome doing alongside NIH. Public impact also depends on infrastructure that connects research to the people who can act on it. Frontiers Science House convened over 100 researchers, policymakers, industry leaders and Nobel laureates from 16 countries alongside the World Economic Forum's January 2026 Annual Meeting in Davos, translating findings into conversations with the people who set policy and allocate capital (https://www.alpsp.org/news-publications/industry-news/100-scientific-leaders-convene-in-davos-to-shape-global-decision-making/). That kind of engagement is the credible middle step between publication and public benefit, and NIH's framework should treat structured translation activity of this kind as evidence of impact.

8. Other Areas: Frontiers urges NIH to state plainly, in whatever framework results from this RFI, that publication and dissemination are not adjacent to NIH's mission. They are how that mission is completed. NIH's own public access, reproducibility and gold standard science initiatives all state this in different words already.

OSTP's July 2026 report raises pointed questions about how research is published, reviewed and rewarded, including the risk that publication metrics “fall to Goodhart's Law as gameable targets” as AI makes it easier to generate plausible-looking research at scale. Frontiers shares that concern and welcomes debate about possible approaches. The scholarly ecosystem exists to enable collaboration and scrutiny, and we look forward to modernizing it in the direction OSTP describes, particularly around AI. Part of what the report asks for is already how we operate. Every Frontiers article is open to every reader immediately, with no embargo, and the evidence on open access is consistent: once age and discipline are accounted for, openly available articles receive around 18% more citations than average, and open outputs are reused and built on more widely (https://peerj.com/articles/4375/). Extending that same openness, review, and curation to data, code, and methods is the practical path to the system the report envisions, and it is a path we would like to take with NIH.

Reform of narrow bibliometrics is needed but should not be read as meaning that publication itself becomes dispensable. Correcting the over-reliance on publication counts and impact factors allows a

richer picture of what publication does, supporting peer review, transparency, correctability, and reuse. Publication is essential for sharing and building on research outputs, and no aspect of research benefits from a smaller role for publication in the research lifecycle. That richer picture of the roles for publication is still being drawn, and Frontiers wants to help draw it with NIH rather than working in parallel.
Frontiers, as a fully open-access publisher operating since 2007, would welcome a direct conversation with NIH on how Frontiers' scientific-impact framework, data and AI programs, as well as its costs and access policies can pull in the directions that match NIH's goals.

Subject: Response to NOT-OD-26-087: Measuring and Rewarding Scientific Impact

Frontiers welcomes the opportunity to respond to NIH's Request for Information on Measuring and Rewarding Scientific Impact. As one of the world's largest and most impactful research publishers — and the fifth most-cited scientific publisher worldwide — Frontiers is dedicated to making peer-reviewed, quality-certified science openly accessible to researchers, clinicians, policymakers, and the taxpayer. We are a fully Gold Open Access publisher and Open Science platform, supporting American researchers by publishing their work in ways that maximize the visibility, accessibility, and impact of publicly funded science. Born digital in 2007, Frontiers has combined human editorial expertise with proprietary AI from the outset — most notably AIRA (AI Review Assistant, in use since 2017), which runs 40+ automated integrity and quality checks on every submission, and FAIR² (Fair Squared, launched October 2025), our peer-reviewed data publication service that turns research data into citable, machine-actionable, AI-ready assets aligned with NIH, Horizon Europe, and UKRI mandates. We submit these comments as a long-standing partner to the U.S. research community — committed to helping NIH translate its priorities into trustworthy, openly accessible science that powers American innovation in health, biotechnology, and the bioeconomy — and we offer the comments below in support of a vision that treats high-quality, open scholarly publishing as a necessary condition for delivering on three main pillars.

Rigor and Reproducibility

Frontiers welcomes NIH's Replication and Reproducibility Initiative and its push toward gold standard science, which we see as the *premise* of good publishing policy rather than its endpoint. As set out in our response to the NIH Request for Information NOT-OD-26-047, the largest gains available to NIH sit in a part of the research system that is currently being significantly changed by the advent of AI: the editorial and integrity workflows that catch error before it enters the record. Frontiers has spent the past eight years engineering that layer, and we would encourage NIH to similarly use integrity in the published scientific records as a clear indicator of rigor. Every indicator NIH is considering depends on accuracy and integrity in practice. A replication study is only informative if the original record is accurate, and preregistration only constrains analysis if deviations are caught at review. Whether NIH is measuring reproducibility, data and software sharing, collaboration, or public impact, accuracy and integrity are essential, and this response draws on Frontiers' operating experience to inform each of those areas below.

The stakes are large and quantified. OSTP's July 2026 report to the President, Science: A New Golden Age, cites published estimates that irreproducible findings in preclinical biomedical research alone misdirect roughly $28 billion a year, and it warns that AI will make plausible results easier to generate than to verify. The same report sets out the Genesis Mission's ambition to unlock federal scientific data and build AI-ready datasets capable of driving discovery at scale. Both goals rest on the same requirement, which is a supply of high quality, structured, reviewed information for AI systems to work from. Peer-reviewed literature and curated, well-determined data are among the most dependable inputs available for that

purpose. Frontiers would welcome a conversation with NIH about contributing reviewed content and AI-ready data to this effort.

Every manuscript submitted to Frontiers passes through AIRA, our AI Review Assistant, which runs more than 40 automated integrity and quality checks before a single reviewer sees the paper, covering language quality, image manipulation, plagiarism, conflicts of interest, scope, and potentially fabricated content. That screening blocks or rejects roughly 32% of submissions before peer review begins. Our 66-person research integrity team includes a dedicated auditing division, created in 2022, that proactively investigates paper-mill networks rather than waiting for a report to arrive. Furthermore, Frontiers holds a COPE Trustee seat, chairs the COPE Papermill Working Group, is a signatory of United2Act, and contributes to the STM Integrity Hub, the shared infrastructure publishers use to flag paper-mill activity, duplicate submissions, and citations to retracted work across the industry before they contaminate someone else's reference list. These are precisely the workflows that must continue to improve as AI generated and hallucinated content reaches the literature in volume, and Frontiers sees real value in iterating and improving these processes with NIH.

None of these pre-review analyses shows up in a citation count, but all of it is what makes a citation trustworthy.

NIH's framework should reward publication of replication studies, null results and confirmatory research; use of registered reports and preregistration; ensuring availability of underlying data, code and protocols; adherence to field-specific reporting standards; and the integrity functions of peer review, editorial assessment, corrections and retractions. Frontiers would add one further indicator: direct recognition of pre-publication screening and post-publication correction activity as evidence of how rigorously the record is being defended, and the quality of each publication validated. Merit review and peer-reviewed publication are already integral to how federal science is evaluated, and Frontiers agrees with the focus of this RFI on broadening the measures of scientific impact. Data, code, protocols, negative results and methodological work deserve to be discoverable and credited too, rather than sitting where neither other researchers nor the public can benefit from them. Team-based science raises a related measurement problem: a paper with dozens of authors does not tell NIH who did which aspects or what percentage of the work. Frontiers adopted the CRediT contributor taxonomy in 2023, which disaggregates authorship into 14 defined roles, from conceptualization and methodology to data curation and funding acquisition. That structured record is directly useful for assessing individual contributions to team-based science, and NIH's framework should recognize CRediT style role disclosure as an indicator in its own right and explore how it can be expanded for data, software, and additional research outputs.

Two cautions. First, NIH should not trade one narrow metric, the publication count, for another equally narrow one such as a single reproducibility or deposit indicator. NIH's own Data Sharing Index (S-index) Challenge models the better approach. It scores how effectively a researcher shares data, weighing FAIR adherence, timeliness, completeness of annotation, actual reuse by others, and the publications and patents that follow. That set of data is a measure of overall quality and impact, the logic we would encourage NIH to carry across the rest of the framework. Second, what replication looks like varies by research field. Data, Software, and Model Sharing

Frontiers supports NIH's effort to reward genuine data and code sharing, a standard that we apply to our own authors. Our policies and publication ethics require that the minimum dataset supporting a paper's conclusions be made available, that standardized data be deposited in the relevant community repositories, and that every article carries an explicit data availability statement. Since October 2025, we have gone further with our FAIR² Data Management service. It publishes data itself as a citable, peer-reviewed article type, with an interactive portal offering AI chat, visualization tools and notebooks for reuse, and an AI data steward that helps researchers get metadata right the first time. FAIR² extends the FAIR principles — Findable, Accessible, Interoperable, Reusable — with AI-readiness and governance, and it is aligned with NIH's and NSF's own data-sharing mandates.

That experience tells us where NIH's incentive design will succeed: on quality rather than volume. OSTP's July 2026 report makes the same point about federally funded data, noting that valuable datasets are "routinely abandoned, sometimes due to a lack of stable funding for storage and curation, and other times because there is no signal on the value of the information." A deposit count rewards quantity and does nothing to improve a dataset that is incomplete, undocumented, or disconnected from the paper that produced it. NIH's framework should instead reward deposition in trusted repositories with links back to the literature, persistent identifiers and community metadata standards, documented evidence of reuse or citation, clear versioning and licensing, and appropriate access controls where privacy, security or participant protection genuinely require them. That is the same balance NIH Director Bhattacharya has set for the agency's own Real-World Data Platform, being built "consistent with a deep respect for individual privacy rights."

Making any of this measurable depends on metadata. Crossref and DataCite both operate services that connect datasets and software to the articles describing them, through data and software citation deposits and the relationships registered between DOIs. The value and longer-term impact of those links depend on publishers supplying complete, accurate metadata at scale. Frontiers integrated with the OA Switchboard in March 2026 to automate metadata exchange with institutions, libraries, and funders. Curated metadata is what makes open science, rigor, and reproducibility monitorable at all.

Publishers are building this infrastructure (i.e., data-article linking, software citation, repository integrations, metadata enhancement) because it is where the field is going. It is also where OSTP's own vision points: *Science: A New Golden Age* anticipates researchers releasing "shorter outputs more frequently, including datasets, code, preliminary findings, and methodological notes," with "dynamic papers" that "update automatically as underlying data changes." A natural role for a publisher in that future is helping researchers document and link their work so that others can find it, build on it and apply it. Done properly, this is what produces AI-ready data and the richer linked research graphs that connect papers, datasets, code, methods and people. That is exactly the substrate programs that the Replication and Reproducibility Initiative and the Genesis Mission need, and it is where we think publishers can be most useful to NIH. The incentive framework should accelerate that connectivity of research, data and outputs, rather than creating a parallel compliance regime that counts deposits and cannot see the connections between them.

Public Impact

Real translational benefit from biomedical research often takes years to surface, which is the same long horizon the *Science: A New Golden Age* report gives as the rationale for federal

science funding itself. Short-term signals such as news coverage, downloads, views, and social media posts measure attention rather than health outcomes, and the report makes the same point about the incentives around publication: “Journal editors want clear narratives. University press offices demand headlines. Nuance dies, as a result, in the race for attention.”

Nevertheless, the pathway to public benefit runs through publication. What NIH can measure with confidence is whether that pathway is intact: whether findings are peer reviewed, indexed, correctable and openly available. NIH's own Public Access Policy says as much. Increasing access to NIH-funded publications “can accelerate future research, lead to collaboration, and allow interested readers and patients to follow the latest advances more closely,” and reflects NIH's commitment to the “responsible stewardship of the Nation's investment in biomedical research by improving transparency and accessibility of taxpayer-funded research, an essential component of fostering trust in research.” Frontiers has delivered exactly that pathway since 2007. Every article is immediately and permanently free to read under CC-BY 4.0, with no embargo and no paywalled version of record, across more than 759,000 articles in 222 journals. Frontiers delivers this open access model at a comparatively lower cost to researchers, institutions, and funding administrations alike — improving efficiency and enabling highly curated distribution of scientific knowledge, while helping administrators save money relative to prevailing market rates.

Frontiers asks NIH to weigh this RFI against a live financial reality it is also facing. GAO reported in May 2026 that federal agencies spent roughly $295 million on article processing charges in 2024, projected to reach $582 to $937 million by 2030. A separate rulemaking now under consideration at OMB would respond to that pressure with a blanket ban on publication and subscription costs, a step Frontiers has urged OMB to withdraw because it would defund the peer review, integrity screening, indexing and correction functions that make the scholarly record trustworthy in the first place. A framework that rewards trusted dissemination as a component of public impact, while a parallel rule removes the funding that sustains it, sends NIH-funded researchers in two directions at once. We ask NIH to treat reasonable publication costs as impact infrastructure, not overhead.

Publication is also where American research competes globally and NIH's direction can strengthen that position rather than simply defend it. China published approximately 1.1 million research articles in 2024, compared with 880,000 from the United States, and the *Science: A New Golden Age* report describes the same shift across the wider enterprise, observing that “America no longer stands alone as the unchallenged leader in science and technology” while China's R&D spending “has surged from a negligible fraction of U.S. levels to full parity on a purchasing-power-adjusted basis.” The answer to that is to broaden what American research shares and how usable it is: open results, reviewed data, documented methods and machine-readable outputs that let computational and AI-driven research move faster on top of them. A framework that treats publication and structured dissemination as central to the mission, and resources them accordingly, is one of the more direct levers NIH has for unlocking U.S. advantage in the quality of our scientific output.

The link between publications and patents merits further attention. Patent citation of the underlying literature is one of the more direct ways to trace research into downstream industrial activity, and it remains comparatively under-tracked next to citation counts. Understanding that connection, and how it varies across fields and institutions, is a natural next step before NIH builds an indicator to assess public impacts. Frontiers’ own publication workflows already build the infrastructure necessary to trace impacts: persistent identifiers, structured metadata and DOI-to-DOI relationships registered through Crossref and DataCite, the same mechanisms that let a patent examiner’s citation be traced back to the paper it drew on. Surfacing those connections for authors and institutions, rather than leaving them buried in citation databases, is

work we would welcome doing alongside NIH. Public impact also depends on infrastructure that connects research to the people who can act on it. Frontiers Science House convened over 100 researchers, policymakers, industry leaders and Nobel laureates from 16 countries alongside the World Economic Forum's January 2026 Annual Meeting in Davos, translating findings into conversations with the people who set policy and allocate capital. That kind of engagement is the credible middle step between publication and public benefit, and NIH's framework should treat structured translation activity of this kind as evidence of impact.

Other Areas

Frontiers urges NIH to state plainly, in whatever framework results from this RFI, that publication and dissemination are not adjacent to NIH's mission. They are how that mission is completed. NIH's own public access, reproducibility and gold standard science initiatives all state this in different words already.

OSTP's July 2026 report raises pointed questions about how research is published, reviewed and rewarded, including the risk that publication metrics "fall to Goodhart's Law as gameable targets" as AI makes it easier to generate plausible-looking research at scale. Frontiers shares that concern and welcomes debate about possible approaches. The scholarly ecosystem exists to enable collaboration and scrutiny, and we look forward to modernizing it in the direction OSTP describes, particularly around AI. Part of what the report asks for is already how we operate. Every Frontiers article is open to every reader immediately, with no embargo, and the evidence on open access is consistent: once age and discipline are accounted for, openly available articles receive around 18% more citations than average, and open outputs are reused and built on more widely. Extending that same openness, review, and curation to data, code, and methods is the practical path to the system the report envisions, and it is a path we would like to take with NIH.

In closing

Reform of narrow bibliometrics is needed but should not be read as meaning that publication itself becomes dispensable. Correcting the over-reliance on publication counts and impact factors allows a richer picture of what publication does, supporting peer review, transparency, correctability, and reuse. Publication is essential for sharing and building on research outputs, and no aspect of research benefits from a smaller role for publication in the research lifecycle. That richer picture of the roles for publication is still being drawn, and Frontiers wants to help draw it with NIH rather than working in parallel.

Frontiers, as a fully open-access publisher operating since 2007, would welcome a direct conversation with NIH on how Frontiers' scientific-impact framework, data and AI programs, as well as its costs and access policies can pull in the directions that match NIH's goals.

Respectfully submitted,

Christopher Charles Erdmann, Head of Public Affairs, North America – christopher.erdmann@frontiersin.org
Stephan Kuster, Director of External Affairs – stephan.kuster@frontiersin.org
Eleonora Colangelo, Policy Lead – External Affairs – eleonora.colangelo@frontiersin.org

221. Alexei Morozov

I am responding: On behalf of myself

Name: Alexei Morozov

Name of Organization: Fralin Biomedical Research Institute, Virginia Tech

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: A) To identify findings that are ripe for replication, NIH needs to solicit proposals to replicate published research. The proposals must be evaluated for their merit and any other NIH-funded grants. Thematic Special Emphasis Panels can evaluate such proposals based on a) replication need, b) qualifications of the applicant, and b) potential conflicts of interest between the authors of the original publication and the replication applicant.

B) To enforce rigor and reproducibility, NIH must engage with post-publication reviewing systems, such as PubPeer. Any PubPeer comment on NIH-supported studies must be evaluated by the Program Officers responsible for the award linked to the publication in question.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: The number of trained PhD students is an important criterion for a PI promotion at many universities. However, the quality of PhD studies is evaluated only by the thesis committee, hand-picked by the PhD advisor, interested in graduating their students. The system guarantees a thesis defense regardless of research outcomes. As a result, PhD programs often recruit unprepared students and produce poorly trained PhDs, while using NIH funds. NIH can improve the situation by requiring more rigid graduation criteria for NIH-supported PhD students, at a minimum, a couple of published first-author papers.

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: Moving away from percentile scoring by study sections, which punishes high-risk proposals, to evaluations by IC programs will give the high-potential proposals and ideas a better chance.

7. Public Impact: Two things can help NIH earn public trust. 1) NIH needs to purge the research enterprise of administrators whose business models focus on recruiting investigators with high promises of bringing in grants and high indirect costs rather than forming unique research schools. 2) Research misconduct, particularly data manipulation, must result in severe punishment, and such cases must be broadly publicized to convince the public that NIH aims to eradicate such behaviors.

8. Other Areas: N/A

222. The 3Rs Collaborative

I am responding: On behalf of an organization

Name: Megan LaFollette

Name of Organization: The 3Rs Collaborative

Type of Organization: Non-Profit Research Organization

Role: Investigator/Researcher

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: The 3Rs Collaborative (3RsC) recommends that NIH treat the 3Rs of animal research, replacement, reduction, and refinement, as infrastructure supporting rigorous, reproducible, and replicable biomedical research rather than solely as an animal welfare framework. Together, they help define the best methods to answer a scientific question, including model selection, study design, and experimental conditions. In all cases, models should be evaluated for fit for purpose, studies designed for rigor and robustness, and methods reported transparently.

Refinement can directly improve rigor and reproducibility by reducing hidden sources of biological variability. Housing, handling, and husbandry practices that induce chronic stress may alter neuroendocrine, metabolic, and immune responses, creating unrecognized confounding variables. We recommend NIH fund research evaluating the impact of refinement practices on data variability and require reporting of husbandry, enrichment, and handling variables. Potential indicators include the proportion of funded studies reporting these variables and reductions in baseline variability across laboratories adopting evidence-based refinement practices such as provision of species-specific enrichment such as sufficient nesting material for mice and tunnel or cup handling of mice.

Reduction is similarly aligned with rigorous study design. Reduction means using the minimum number of animals necessary for a valid experimental and statistical design to answer a justifiable question. NIH should continue promoting randomization, blinded outcome assessment, prespecified outcomes, sample size justification, and consideration of sex as a biological variable such as requiring the Sex Inclusive Research Framework (https://openinnovation.astrazeneca.com/preclinical-research/sex-inclusive-research-framework.html) in applications to help NIH reviewers determine when single sex justifications are valid or not (Landis et al., Nature, 2012). NIH should also support research evaluating model validity and approaches that balance increasing external validity (such as adding deliberate heterogenization) with efficient study design (Voelkl et al., PLOS Biology, 2018). Reviewer training in experimental design, validity, and translation, as well as recruiting statisticians to sit in on review panels, is equally important, since reviewer expectations strongly influence research behavior.

The 3Rs Collaborative's 3Rs Certificate Course, which teaches key concepts in replacement, reduction, and refinement, could be adopted nationally as part of infrastructure to support the reproduction and replication of animal research.

A key opportunity for NIH is to strengthen adoption and enforcement of existing standards. PREPARE, ARRIVE, and the recently released DRIVER guidelines provide established frameworks for planning and reporting in vivo and in vitro research (Smith et al., Laboratory Animals, 2018; Percie du Sert et al., PLOS Biology, 2020; NC3Rs 2026). We recommend NIH move beyond endorsement and incorporate verification of compliance through progress reporting, audits, and renewal review.

To support reproducibility across research models, NIH should require standardized reporting of cell source and animal-derived reagents (as required by the DRIVER guidelines), including source, species, and lot information, and support development of chemically defined, animal-free reagents (https://nc3rs.org.uk/3rs-resource-library/moving-animal-free-scaffolds-construction-3d-organotypic-models). Such reporting and development would reduce an important but underappreciated source of experimental variability and validity.

Finally, NIH should support replication studies by prioritizing findings with substantial downstream scientific or translational impact and recognizing replication efforts as valuable scientific contributions.

2. Data, Software, and Model Sharing: 3RsC recommends that NIH incentivize standardized data templates and metadata practices aligned with FAIR principles and existing reporting standards. Standardization enables meaningful data reuse and reduces unnecessary duplicative experimentation by helping investigators identify questions that have already been addressed through robust evidence.

NIH should also support mechanisms for sharing control datasets and developing validated approaches for virtual or historical controls, where scientifically appropriate. Reuse of existing data has significant potential to improve efficiency while reducing unnecessary animal use.

We further recommend NIH establish safe-harbor mechanisms that encourage publication of negative results, failed replications, and unsuccessful model-validation studies. These findings are rarely shared despite their considerable value in guiding future research decisions and preventing duplication of effort.

Importantly, NIH should reward not only data deposition but also demonstrated reuse. Indicators might include standards-compliant dataset submission rates, documented dataset reuse, use of shared controls, publication of negative findings, and evidence that shared resources informed subsequent studies. Existing NIH-supported collaborative programs, including Complement-ARIE, ORIVA, the Technology Development Centers, and the FNIH NAMs Validation and Qualification Network, provide useful models for this approach.

3. Training and Mentorship: The 3RsC considers training and mentorship the areas where NIH has the most leverage. Most failures of rigor originate upstream of execution, in how the question was framed and whether it needed answering. Reporting checklists do not catch this, since a checklist assumes the study was worth doing.

NIH should support training programs that build interdisciplinary competency across comparative medicine, animal science, computational biology, experimental design, statistics, and regulatory science rather than training researchers within methodological silos. The ability to evaluate and select the most appropriate approach for a scientific question is increasingly important in modern biomedical research.

This includes re-training for established faculty on the most up to date methods.

In addition to technical skills, training programs should emphasize question formulation, critical appraisal of the literature, model evaluation, harm-benefit analysis, and study design principles that support reproducibility and translational success. These competencies influence research quality before any experiment begins. Appropriate scientific question formulation helps drive key experimental constraints and hypothesis generation. Critical appraisal of the literature, including systematic searching, ensures investigators do not repeat settled experiments or build programs on fragile findings. Model evaluation is essential to ensure the selected model is able to answer the scientific questions at hand, while considering both model validity and translation. Harm-benefit analysis should be conducted during design rather than as a form completed for a committee, since institutional review performs a version of this analysis only after the design is fixed.

As a measurable indicator, NIH could track adoption of standardized 3Rs curricula such as the 3Rs Collaborative's 3Rs Certificate Course as part of Responsible Conduct of Research. Course completion should be paired with downstream outcomes including reporting quality, study design practices, and research reproducibility rather than relying solely on participation metrics. Additionally, to ensure workforce stability, retention should be tracked of all key personnel, including not only investigators but also key support staff such as comparative medicine employees.

We recommend NIH fund T32, K, and professional development mechanisms building competency across comparative medicine, animal science, computational biology, statistics, and regulatory science. Workforce indicators should also recognize veterinarians, animal care professionals, technicians, and IACUC personnel, whose expertise is essential for implementation of the 3Rs and overall research quality.

4. Collaboration: The 3Rs Collaborative (3RsC) convenes academia, industry, technology providers, contract research organizations, and federal agencies, and comments from that experience.

As biomedical research becomes increasingly interdisciplinary, NIH should recognize collaboration that bridges traditionally separate communities, including animal researchers, developers of new approach methodologies (LaFollette et al, 2025, doi: 10.1177/02611929241310566) , computational scientists, clinicians, and regulatory experts. Scientific progress is strengthened when these groups work toward shared objectives rather than operating in isolation.

Potential indicators include cross-sector and cross-disciplinary co-authorship, participation in collaborative consortia, contribution to shared resources, and diverse representation on study sections and advisory groups. NIH should also encourage use of contribution taxonomies that better recognize activities such as model validation, method development, data curation, and technical expertise.

Because incentive structures drive behavior, collaboration should be recognized in biosketches, progress reports, and review criteria. Special attention should be paid to ensuring that early-career investigators receive appropriate credit for team-science contributions.

NIH should also be attentive to collaboration health: harassment, vilification, or dismissal of investigators

based on the methods they use undermines both scientific progress and public trust, while driving investigators away from key methodological conversation. NIH-funded infrastructure providing neutral, trusted convening space merits recognition and support, and 3RsC would welcome expanded partnership with NIH in that capacity.

5. Entrepreneurship and Translation: Indicators of translational success should focus on a model or method's demonstrated ability to improve decision-making and reduce costly late-stage failures in research and development. This principle applies equally to animal-based models, human-based models, NAMs, and integrated approaches alike.

NIH should support systematic evaluation of where specific models perform well, where limitations exist, and where new approaches may offer complementary or superior predictive value for defined contexts of use. Context of use is the operative concept: a method is valid for a defined question, in a defined biological system, against defined endpoints, rather than valid in general. Characterization and validation efforts, including public-private collaborations, are essential infrastructure for scientific translation. This includes funding characterization and validation studies such as the 3RsC's drug-induced liver injury (DILI) project with the FDA and 8 commercial providers (LaFollette et al. 2026, doi: https://doi.org/10.1016/j.yrtph.2026.106189).

Incentivizing entrepreneurship. Method and platform development is frequently commercialized through small companies, and the academic reward structure gives limited credit for it. We recommend NIH recognize entrepreneurial contribution directly through SBIR and STTR participation, spinouts and licensing arising from method development, and adoption of validated methods by other laboratories or by industry and encourage institutions to count these as scholarly output in promotion review.

6. Foundational Scientific Exploration: The 3Rs Collaborative (3RsC) notes that basic and high-risk research characterizing where models, including animal models, diverge from human physiology is chronically underfunded, because it yields no immediate product even though it establishes the evidentiary base later validation depends on. The same holds for early-stage validation science, which carries high scientific risk, long timelines, and low publication yield.

We recommend NIH protect funding for domain-mapping research and early-stage validation and treat both as infrastructure. Indicators include portfolio share devoted to model characterization and early validation, time from characterization to defined context-of-use qualification, and downstream dependence of applied programs on characterization outputs.

We recommend NIH state explicitly in review guidance that rigorous negative characterization and completed validation studies count as productivity, encourage institutions to weight them in promotion and tenure review, and support protected time for investigators carrying long-timeline characterization work. Institutions follow what NIH scores, so guidance to review panels is the most direct available lever.

7. Public Impact: We recommend that NIH publicly report portfolio-level indicators of 3Rs implementation, including use of valid models and designs, extent of refinement adoption, and replacement efforts, where appropriate. Transparent reporting of these indicators, along with publication of negative findings and validation studies, would help demonstrate NIH's commitment to rigorous, accountable science.

3Rs implementation bears on the dimensions NIH names. On health outcomes and clinical practice, methods validated for a defined context of use reduce the late-stage failures that delay therapies reaching patients. On economic growth, avoided duplicative studies, reusable datasets, and reduced late-stage attrition represent recoverable cost, and reproducibility failures carry a documented and substantial price (Freedman et al., PLOS Biology, 2015). On accessibility, standardized protocols, shared control data, and free reporting instruments lower the barrier for institutions without large research infrastructure. On public trust and societal benefit, the public has a durable interest in how research animals are treated, and 3Rs progress is among the few research-quality measures the public can readily understand and evaluate.

On recognition rather than assessment, we recommend NIH report these indicators publicly at portfolio level and name 3Rs progress explicitly when describing research quality, since what an agency reports on is what institutions come to prioritize.

To avoid unintended consequences, we recommend that indicators for all 3Rs should be reported and interpreted together rather than individually. Public indicators should also be normalized by institution size and award volume, since raw comparisons would penalize smaller institutions without dedicated 3Rs staff. For example, only counting animal numbers could result in underpowered studies or studies moved to a different institution, so reduction should include indicators for design-quality.

8. Other Areas: We encourage NIH to recognize progress on the 3Rs themselves (validated replacement, demonstrated reduction, and measurable refinement) as an important category of scientific impact. Progress in the 3Rs directly supports the rigor, reproducibility, efficiency, and translational value that NIH seeks to promote through this initiative. It is inseparable from the rigor, reproducibility, and translational value this RFI seeks to reward, and currently the dimension of research quality least visible in NIH's indicators.

Tracking it at portfolio scale calls for a body positioned to develop standards, deliver training, curate shared data, and measure adoption nationally. The United Kingdom has had one for two decades in the National Centre for the Replacement, Refinement and Reduction of Animals in Research, (NC3Rs) which supplies training, data resources, funding calls, guideline development, and cross-sector convening, and which developed the DRIVER guidelines released in July 2026. The United States has no equivalent, so 3Rs progress here is distributed across individual institutions, investigators, and voluntary effort, which makes it difficult to capture in any portfolio-level metric.

We recommend NIH support establishing an independent, U.S.-based 3Rs center on that model, and expand federal partnership with and funding for The 3Rs Collaborative in that capacity. 3RsC is a nonpartisan nonprofit working across all three Rs and already collaborates with NIH and FDA through the FNIH NAMs Validation and Qualification Network and through federal representation on its board and initiatives. We have developed a 3Rs Certificate Course suitable for wider adoption, conducted validation work including a DILI project with FDA and eight commercial providers (LaFollette et al. 2026, doi: https://doi.org/10.1016/j.yrtph.2026.106189), and convene cross-sector dialogue spanning academia, industry, technology providers, contract research organizations, and regulators.

We thank NIH for the opportunity to comment and would welcome the opportunity to work with the agency on the indicators described in this response.

Description: The 3Rs Collaboratives Response (Formatted)

The 3Rs Collaborative's Response to NIH's RFI on Measuring and Rewarding Scientific Input

Background: The National Institutes of Health (NIH) recently launched a new agency-wide Replication and Reproducibility Initiative to incentivize and institutionalize replication and reproducibility efforts across the biomedical research enterprise. NIH aims to incentivize and reward rigorous research that delivers value to the American public, but current metrics of scientific success rely heavily on individual-level indicators of productivity, such as publication counts and citation metrics. NIH seeks to better align its measures of success with its core mission; generating knowledge that enhances health, lengthens life, and reduces illness and disability.

To support these efforts, NIH has issued a Request for Information which requests stakeholders to identify specific, measurable indicators and incentives that reflect the collaborative, rigorous, and mission-drive nature of modern biomedical science.

While NIH welcomes all comments, we are specifically interested in receiving feedback related to topics listed below. NIH is particularly interested in comments that include specific examples of measurable indicators, implementation approaches, potential benefits or unintended consequences, and considerations for feasibility across career stages, disciplines, and institution types.

Box 1: Rigor and Reproducibility. Reproducible and replicable biomedical approaches are foundational to rigorous research. New strategies are needed to identify areas ripe for replication and reproducibility efforts, as well as incentives and infrastructure to support the reproduction and replication of existing findings.

The 3Rs Collaborative (3RsC) recommends that NIH treat the 3Rs of animal research, replacement, reduction, and refinement, as infrastructure supporting rigorous, reproducible, and replicable biomedical research rather than solely as an animal welfare framework. Together, they help define the best methods to answer a scientific question, including model selection, study design, and experimental conditions. In all cases, models should be evaluated for **fit** for purpose, studies designed for rigor and robustness, and methods reported transparently.

Refinement can directly improve rigor and reproducibility by reducing hidden sources of biological variability. Housing, handling, and husbandry practices that induce chronic stress may alter neuroendocrine, metabolic, and immune responses, creating unrecognized confounding variables. We recommend NIH fund research evaluating the impact of refinement practices on data variability and require reporting of husbandry, enrichment, and handling variables. Potential indicators include the proportion of funded studies reporting these variables and reductions in

baseline variability across laboratories adopting evidence-based refinement practices such as provision of species-specific enrichment such as sufficient nesting material for mice and tunnel or cup handling of mice.

Reduction is similarly aligned with rigorous study design. Reduction means using the minimum number of animals necessary for a valid experimental and statistical design to answer a justifiable question. NIH should continue promoting randomization, blinded outcome assessment, prespecified outcomes, sample size justification, and consideration of sex as a biological variable such as requiring the Sex Inclusive Research Framework (https://openinnovation.astrazeneca.com/preclinical-research/sex-inclusive-research-framework.html) in applications to help NIH reviewers determine when single sex justifications are valid or not (Landis et al., Nature, 2012). NIH should also support research evaluating model validity and approaches that balance increasing external validity (such as adding deliberate heterogenization) with efficient study design (Voelkl et al., PLOS Biology, 2018). Reviewer training in experimental design, validity, and translation, as well as recruiting statisticians to sit in on review panels, is equally important, since reviewer expectations strongly influence research behavior.

The 3Rs Collaborative's 3Rs Certificate Course, which teaches key concepts in replacement, reduction, and refinement, could be adopted nationally as part of infrastructure to support the reproduction and replication of animal research.

A key opportunity for NIH is to strengthen adoption and enforcement of existing standards. PREPARE, ARRIVE, and the recently released DRIVER guidelines provide established frameworks for planning and reporting in vivo and in vitro research (Smith et al., Laboratory Animals, 2018; Percie du Sert et al., PLOS Biology, 2020; NC3Rs 2026). We recommend NIH move beyond endorsement and incorporate verification of compliance through progress reporting, audits, and renewal review.

To support reproducibility across research models, NIH should require standardized reporting of cell source and animal-derived reagents (as required by the DRIVER guidelines), including source, species, and lot information, and support development of chemically defined, animal-free reagents (https://nc3rs.org.uk/3rs-resource-library/moving-animal-free-scaffolds-construction-3d-organotypic-models). Such reporting and development would reduce an important but underappreciated source of experimental variability and validity.

Finally, NIH should support replication studies by prioritizing findings with substantial downstream scientific or translational impact and recognizing replication efforts as valuable scientific contributions.

BOX 2: Data, Software, and Model Sharing. **Sharing scientific data and tools accelerates biomedical research discovery, in part, by enabling validation of research results, providing accessibility to high-value datasets, and promoting data reuse for future research studies. NIH seeks to incentivize and reward these activities to maximize the value of research investments, catalyze collaborations, and accelerate scientific impact.**

3RsC recommends that NIH incentivize standardized data templates and metadata practices aligned with FAIR principles and existing reporting standards. Standardization enables meaningful data reuse and reduces unnecessary duplicative experimentation by helping investigators identify questions that have already been addressed through robust evidence.

NIH should also support mechanisms for sharing control datasets and developing validated approaches for virtual or historical controls, where scientifically appropriate. Reuse of existing data has significant potential to improve efficiency while reducing unnecessary animal use.

We further recommend NIH establish safe-harbor mechanisms that encourage publication of negative results, failed replications, and unsuccessful model-validation studies. These findings are rarely shared despite their considerable value in guiding future research decisions and preventing duplication of effort.

Importantly, NIH should reward not only data deposition but also demonstrated reuse. Indicators might include standards-compliant dataset submission rates, documented dataset reuse, use of shared controls, publication of negative findings, and evidence that shared resources informed subsequent studies. Existing NIH-supported collaborative programs, including Complement-ARIE, ORIVA, the Technology Development Centers, and the FNIH NAMs Validation and Qualification Network, provide useful models for this approach.

BOX 3: Training and Mentorship. **NIH recognizes that advancing its mission requires promoting the growth and stability of the biomedical research workforce. While NIH supports training and protects time through existing policies and programs, additional indicators are needed to assess and quantify the impact of these efforts.**

The 3RsC considers training and mentorship the areas where NIH has the most leverage. Most failures of rigor originate upstream of execution, in how the question was framed and whether it

needed answering. Reporting checklists do not catch this, since a checklist assumes the study was worth doing.

NIH should support training programs that build interdisciplinary competency across comparative medicine, animal science, computational biology, experimental design, statistics, and regulatory science rather than training researchers within methodological silos. The ability to evaluate and select the most appropriate approach for a scientific question is increasingly important in modern biomedical research. This includes re-training for established faculty on the most up to date methods.

In addition to technical skills, training programs should emphasize question formulation, critical appraisal of the literature, model evaluation, harm-benefit analysis, and study design principles that support reproducibility and translational success. These competencies influence research quality before any experiment begins. Appropriate scientific question formulation helps drive key experimental constraints and hypothesis generation. Critical appraisal of the literature, including systematic searching, ensures investigators do not repeat settled experiments or build programs on fragile findings. Model evaluation is essential to ensure the selected model is able to answer the scientific questions at hand, while considering both model validity and translation. Harm-benefit analysis should be conducted during design rather than as a form completed for a committee, since institutional review performs a version of this analysis only after the design is fixed.

As a measurable indicator, NIH could track adoption of standardized 3Rs curricula such as the 3Rs Collaborative's 3Rs Certificate Course as part of Responsible Conduct of Research. Course completion should be paired with downstream outcomes including reporting quality, study design practices, and research reproducibility rather than relying solely on participation metrics. Additionally, to ensure workforce stability, retention should be tracked of all key personnel, including not only investigators but also key support staff such as comparative medicine employees.

We recommend NIH fund T32, K, and professional development mechanisms building competency across comparative medicine, animal science, computational biology, statistics, and regulatory science. Workforce indicators should also recognize veterinarians, animal care professionals, technicians, and IACUC personnel, whose expertise is essential for implementation of the 3Rs and overall research quality.

BOX 4: Collaboration. As biomedical research becomes increasingly interdisciplinary and convergent, collaboration is growing in both scale and complexity. NIH seeks new approaches for assessing and recognizing contributions to team-based science.

The 3Rs Collaborative (3RsC) convenes academia, industry, technology providers, contract research organizations, and federal agencies, and comments from that experience.

As biomedical research becomes increasingly interdisciplinary, NIH should recognize collaboration that bridges traditionally separate communities, including animal researchers, developers of new approach methodologies (LaFollette et al, 2025, doi: 10.1177/02611929241310566) , computational scientists, clinicians, and regulatory experts. Scientific progress is strengthened when these groups work toward shared objectives rather than operating in isolation.

Potential indicators include cross-sector and cross-disciplinary co-authorship, participation in collaborative consortia, contribution to shared resources, and diverse representation on study sections and advisory groups. NIH should also encourage use of contribution taxonomies that better recognize activities such as model validation, method development, data curation, and technical expertise.

Because incentive structures drive behavior, collaboration should be recognized in biosketches, progress reports, and review criteria. Special attention should be paid to ensuring that early-career investigators receive appropriate credit for team-science contributions.

NIH should also be attentive to collaboration health: harassment, vilification, or dismissal of investigators based on the methods they use undermines both scientific progress and public trust, while driving investigators away from key methodological conversation. NIH-funded infrastructure providing neutral, trusted convening space merits recognition and support, and 3RsC would welcome expanded partnership with NIH in that capacity.

BOX 5: Entrepreneurship and Translation. To advance the translation of discoveries into products for people, NIH fosters the maturation of discoveries from bench to bedside and promotes innovation across sectors. More can be done to incentivize, assess, and integrate the impact of innovation and entrepreneurial efforts as critical to the NIH mission.

Indicators of translational success should focus on a model or method's demonstrated ability to improve decision-making and reduce costly late-stage failures in research and development. This principle applies equally to animal-based models, human-based models, NAMs, and integrated approaches alike.

NIH should support systematic evaluation of where specific models perform well, where limitations exist, and where new approaches may offer complementary or superior predictive value for defined contexts of use. Context of use is the operative concept: a method is valid for a defined question, in a defined biological system, against defined endpoints, rather than valid in general. Characterization and validation efforts, including public-private collaborations, are essential infrastructure for scientific translation. This includes funding characterization and validation studies such as the 3RsC's drug-induced liver injury (DILI) project with the FDA and 8 commercial providers (LaFollette et al. 2026, doi: https://doi.org/10.1016/j.yrtph.2026.106189).

Incentivizing entrepreneurship. Method and platform development is frequently commercialized through small companies, and the academic reward structure gives limited credit for it. We recommend NIH recognize entrepreneurial contribution directly through SBIR and STTR participation, spinouts and licensing arising from method development, and adoption of validated methods by other laboratories or by industry and encourage institutions to count these as scholarly output in promotion review.

BOX 6: Foundational Scientific Exploration. Basic research and high-risk, high-reward initiatives represent foundational scientific exploration with an inherent risk of failure but the potential for paradigm-shifting breakthroughs. Further embedding these approaches within the academic enterprise is essential to ensuring continued support for bold and innovative research directions.

The 3Rs Collaborative (3RsC) notes that basic and high-risk research characterizing where models, including animal models, diverge from human physiology is chronically underfunded, because it yields no immediate product even though it establishes the evidentiary base later validation depends on. The same holds for early-stage validation science, which carries high scientific risk, long timelines, and low publication yield.

We recommend NIH protect funding for domain-mapping research and early-stage validation and treat both as infrastructure. Indicators include portfolio share devoted to model characterization and early validation, time from characterization to defined context-of-use qualification, and downstream dependence of applied programs on characterization outputs.

We recommend NIH state explicitly in review guidance that rigorous negative characterization and completed validation studies count as productivity, encourage institutions to weight them in promotion and tenure review, and support protected time for investigators carrying long-timeline characterization work. Institutions follow what NIH scores, so guidance to review panels is the most direct available lever.

BOX 7: Public Impact. NIH seeks approaches for assessing and recognizing the broader public impact of biomedical research, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit.

We recommend that NIH publicly report portfolio-level indicators of 3Rs implementation, including use of valid models and designs, extent of refinement adoption, and replacement efforts, where appropriate. Transparent reporting of these indicators, along with publication of negative findings and validation studies, would help demonstrate NIH's commitment to rigorous, accountable science.

3Rs implementation bears on the dimensions NIH names. On health outcomes and clinical practice, methods validated for a defined context of use reduce the late-stage failures that delay therapies reaching patients. On economic growth, avoided duplicative studies, reusable datasets, and reduced late-stage attrition represent recoverable cost, and reproducibility failures carry a documented and substantial price (Freedman et al., PLOS Biology, 2015). On accessibility, standardized protocols, shared control data, and free reporting instruments lower the barrier for institutions without large research infrastructure. On public trust and societal benefit, the public has a durable interest in how research animals are treated, and 3Rs progress is among the few research-quality measures the public can readily understand and evaluate.

On recognition rather than assessment, we recommend NIH report these indicators publicly at portfolio level and name 3Rs progress explicitly when describing research quality, since what an agency reports on is what institutions come to prioritize.

To avoid unintended consequences, we recommend that indicators for all 3Rs should be reported and interpreted together rather than individually. Public indicators should also be normalized by institution size and award volume, since raw comparisons would penalize smaller institutions without dedicated 3Rs staff. For example, only counting animal numbers could result in underpowered studies or studies moved to a different institution, so reduction should include indicators for design-quality.

BOX 8. Other Areas.

We encourage NIH to recognize progress on the 3Rs themselves (validated replacement, demonstrated reduction, and measurable refinement) as an important category of scientific impact. Progress in the 3Rs directly supports the rigor, reproducibility, efficiency, and translational value that NIH seeks to promote through this initiative. It is inseparable from the rigor, reproducibility, and translational value this RFI seeks to reward, and currently the dimension of research quality least visible in NIH's indicators.

Tracking it at portfolio scale calls for a body positioned to develop standards, deliver training, curate shared data, and measure adoption nationally. The United Kingdom has had one for two decades in the National Centre for the Replacement, Refinement and Reduction of Animals in Research, (NC3Rs) which supplies training, data resources, funding calls, guideline development, and cross-sector convening, and which developed the DRIVER guidelines released in July 2026. The United States has no equivalent, so 3Rs progress here is distributed across individual institutions, investigators, and voluntary effort, which makes it difficult to capture in any portfolio-level metric.

We recommend NIH support establishing an independent, U.S.-based 3Rs center on that model, and expand federal partnership with and funding for The 3Rs Collaborative in that capacity. 3RsC is a nonpartisan nonprofit working across all three Rs and already collaborates with NIH and FDA through the FNIH NAMs Validation and Qualification Network and through federal representation on its board and initiatives. We have developed a 3Rs Certificate Course suitable for wider adoption, conducted validation work including a DILI project with FDA and eight commercial providers (LaFollette et al. 2026, doi: https://doi.org/10.1016/j.yrtph.2026.106189), and convene cross-sector dialogue spanning academia, industry, technology providers, contract research organizations, and regulators.

We thank NIH for the opportunity to comment and would welcome the opportunity to work with the agency on the indicators described in this response.

Re: Comments on the Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Submitted electronically

SPARC, a non-profit organization of more than 190 libraries and academic organizations across the United States that supports research and education systems that enable everyone, everywhere to access, contribute to, and benefit from shared knowledge, appreciates the opportunity to comment on NIH's Request for Information on Measuring and Rewarding Scientific Impact.

SPARC commends NIH for using this RFI to reconsider how scientific success is measured. NIH's stated aim, to align its measures of success with its core mission of generating knowledge that improves health, is one SPARC strongly supports, and it is a natural complement to NIH's Replication and Reproducibility Initiative. SPARC also commends NIH for its leadership for early steps to give investigators room to describe and be credited for a broader range of research products, such as the recent Biosketch revisions.

Our comments focus on two recommendations that speak directly to that aim: NIH should (1) move away from proxy metrics that are poorly correlated with research quality, rigor, or impact, and (2) name and reward open research practices explicitly as indicators of scientific success.

To that end, SPARC recommends that NIH:

- Explicitly deprioritize publication counts and journal-level metrics, such as the Journal Impact Factor, as indicators of investigator quality, rigor, or impact in any indicators or guidance that result from this RFI, consistent with the San Francisco Declaration on Research Assessment (DORA).
- Recognize open, reusable data, software, and other research outputs as core indicators of scientific contribution.
- Require or incentivize the use of persistent identifiers for researchers, organizations, and research outputs across NIH-funded research.
- Encourage adoption of contribution-based credit frameworks in place of author-order-driven credit, particularly for team-based and interdisciplinary science.
- Favor non-proprietary, community-governed infrastructure over proprietary vendor metrics and platforms when NIH adopts tools to measure and report on the indicators identified through this RFI.

- Adopt a holistic, multi-indicator approach to research assessment and avoid overreliance on any single metric, however well-intentioned, since a single metric used as a target for reward or funding decisions is inherently vulnerable to gaming.

Below is a more in-depth look at the recommendations to help NIH reach its stated goals.

Move Away from Proxies

Publication counts, journal prestige, and related bibliometric indicators such as Journal Impact Factor are poor proxies for research quality, rigor, or real-word impact. The Journal Impact Factor, in particular, was not designed to evaluate individual researchers or individual articles; it was created as a tool for librarians making journal purchasing decisions, and it carries well-documented deficiencies as a measure of research quality.[1] That is why the San Francisco Declaration on Research Assessment (DORA), now signed by thousands of individual researchers and hundreds of research organizations and funders, calls on institutions not to use journal-based metrics as a surrogate for the quality of an individual scientist's contributions or in funding decisions.[2] Peer national funding agencies have already acted on this principle. Canada's tri-agencies, for example, are DORA signatories and have updated their peer review guidance to direct reviewers away from journal-based metrics and toward a broader, more qualitative assessment of contribution and impact.[3]

Continuing to rely on these proxies is not a neutral choice. It actively incentivizes the behavior NIH is trying to move away from, such as:

- **Rewarding volume over quality.** Counting publications creates pressure to fragment findings into the smallest publishable unit, rather than to produce fewer, more complete, and more rigorous studies.
- **Rewarding novelty over replication.** Journals and reviewers favor novel, positive findings, which discourages the replication and null-result reporting that NIH's own Replication and Reproducibility Initiative identifies as foundational to rigorous science.
- **Undervaluing collaboration.** Author-order and citation-based metrics were built for an era of small, single-investigator science and struggle to fairly credit the large, interdisciplinary, team-based projects that this RFI's Collaboration category identifies as increasingly central to biomedical research.

SPARC recommends that NIH explicitly deprioritize publication counts and journal-level metrics as indicators of investigator or research quality in any indicators or guidance that emerge from this RFI, and instead consider indicators that assess the research itself: its rigor, transparency, and reusability, rather than where or how often it was published.

Move Toward Open Research Practices

---

[1] Seglen, Per O. "Why the Impact Factor of Journals Should Not Be Used for Evaluating Research." *BMJ* 314, no. 7079 (1997): 498–502. https://pmc.ncbi.nlm.nih.gov/articles/PMC2126010/pdf/9056804.pdf

[3] Canadian Institutes of Health Research, “Responsible Research Assessment at CIHR” https://cihr-irsc.gc.ca/e/51731.html.

Open research practices directly support NIH's stated goals around reproducibility and data sharing, and this RFI is an opportunity for NIH to name these practices explicitly as indicators worth measuring and rewarding, rather than leaving them as implicit or secondary considerations.

Requiring and rewarding open accessibility of research outputs. Making data, code, software, protocols, and other research outputs openly available, not merely "available upon request," should be recognized as a core scientific contribution in its own right, not an afterthought to publication. Openly shared outputs are what make replication and reuse possible in the first place, and NIH should consider both requiring and then rewarding indicators that capture whether outputs are measurably and actively reusable.

Adoption of persistent identifiers. Consistent use of persistent identifiers (PIDs), including identifiers such as ORCID iDs for researchers, ROR IDs for organizations, and DOIs or ARKs for datasets and software makes contributions traceable, attributable, and machine-readable across the research lifecycle. Persistent identifiers are also the connective tissue that makes many of the other indicators in this RFI measurable at all. Without them, NIH cannot reliably track data reuse, software citation, or team contribution at scale. NIH is well positioned to require or strongly incentivize their use across their intramural research programs and the grants it funds.

Contribution-based credit instead of author-order-driven credit. Author order is a poor and increasingly outdated signal of who did what on a project, particularly for large, team-based, or interdisciplinary science. For example, the Contributor Roles Taxonomy (CRediT), which defines fourteen distinct contributor roles, offers a structured alternative that captures roles like data curation, software development, and project administration alongside traditional writing and conceptualization roles.[4] NIH's own Intramural Research Program already uses CRediT to adjudicate authorship disputes, resolving roughly a dozen such conflicts a year with a common vocabulary for contribution.[5] This is the type of credit system that NIH is well positioned to extend outward that can encourage structured, contribution statements across the research it funds so that credit reflects actual roles rather than position in an author list. Finding ways to both surface contributions as well as provide meaningful attribution (such as with the Open Exchange Architecture[6])would directly support NIH's interest in better recognizing collaboration and team science.

Use of non-proprietary, community-governed platforms and repositories. Reliance on proprietary vendor metrics and platforms concentrates control over how scientific value is defined in the hands of commercial entities whose incentives may not align with NIH's mission. As NIH adopts tools to track the indicators identified through this RFI, SPARC urges the agency

[6] Rowan Cockett, "Introducing the Open Exchange Architecture," OXA, January 28, 2026 https://oxa.dev/articles/introducing-oxa

to favor infrastructure, including repositories, identifier systems, and evaluation tools, that is non-commercial and openly governed by the scientific community, ensuring that the metrics used to evaluate NIH-funded science remain aligned with public, mission-driven goals rather than commercial ones.

Guard Against Overreliance on Any Single Metric

SPARC's recommendation calls on NIH to move away from proxy metrics and toward supporting open research communication practices. Any metric or indicator that NIH ultimately adopts through this process should be part of a holistic, multi-indicator approach to assessment rather than a singular number that stands in for scientific quality. A metric of data-sharing activity, persistent identifier use, or open-source contribution can be just as easily gamed as a citation count or a journal placement once researchers understand that it drives funding or advancement decisions. Compliance can become a matter of checking a box rather than genuinely advancing rigor, reproducibility, or reuse.

Consistent with that principle,[7] SPARC recommends that NIH:

- Use any new indicators that emerge from this RFI in combination with one another and alongside qualitative, expert-driven review, rather than allowing any single indicator to become a de facto target or threshold.
- Periodically revisit and revise the indicators it adopts, with community input, recognizing that any measure, once it becomes consequential, will attract efforts to satisfy it in form rather than substance.
- Be explicit, in any resulting guidance, that the goal is a fuller and more accurate picture of rigor, reproducibility, collaboration, and impact, not a replacement scorecard.

Conclusion

Taken together, these recommendations would give NIH a more direct, accurate, and durable way to assess the rigor, reproducibility, collaboration, and real-world impact of the science it funds.

The research community has already developed and tested frameworks for assessing contribution, openness, and quality more holistically, and elements of that work are already in use inside NIH's own Intramural Research Program. What is needed is for NIH to work closely with the community to adapt and formalize these frameworks as indicators of scientific success, used holistically and in combination, across the extramural research it funds. SPARC appreciates NIH's willingness to solicit input on this topic and urges the agency to adopt the recommendations above in any resulting policy or guidance.

Respectfully submitted,
Corinna Turbes,
Senior Manager of Government Affairs

Re: Request for Information on Measuring and Rewarding Scientific Impact
[NOT-OD-26-087]

Dear Director Bhattacharya,

Thank you for the opportunity to respond to the National Institutes of Health's Request for Information on Measuring and Rewarding Scientific Impact.

The Bayh-Dole Coalition is a group of innovation-oriented organizations and individuals committed to celebrating and protecting the Bayh-Dole Act, a 1980 law that allows universities, small businesses, and federal laboratories to partner with the private sector to translate federally funded research into real-world products.

We applaud NIH for undertaking the important effort of accurately measuring the impact of federally funded research. Key academic metrics like publications and citations are important measures of scientific productivity and dissemination. But such metrics only tell part of the story—a promising finding may be published and widely cited without ever becoming a therapy, diagnostic tool, or product.

To understand a discovery's true impact, the NIH must consider whether a discovery ultimately reaches patients and consumers. We therefore urge the NIH to recognize commercialization and technology transfer metrics as key indicators of success.

Lawmakers have previously recognized the importance of technology transfer and commercialization. Before 1980, when the government retained the patent rights to federally funded discoveries, research institutions regularly made important breakthroughs—but

those discoveries rarely reached consumers. The government licensed less than 5% of its 28,000 patents to private companies. Promising discoveries were left on laboratory shelves.

In response, Congress passed the Bayh-Dole Act, which empowered research institutions to patent and license those federally funded discoveries. That framework for technology transfer and commercialization has since allowed thousands of federally funded discoveries to move from universities and federal labs into the private sector for development—and eventually, to reach patients and consumers.

The NIH ought to reward and preserve this framework. It should therefore recognize metrics that capture patenting efforts and industry collaboration, including issued patents and patent quality, licensing activity, startup and spinout formation, follow-on private investment, and industry partnerships.

It should also measure the longer term impacts of discoveries. Many of the most important biomedical breakthroughs take years—or decades—to reach patients even after licensing. The NIH should incorporate measures that capture downstream outcomes, such as clinical development milestones, FDA approvals, and adoption by patients, physicians, or healthcare systems. The NIH should also include longer-term economic indicators like job creation and regional growth.

Including such metrics will help ensure that researchers do not feel that patenting, licensing, entrepreneurship, and industry collaboration is viewed as less valuable than publishing another paper.

To that end, the NIH should also pay close attention to the growing use of Other Transaction Agreements (OTAs). While OTAs are an important part of the R&D system, designed to bring innovative companies into government projects without invoking the onerous requirements of the Federal Acquisition Regulations, it appears that some agencies are misusing them as a workaround the Bayh-Dole Act—denying academic institutions the rights guaranteed them by Congress which are critical for commercializing critical government funded medical research. That is particularly wrong headed at a time when China is going all out to eclipse our lead in the life sciences—a lead we enjoy because

Bayh-Dole helps transform NIH funded research into useful products protecting and improving lives here and around the world.

The Bayh-Dole Act transformed federally funded research by creating a pathway for universities, small businesses, and federal labs to turn early-stage discoveries into real products. The NIH's evaluation framework should similarly recognize that the ultimate measure of scientific impact is not only what researchers publish, but what reaches patients and grows the economy.

Thank you again for taking on this important effort, and for the opportunity to comment.

Sincerely,

Joseph P. Allen
Executive Director
Bayh-Dole Coalition

Re: Request for Information (RFI) on Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Submitted online at https://osp.od.nih.gov/comment-form-measuring-and-rewarding-scientific-impact/

To Whom It May Concern,

The Association of Public and Land-grant Universities (APLU) appreciates the opportunity to respond to NIH's Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087). APLU is a membership organization that fosters a community of university leaders collectively working to advance the mission of public research universities. Founded in 1887, APLU is the oldest higher education association in the United States and its U.S. membership consists of more than 240 public research universities, land-grant institutions, state university systems, and affiliated organizations spanning across all 50 states, the District of Columbia, and six U.S. territories. The association and its members collectively focus on increasing student success and workforce readiness; promoting pathbreaking scientific research; and bolstering economic and community engagement. Annually, its U.S. member campuses enroll 4.6 million undergraduates and 1.4 million graduate students, award 1.3 million degrees, employ 1.3 million faculty and staff, and conduct $70 billion in university-based research.

Supporting Foundational Scientific Exploration

APLU supports NIH's objectives to incentivize and reward rigorous research that delivers value to the American public. The research enterprise, built on curiosity-driven and use-inspired research evaluated through merit-based peer review, has produced statins, MRI technology and diagnostics, early detection of pancreatic cancer, the Human Genome Project, and more. Each of these advancements depended on decades of foundational NIH

investment before the impact on human health was realized. The next generation of cures and technologies will require the same sustained commitment to foundational science and high-risk, high-reward initiatives. The enterprise that produced these results is worth protecting, and 21st-century reforms should build on what has made it so successful.

This commitment must span the full range of health-relevant science, including behavioral and social science research methods that determine whether treatments reach people. Treatment adherence and chronic disease management across populations depend on understanding human behavior and social determinants of health. Ensuring that new approaches to measuring scientific impact recognize this full range of contributions is essential to advancing NIH's mission.

Expanding how to evaluate scientific success

NIH seeks to align how it measures scientific success with its mission to generate knowledge that "enhances health, lengthens life, and reduces illness and disability." APLU agrees that important conversations are needed about better assessing research impacts that capture the full range of what the research community and broader public value. However, the problem is not a shortage of indicators; the research community has identified approximately 250 potential indicators across 10 domains of impact (Aurbach et al, 2025). The problem is that the research community has not converged on what constitutes impact or how to evaluate it consistently across the spaces where research evaluation occurs.

This is a significant consensus and coordination challenge. Researchers serve on tenure committees, journal editorial boards, NIH study sections, and disciplinary society conference panels. They make choices based on what they believe is valuable scholarship and what the system currently rewards. Those beliefs are shaped by the incentive structures of government, non-profit, and industry funders; departments and institutions; disciplinary societies; and publishers, and change to the incentive structure in one sector without corresponding change in the others will be ineffective. If institutions reform promotion and tenure, but researchers cannot be funded or published for translation work and their graduate students cannot build the publication records needed to compete on the job market, the reform will stall. If they can get funded but their work is not legible to their department, they may not get promoted or have access to graduate students. This is an interconnected evaluation system that requires cross-sector coordination to change, and NIH is well-positioned to catalyze that coordination.

If we can align reward and incentive structures across the spaces where research is evaluated, we can build a system that more quickly moves discoveries into treatments that

advance NIH's mission to enhance health, lengthen life, and reduce illness and disability.

Reducing researcher burden

Researchers have finite time, and every new expectation competes with existing obligations. Faculty are currently evaluated on being excellent in teaching, research, and service, but NIH's RFI could be interpreted to expect all researchers to also excel at team science, entrepreneurship, data sharing, mentorship, and public impact. Therefore, reforms must account for how they increase workload, provide researchers with the training and guidance to successfully meet new expectations, and reduce burden where possible.

Institutions face some of the same constraints and finite capacity. New requirements that assume infrastructure that does not yet exist will concentrate research capacity in fewer universities and fewer regions, the opposite of what a robust national research enterprise requires. NIH has the opportunity to use its influence to move the system, to work with the other federal agencies to harmonize policies, engage the research community to define what to measure, invest in the infrastructure researchers need to meet those expectations, and coordinate across sectors to align how research is evaluated and rewarded in all the contexts that matter to researchers. NIH cannot and should not do this alone. This is a system-wide challenge.

Given these considerations and constraints, APLU offers the following suggestions. APLU draws on its work developing Public Impact Research (PIR) as an organizing concept for how research serves society (APLU, 2019; Aurbach et al., 2023; Redd et al., 2024) and its experience leading cross-sector and multi-institution convenings.

Recommendation 1. Organize and fund cross-sector convenings around the seven RFI topic areas

As the framing above makes clear, no single sector can shift the evaluation system alone. NIH should organize cross-sector convenings that bring together researchers, institutional leaders, funders, disciplinary societies, publishers, and aligned national reform efforts to define mutual roles and obligations across the seven RFI topic areas.

NIH is already engaging the community in measurement design through the RFI and the S-index challenge for data sharing. APLU recommends expanding these engagements to multi-institution and cross-sector convenings. As an example, APLU's 2024 Fostering a Public Impact Research Ecosystem Workshop, co-convened with the Pew Charitable Trusts, brought sixty participants across eight sectors to identify where cross-sector alignment was needed and what each sector could do. The workshop produced

recommended actions for federal agencies, including establishing guidelines for including public impact research in grant proposals and project reports, expanding cross-agency partnerships to scale funding, and enhancing professional development for researchers engaged in public impact work (Redd et al, 2024). Similarly, the Accelerating Public Access to Research Data (APARD) initiative, co-sponsored by NIH and NSF and led by APLU and the Association of American Universities (AAU), worked with more than 100 institutions to produce aligned policies and practices for data governance, infrastructure, training, and culture change for data sharing (Redd et al, 2022). NIH could support similar convenings for rigor and reproducibility, entrepreneurship and translation, and the other areas identified in the RFI.

Recommendation 2. Engage NIH-relevant disciplinary societies to convene researchers

Academic fields set their disciplinary norms, and disciplinary societies are the venue where researchers convene to develop those norms, codify them into standards, and share them with the next generation of researchers in their field. NIH should work with these societies on interventions that advance each of the seven RFI areas of interest.

There is a model for this. In 2007, NSF, NIH, HHMI, and AAAS launched Vision and Change in Undergraduate Biology Education (AAAS, 2011). AAAS managed a series of regional conversations with biology educators, researchers, and administrators, followed by a national conference in 2009 that brought more than 500 participants together to build consensus. The resulting report established shared standards that the community adopted. Within four years, citations of Vision and Change in NSF education proposals rose from under 1% to as high as 67%, and professional societies built training programs and implementation networks around its recommendations (Vasaly et al., 2014). A 2013 follow-up conference assessed progress and identified remaining gaps.

This model is particularly needed for public impact research. APLU has worked with institutional leaders to put supportive policies and processes in place (APLU, 2019; Aurbach et al., 2023), but institutional infrastructure and policies alone do not produce culture change. Researchers need discipline-specific guidance on what public impact means in their field and how it is evaluated. NIH could fund disciplinary societies to develop that guidance, much as NSF funded AAAS to build consensus around undergraduate biology education reform. Complementary efforts, such as the NSF-funded Promotion and Tenure Innovation and Entrepreneurship (PTIE) initiative, are demonstrating similar approaches for research translation at the departmental level (Carter et al., 2021).

Public impact is one area where this approach is needed, but the model applies across all seven RFI topic areas. Ideas that might emerge from researcher-driven conversations include uncoupling data management and community partner costs from modular grant caps, resources to develop discipline-specific guidance for each area of interest, or supplemental funding for the different areas in the RFI. When NIH funds community-engaged research, data sharing infrastructure, or translational work, it sends an important signal to researchers and departments. Additional resources are a strong motivator for changing researcher practice, and they signal NIH values these practices.

Recommendation 3. Coordinate with other federal agencies to harmonize research requirements

NIH can help lead interagency coordination. Institutions cannot build bespoke recognition structures for each funder or discipline. Broader impacts, data sharing, and public engagement are each defined differently by each agency. If NIH, NSF, DoW, DoE, and USDA each define impact differently, institutions and researchers face an impossible compliance puzzle, one that has grown substantially: sixty-six percent of federal research requirements were issued in the last decade (COGR, 2026). This growing compliance burden impedes institutional change efforts that could focus resources on strengthening the research enterprise. NIH should lead interagency harmonization of research requirements across federal funders that could free up resources for accelerating science.

Additionally, if NIH's new approaches to evaluation are STEM-centric, they will fail to capture the full range of research with public benefit and will have limited adoption. Institutions evaluate all scholarly activity, and evaluation approaches that cannot represent disciplines beyond STEM, including arts, humanities, and social sciences, will be difficult for institutions to integrate. Coordinating with NSF, NEH, and other agencies increases the likelihood that new approaches are appropriate for all disciplines and scholarly venues, making them more likely to gain widespread adoption.

Recommendation 4. Build the shared infrastructure that rigorous, reproducible science requires

NIH should engage the research community on what national infrastructure investments are needed to accelerate science and ensure it is rigorous and reproducible. These might include data stewardship and curation services, secure compute enclaves for sensitive health data, prototyping facilities and translational cores, a PubMed equivalent for datasets, and increased access to compute, data and AI infrastructure. It should include additional investment in research infrastructure through existing mechanisms: C06, G20, and S10 programs for facilities and instrumentation. APLU further discussed investment in research infrastructure and deferred maintenance in its comments on the NIH Strategic

Plan. Without these investments, new expectations around data sharing, reproducibility, and public impact will disproportionately burden institutions with fewer resources, which risks concentrating research capacity in fewer institutions.

Recommendation 5. Pilot reform internally and evaluate outcomes
NIH should pilot measurement reform internally through its intramural research program before extending new indicators to the extramural community. NIH should apply scientific rigor to assessment reform itself. Monitor whether policy changes produce the outcomes sought and be transparent with the broader community about the lessons learned.

APLU has provided some suggested readings and resources from partners it collaborates with on PIR, entrepreneurship and translation, and data sharing. APLU looks forward to ongoing conversations with NIH as it further develops its plan to support a more robust research enterprise.

Sincerely,

Kacy Redd, PhD
Associate Vice President, Research & STEM Education,
Association of Public and Land-grant Universities

226. Association of American Publishers

I am responding: On behalf of an organization

Name: J. Carl Maxwell

Name of Organization: Association of American Publishers

Type of Organization: Professional Organization/Association

Role: Other

Role - Other: Senior Vice President of Public Policy

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: The Association of American Publishers (AAP) welcomes this opportunity to provide suggestions for the NIH Request for Information on Measuring and Rewarding Scientific Impact. AAP represents over 80 professional and scholarly publishers, including dozens of domestic scholarly societies. Globally, technical, engineering, and medical (STEM) publishing is a $11 billion industry, a small but important part of the nearly $3 trillion worldwide research enterprise. AAP STEM members directly employee over 27,100 employees domestically, with over 1.6 million individual members of the global scientific and medical community.

The Role and Value of Scholarly Publishing

For two hundred years, STEM publishers have played a key role in the medium through which science is communicated, scrutinized, and ultimately used to support future research and cures. We manage peer review, curating and editing research outputs, disseminating publications and making them easily discoverable, while preserving the validated scientific record over time. Each published article is a data point in a cumulative, iterative scientific process, not an endpoint. Publishers help ensure that what enters that record has been vetted, is traceable, and can be corrected when necessary. Moreover, publishers create an entire research infrastructure to incorporate metadata, indexing, and other elements of the research process to enhance discoverability.

Most major research funders expect grantees to publish their findings in peer reviewed journals, even though this is not an explicit obligation of their grants, precisely because publication in such journals confers key benefits: amplification of results, formal dissemination to the relevant communities, validation and quality control through peer review and editorial processes, and durable integration into the literature. For researchers, journals are an important signaling mechanism, allowing readers to sort through the flood of information to find the true marker of scientific discovery and information.

Scientific publishing is not a luxury add on to research; it is integral to how research is communicated, scrutinized, and built upon. For this reason it is important that adequate and sustained funding continues to be available in NIH grants for publishing costs and subscriptions so that researchers can both contribute to and benefit from “the minutes of science.” Scientific publishing, when combined with

artificial intelligence and other evolving data and research products, stands at the forefront of a scientific revolution.

Ensuring the Integrity of Gold Standard Science

AAP members continually invest to ensure the quality and integrity of the scholarly record. They deploy plagiarism and image manipulation detection, AI generated content checks, and specialized integrity teams. They refine peer review and editorial processes and support robust systems for corrections, expressions of concern, retractions, disclosure of conflicts of interests, and sharing of data.

Publishers' work supporting the integrity, transparency and reproducibility of the scientific record is resource intensive and must be adequately funded in order to ensure the highest possible standards in research and science, and in order to ensure that taxpayers can rely on the accuracy of federally supported research.
Preprints, or pre-publisher manuscripts, illustrate both opportunity and risk. They are valuable for rapid scientific dialogue and early sharing of results, but because their trustworthiness is uncertain, they are not substitutes for peer reviewed articles. To non-specialist readers and the media, preprints can appear to be as authoritative as journal articles even though they have not been vetted and may have errors or preliminary interpretations. Government and research funder policies should recognize the distinct roles of preprints and peer reviewed publications and avoid treating them as interchangeable in metrics frameworks.

Understanding Existing Journal Metrics

Journal Impact Factors and citation metrics provide important, standardized signals to help researchers, institutions, and funders navigate an increasingly expansive global scientific landscape. By quantifying how often published work is referenced and built upon by peers, citation-based measures offer an objective, scalable proxy for academic reach, community engagement, and editorial selectivity. For publishers, a high-impact journal reflects a sustained investment in rigorous peer review, diligent editorial curation, and the long-term stewardship of notable research. These metrics serve as valuable benchmarks to help signal quality and contextualize a publication's role within its broader discipline and enabling readers and institutions to identify trusted venues where significant scientific dialogue is taking place.

At the same time, responsible publishers recognize citation metrics capture only one aspect of research value. Critical scientific advances—such as specialized clinical innovations, foundational methodological tools, or niche interdisciplinary breakthroughs—take time to accumulate citations or may deliver public benefits that raw citation counts cannot capture. Consequently, publishers increasingly support using Impact Factor and citation metrics as part of a holistic evaluation framework that pairs quantitative metrics with expert qualitative peer review to assess the full merit and real-world utility of scientific research.

Policy Risks to Avoid

Well intentioned policies can have unintended consequences if they overlook how the publishing ecosystem functions. Focusing on one output, rather than looking holistically at the scientific and medical community ecosystem, jeopardizes the quality and integrity of research. For example:
1) Treating preprints or other non-reviewed products as functional equivalents of peer reviewed articles for assessment purposes risks amplifying misinformation and devaluing scientific integrity.
2) Scoring various open science practices (article deposit, open-source code, open laboratory notebooks, FAIR data practices) as a measure of research quality rather than a measure of transparency.
3) Policies treating publication and access cost recovery as "diversions" of research funding, rather than as necessary and essential components of the research process, risk pushing systems toward the lowest cost, lowest integrity publications.

At a time of rising integrity challenges, including organized fraud and AI enabled manipulation, the answer is more robust peer review and editorial oversight, not less.

Recommendations for NIH

AAP supports continued robust investment in federal research as critical to the advancement of American science. The United States should cultivate the discoveries which have led our great nation to a position of leadership in health innovation and cures. Publishing is an important part of the scientific and medical ecosystem and is necessary to ensure we can overcome the challenges of the 21st century.

AAP offers the following recommendations to NIH as the agency considers updating metrics:

1. Prioritize integrity and quality in publication and reproducibility.
• Recognize peer reviewed publication and the Version of Record (VoR) as the primary, trusted record of research findings.
• Invest and fund research into reproducibility, including metrics encouraging researchers to pursue reproducibility studies and share a broad range of research inputs as additive to a professional career path.
• Develop metrics to support and encourage study pre-registration, study protocols, and registered reports to detail and establish research methods in advance of experimentation and data collection.
• Encourage grant-funding agencies to prioritize outputs with strong integrity safeguards in grant reviews and policy design.
• Support initiatives to expand and improve peer review, including metrics to reward peer review participation, training, and support for structured peer review.

2. Support sustainable public access.
• Preference appropriately licensed and funded VoR in public repositories and clearly label material that has not been peer reviewed or formally published.
• Ensure sustained and robust funding continues to be available for publishing costs as part of NIH grants. Avoid one size fits all mandates or metrics that undermine the financial sustainability of domestic non-profit scientific and medical societies and other high integrity publishers.

3. Preserve author's choice and intellectual property.

• Allow researchers to choose where and how to publish their work, including the licenses applied, within a framework that advances public health.
• Uphold robust intellectual property protections and contractual freedom as foundational to a vibrant, competitive publishing marketplace that can innovate in support of open science and AI era needs.

4. Partner with publishers on open science and AI.
• Collaborate with publishers to design metrics to encourage public access, data sharing, and AI related policies that use existing infrastructure for provenance, corrections, retractions, and integrity checks.
• Encourage the use of licensed, verified VoR and curated datasets as preferred inputs for high-stakes AI systems, recognizing publishers as part of the trust and safety infrastructure for scientific information.

A financially sustainable and collaborative open science system that engages the publishing community can be a powerful engine for research and innovation. AAP members stand ready to work with NIH to ensure the agency's investment in science advances human health and welfare, supports high-quality jobs, and strengthens U.S. leadership in discovery and innovation

RE: Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

To Whom It May Concern:

The Association of American Publishers (AAP) welcomes this opportunity to provide suggestions for the NIH Request for Information on Measuring and Rewarding Scientific Impact. AAP represents over 80 professional and scholarly publishers, including dozens of domestic scholarly societies. Globally, technical, engineering, and medical (STEM) publishing is a $11 billion industry, a small but important part of the nearly $3 trillion worldwide research enterprise. AAP STEM members directly employee over 27,100 employees domestically, with over 1.6 million individual members of the global scientific and medical community.

The Role and Value of Scholarly Publishing

For two hundred years, STEM publishers have played a key role in the medium through which science is communicated, scrutinized, and ultimately used to support future research and cures. We manage peer review, curating and editing research outputs, disseminating publications and making them easily discoverable, while preserving the validated scientific record over time. Each published article is a data point in a cumulative, iterative scientific process, not an endpoint. Publishers help ensure that what enters that record has been vetted, is traceable, and can be corrected when necessary. Moreover, publishers create an entire research infrastructure to incorporate metadata, indexing, and other elements of the research process to enhance discoverability.

Most major research funders expect grantees to publish their findings in peer reviewed journals, even though this is not an explicit obligation of their grants, precisely because publication in such journals confers key benefits: amplification of results, formal dissemination to the relevant communities, validation and quality control through peer review and editorial processes, and durable integration into the literature. For researchers, journals are an important signaling mechanism, allowing readers to sort through the flood of information to find the true marker of scientific discovery and information.

Scientific publishing is not a luxury add on to research; it is integral to how research is communicated, scrutinized, and built upon. For this reason it is important that adequate and sustained funding continues to be available in NIH grants for publishing costs and subscriptions so that researchers can both contribute to and benefit from "the minutes of science." Scientific publishing, when combined with artificial intelligence and other evolving data and research products, stands at the forefront of a scientific revolution.

Ensuring the Integrity of Gold Standard Science

AAP members continually invest to ensure the quality and integrity of the scholarly record. They deploy plagiarism and image manipulation detection, AI generated content checks, and specialized integrity teams. They refine peer review and editorial processes and support robust systems for corrections, expressions of concern, retractions, disclosure of conflicts of interests, and sharing of data.

Publishers' work supporting the integrity, transparency and reproducibility of the scientific record is resource intensive and must be adequately funded in order to ensure the highest possible standards in research and science, and in order to ensure that taxpayers can rely on the accuracy of federally supported research.

Preprints, or pre-publisher manuscripts, illustrate both opportunity and risk. They are valuable for rapid scientific dialogue and early sharing of results, but because their trustworthiness is uncertain, they are not substitutes for peer reviewed articles. To non-specialist readers and the media, preprints can appear to be as authoritative as journal articles even though they have not been vetted and may have errors or preliminary interpretations. Government and research funder policies should recognize the distinct roles of preprints and peer reviewed publications and avoid treating them as interchangeable in metrics frameworks.

Understanding Existing Journal Metrics

Journal Impact Factors and citation metrics provide important, standardized signals to help researchers, institutions, and funders navigate an increasingly expansive global scientific landscape. By quantifying how often published work is referenced and built upon by peers, citation-based measures offer an objective, scalable proxy for academic reach, community engagement, and editorial selectivity. For publishers, a high-impact journal reflects a sustained investment in rigorous peer review, diligent editorial curation, and the long-term stewardship of notable research. These metrics serve as valuable benchmarks to help signal quality and contextualize a publication's role within its broader discipline and

enabling readers and institutions to identify trusted venues where significant scientific dialogue is taking place.

At the same time, responsible publishers recognize citation metrics capture only one aspect of research value. Critical scientific advances—such as specialized clinical innovations, foundational methodological tools, or niche interdisciplinary breakthroughs—take time to accumulate citations or may deliver public benefits that raw citation counts cannot capture. Consequently, publishers increasingly support using Impact Factor and citation metrics as part of a holistic evaluation framework that pairs quantitative metrics with expert qualitative peer review to assess the full merit and real-world utility of scientific research.

Policy Risks to Avoid

Well intentioned policies can have unintended consequences if they overlook how the publishing ecosystem functions. Focusing on one output, rather than looking holistically at the scientific and medical community ecosystem, jeopardizes the quality and integrity of research. For example:

1) Treating preprints or other non-reviewed products as functional equivalents of peer reviewed articles for assessment purposes risks amplifying misinformation and devaluing scientific integrity.
2) Scoring various open science practices (article deposit, open-source code, open laboratory notebooks, FAIR data practices) as a measure of research quality rather than a measure of transparency.
3) Policies treating publication and access cost recovery as "diversions" of research funding, rather than as necessary and essential components of the research process, risk pushing systems toward the lowest cost, lowest integrity publications.

At a time of rising integrity challenges, including organized fraud and AI enabled manipulation, the answer is more robust peer review and editorial oversight, not less.

Recommendations for NIH

AAP supports continued robust investment in federal research as critical to the advancement of American science. The United States should cultivate the discoveries which have led our great nation to a position of leadership in health innovation and cures. Publishing is an important part of the scientific and medical ecosystem and is necessary to ensure we can overcome the challenges of the 21st century.

AAP offers the following recommendations to NIH as the agency considers updating metrics:

1. **Prioritize integrity and quality in publication and reproducibility.**
    - Recognize peer reviewed publication and the Version of Record (VoR) as the primary, trusted record of research findings.
    - Invest and fund research into reproducibility, including metrics encouraging researchers to pursue reproducibility studies and share a broad range of research inputs as additive to a professional career path.
    - Develop metrics to support and encourage study pre-registration, study protocols, and registered reports to detail and establish research methods in advance of experimentation and data collection.
    - Encourage grant-funding agencies to prioritize outputs with strong integrity safeguards in grant reviews and policy design.
    - Support initiatives to expand and improve peer review, including metrics to reward peer review participation, training, and support for structured peer review.
2. **Support sustainable public access.**
    - Preference appropriately licensed and funded VoR in public repositories and clearly label material that has not been peer reviewed or formally published.
    - Ensure sustained and robust funding continues to be available for publishing costs as part of NIH grants. Avoid one size fits all mandates or metrics that undermine the financial sustainability of domestic non-profit scientific and medical societies and other high integrity publishers.
3. **Preserve author's choice and intellectual property.**
    - Allow researchers to choose where and how to publish their work, including the licenses applied, within a framework that advances public health.
    - Uphold robust intellectual property protections and contractual freedom as foundational to a vibrant, competitive publishing marketplace that can innovate in support of open science and AI era needs.
4. **Partner with publishers on open science and AI.**
    - Collaborate with publishers to design metrics to encourage public access, data sharing, and AI related policies that use existing infrastructure for provenance, corrections, retractions, and integrity checks.

- Encourage the use of licensed, verified VoR and curated datasets as preferred inputs for high-stakes AI systems, recognizing publishers as part of the trust and safety infrastructure for scientific information.

A financially sustainable and collaborative open science system that engages the publishing community can be a powerful engine for research and innovation. AAP members stand ready to work with NIH to ensure the agency's investment in science advances human health and welfare, supports high-quality jobs, and strengthens U.S. leadership in discovery and innovation.

With Regards,

J. Carl Maxwell

227. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Non-Profit Research Organization

Role: Investigator/Researcher

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: Rigor and reproducibility are fundamental aspect of research, and we do our best to follow these principles. However, investigators who focus on reproducibility and scientific rigor often face more challenges in securing fundings. I would recommend the following actions:

1- Add extra points to grant proposals that include independent replications of the results and are conducted by independent investigators
2- Reward team science by adding extra points to research team with multiple PIs and include at least one mPI focused on the computational work
3- Publish new RFA that are focused on secondary analysis of data

A growing and urgent challenge for U.S. investigators is the escalating cost of publishing research under mandatory open-access policies. For many federally funded scientists, including myself, the publication fees required by top-tier journals have become prohibitive. For example, Nature now charges approximately $13,000 for an open-access article. These costs are not covered by most grants, and they far exceed what individual investigators or small laboratories can absorb. As a result, many researchers are effectively excluded from publishing in journals that provide the most rigorous peer review and highest visibility. This undermines the very goals of rigor, reproducibility, and scientific impact that NIH seeks to promote. If investigators cannot afford to publish in journals with strong editorial standards, then efforts to strengthen scientific quality become aspirational rather than achievable. Sustainable solutions to open-access publishing costs are essential to ensure that high-quality science remains accessible, equitable, and competitive.

2. Data, Software, and Model Sharing: Data sharing is mandated by NIH but many investigators still manage to avoid sharing of data. I would like to suggest these actions:

1- Reward data sharing by providing extra funds to investigators who shared data and would like to maintain the data by sharing updates
2- Add extra points to grant proposals that will augment data repository
3- Publish new RFA that support generation and sharing of software

3. Training and Mentorship: Training and mentorship are important, and mentors usually do this for free. It is important to support time dedicated to mentoring with salary support

4. Collaboration: It is important to appreciate grant proposals with multiple PIs that cover every aspect of a complex project. Statisticians and bioinformaticians role should be elevated to an mPI role

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: This is all well said. The reality is that reviewers in study sections kill grant proposals that do not include preliminary data, for example R21 proposals. Reviewers scores should be redacted when they make these mistakes

7. Public Impact: Grant proposals should include a clear dissemination plan that goes beyond publications in scientific journals. It would be important to reward investigators who include panels of stakeholders and have a plan to engage the community using modern ways of communications, e.g. blogs, social media, press release, interviews with reputable journalists

8. Other Areas: N/A

228. Biophysical Society

I am responding: On behalf of an organization

Name: Leann Fox

Name of Organization: Biophysical Society

Type of Organization: Professional Organization/Association

Role: Other

Role - Other: Director, Advocacy and Public Affairs

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: The scientific research enterprise has long been built on a foundation of rigor and reproducibility, treating them as essential safeguards for ensuring public trust. Across disciplines, researchers have relied on systematic methods, peer review, transparent documentation, and replication studies to ensure that findings can be independently verified. This commitment has shaped everything from laboratory protocols to data sharing norms - reinforcing the idea that scientific progress depends not just on discovery, but on the ability of others to reliably reproduce and build upon that work.

2. Data, Software, and Model Sharing: Collaboration has been a defining strength of modern science since the post WWII era, when domestic cooperation and international partnerships became central to advancing knowledge and addressing global challenges. This collaborative principle underpins modern practices of data, software, and resource sharing, which accelerate discovery by enabling validation of results, expanding access to high value datasets, and supporting reuse that fuels new lines of inquiry. By incentivizing these shared resources, NIH reinforces a long standing pillar of science: that collective effort—across institutions, disciplines, and borders—drives innovation and maximizes the impact and society benefit of research investments.

3. Training and Mentorship: Investment in the foundational and biomedical research workforce is essential to sustaining U.S. scientific and technological leadership, and it begins with building a strong domestic pipeline that can grow and thrive over time. Like any other endeavor, U.S. prominence at scientific frontiers depends on predictable, long term funding and on creating meaningful opportunities for early career researchers to develop their skills, establish independence, and contribute new ideas. Training and mentorship are central to this effort: they strengthen the research workforce, support stability, and ensure that emerging scientists have the guidance and protected time needed to advance their careers. By deepening its commitment to these investments and improving how their impacts are measured, NIH can help secure a strong and innovative research workforce for the future.

4. Collaboration: Collaboration has been a defining feature of the scientific enterprise since WWII, when the United States and its allies built a model of cooperative research that brought together leading experts to confront global challenges. Today's increasingly interdisciplinary and convergent biomedical research continues to rely on that foundation, drawing strength from partnerships that span fields,

institutions, and national borders. Such collaboration enables teams to integrate diverse expertise, accelerate discovery, and produce cutting edge science that no single discipline or country could achieve alone. As NIH explores new ways to assess and recognize contributions to team based research, maintaining a strong commitment to collaboration in all its forms remains essential to advancing scientific innovation.

5. Entrepreneurship and Translation: Basic, foundational research remains the engine of biomedical innovation, providing discoveries and insights that make future medical advances possible. History repeatedly shows that transformative breakthroughs—from new therapies to cutting edge technologies—emerge from sustained investment in early stage fundamental scientific enquiry. As NIH works to continually accelerate translation from bench to bedside and strengthen innovation across sectors, it must also preserve robust opportunities for foundational research, ensuring that efforts to spur entrepreneurship and product development do not come at its expense. Protecting this balance is essential to maintaining a research ecosystem where curiosity driven discovery and translational progress reinforce one another and continue to deliver medical advances for the public.

6. Foundational Scientific Exploration: Foundational and high risk, high reward research are both essential to a thriving scientific ecosystem, and each depends on a commitment to curiosity driven exploration. Foundational research expands the boundaries of knowledge, while bold, high risk efforts push science toward breakthroughs that can redefine entire fields. Repeatedly, history shows that new basic knowledge can give rise to cutting edge and curative advances in unexpected ways, making it vital NIH continue to support these approaches in equal measure. Embedding both forms of inquiry within the academic enterprise ensures that scientists have the freedom to explore, experiment, and imagine—conditions that make transformative discovery possible.

7. Public Impact: NIH's focus on assessing and recognizing the broader public impact of biomedical research highlights how deeply science contributes to positive health outcomes, domestic economic growth, and advances in clinical practices and their accessibility. These benefits depend on a strong and sustained research enterprise—one that continues to earn public trust by delivering tangible improvements in people's lives. To maintain this momentum, increased and predictable funding is essential, ensuring that researchers have the stability and resources needed to drive innovation and translate discoveries into broad public benefit.

Re: Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Submitted via https://osp.od.nih.gov/comment-form-measuring-and-rewarding-scientific-impact/

The AAMC[1] appreciates the opportunity to comment to NIH on indicators and incentives for measures of scientific success that align with the agency's core mission. We strongly agree that scientific impact can be reflected in a myriad of outputs beyond publications and citation metrics and believe that the use of additional indicators can enhance our understanding of both research productivity and the effectiveness of grant funding.

To frame these comments, first we would like to stress the importance of building on and amplifying existing community efforts across the identified areas, including the development of infrastructure, standards, metrics for evaluation and assessment. NIH has a key role in uplifting these initiatives as well as lending credibility and value to these additional measures of success by integrating them throughout the grants process, including at the application stage, within progress reports, and as an internal indicator to understand the full return of NIH investment. The agency should consider how its policies, processes, and funding priorities may inhibit or promote these activities, particularly in areas such as collaboration, foundational research, and rigor/reproducibility. We also note that the effectiveness of specific indicators will vary widely, depending on the scientific discipline, career stage, and resources available to an individual investigator. The adoption of additional measures of

[1] Established in 1876, the AAMC is a nonprofit association dedicated to improving the health of people everywhere through medical education, clinical care, biomedical research, and community collaborations. Its members are all 163 U.S. medical schools accredited by the Liaison Committee on Medical Education; 12 Canadian medical schools accredited by the Committee on Accreditation of Canadian Medical Schools; more than 400 academic health systems and teaching hospitals; and more than 70 academic societies. The AAMC also collaborates with the Department of Veterans Affairs (VA) and VA medical centers through their academic affiliations with AAMC-member institutions. Through these institutions and organizations, the AAMC leads and serves America's medical schools, academic health systems and teaching hospitals, and the millions of individuals across academic medicine, including more than 220,000 full-time faculty members, 100,000 medical students, 167,000 resident physicians, and 60,000 graduate students and postdoctoral researchers in the biomedical sciences. Through the Alliance of Academic Health Centers International, AAMC membership reaches more than 60 international academic health centers throughout five regional offices across the globe.

success by NIH could facilitate a culture change in how the outcomes of biomedical research are valued and incentivized across the enterprise.

The AAMC conducted a comprehensive study in 2016[2] in collaboration with RAND Europe, on metrics which can be used to assess and communicate the value of biomedical research. We would like to recommend these findings to NIH as a key resource that responds to many of the areas which NIH cites in this RFI and identifies many potential metrics for the agency to consider, particularly in the areas of training and mentorship, entrepreneurship and translation, and public impact. The report details how each of these metrics might be obtained, as well as caveats or limitations on their use. The report was released alongside additional resources,[3] including a brief on developing a research evaluation framework and proceedings from a workshop discussing how the framework could be applied within a variety of institutional structures, missions, and disciplines across the spectrum of biomedical research. We would be pleased to engage with NIH in a discussion of how these metrics could be incorporated into this initiative.

We can provide particular insight into metrics and incentives for scientific data, model, and software sharing based on years of work in collaboration with NIH and many other stakeholders across the research enterprise. The AAMC strongly supports policies which facilitate meaningful sharing and re-use of the data resulting from NIH-funded research projects, and the development and implementation of mechanisms which would track and incentivize these research activities. To further this goal, the AAMC, along with the New England Journal of Medicine and the Multi-Regional Clinical Trials Center of Brigham and Women's Hospital and Harvard, carried out an effort titled "Credit for Data Sharing,"[4] which describes a system to appropriately credit researchers for sharing data[5]. This multi-sector initiative convened academic institutions, nonprofits, publishers, and funders to discuss the actions needed by these partners to enable such a system.

We understand that this is long-term work which involves both technical infrastructure and standards, as well as changes to incentives and the current culture of which research outputs are valued. In order to incentivize data and software sharing, we must first provide guidance and support for its curation, storage, dissemination, and tracking. We are pleased to engage with NIH's initiative to do just that, through the S-index Challenge,[6] and engage in the follow-up efforts of socializing the resulting model(s) and metrics developed within the academic research community. The more these metrics are recognized and accepted by institutions and investigators, the more straightforward it will be to incorporate them into current measures of research success.

1. Rigor and Reproducibility: USASP supports NIH's efforts to strengthen rigor, transparency, reproducibility, and replicability as related but distinct dimensions of trustworthy research. Findings may be reproduced across studies that share the same biases, for example, while differences among studies may reveal meaningful variation across populations, methods, models, or settings. USASP recommends that NIH evaluate reproducibility within a broader framework that rewards rigorous design, transparent reporting, appropriate interpretation of uncertainty, independent validation, and communication of null and negative findings.

Prioritizing Replication and Validation. Replication investments should focus on findings whose failure would carry substantial scientific, clinical, or public consequences. Relevant considerations include uncertainty or conflict in the existing evidence; reliance of subsequent research or clinical decisions on the finding; burden of illness or disability; and the importance of the question and outcomes to people affected by the condition. Replication need not mean repeating a study identically. Conceptual replication, multisite validation, reanalysis, and evaluation across populations, methods, models, or real-world settings may provide greater scientific value and clarify generalizability—an especially important consideration in heterogeneous fields such as pain research.

Strengthening Review and Reporting. USASP recommends that NIH ensure reviewers have access to the methodological expertise and training needed to determine whether a study can credibly answer its research question. Review should address field-relevant considerations such as sample-size justification, safeguards against bias, measurement validity, predefined data-handling decisions, relevant biological variables, authentication of key resources, and alignment between the research question and analytic plan. For causal claims, reviewers should assess whether the design, assumptions, comparison groups, and analyses support causal inference and whether the conclusions appropriately distinguish causation from association. Existing initiatives, including the Landis reporting principles and IMI-Europain recommendations, demonstrate how consequential design decisions can be made visible while allowing standards to vary across research contexts (Landis et al., 2012; Knopp et al., 2015).

Potential Indicators. Indicators of rigor and reproducibility should make consequential research decisions and evidence of independent validation visible while preserving expert assessment of quality. Relevant

evidence could include transparent reporting of design and analytic decisions; protocol availability when appropriate; documentation of deviations and limitations; responsible availability of methods, data, software, and code; independent validation; and dissemination of rigorous null, negative, and replication findings. NIH could also identify subsequent studies that independently confirm, extend, refine, or challenge NIH-supported findings and allow investigators to document verified examples of downstream validation. Citation context may help identify these relationships, but a supportive citation should not be considered replication unless the citing study tests the relevant finding. NIH should address publication bias by supporting prospective registration and registered reports where appropriate, encouraging publication or repository pathways for rigorous null and negative findings, and recognizing complete reporting as a scientific contribution. No indicator should be treated as proof of research quality. Indicators must be interpreted in context to determine whether the methods were appropriate and the conclusions supported.

Measuring Scientific Contribution. Journal prestige, publication volume, citation counts, and researcher-level indices such as the h-index are poor proxies for methodological rigor or scientific contribution. Macleod et al. found no relationship between journal impact factor and reported safeguards against bias in preclinical research (2015). NIH should instead consider what research changes or enables, including whether it clarifies uncertainty, redirects subsequent work, improves methods or shared resources, enables discovery, influences health or practice, or prevents unproductive investment. These contributions may take years to emerge and should not be collapsed into another universal numerical "impact factor."

Consideration of impact beyond medical researchers is important. This includes ensuring that the presentation of data always strives to provide easily understood graphs (and tables) of results and careful explanation of the implications in language understandable to non-scientists and other affected communities. The inclusion of community members in the conduct, presentation, and publication of research can help to ensure that presentation of results will be more impactful on the people impacted by the findings. Quantifying impact into additional areas such as clinical, community, economic, and policy domains as described as part of the Translational Science Benefits Model (TSBM), helps to expand the influence of funded research. Researchers should be trained to be part of research training programs.

Building a Culture of Trustworthy Research. Sustainable improvement requires aligned action by NIH, research institutions and centers, journals, investigators, and professional societies. NIH should pair its expectations with support for replication, methodological expertise, research personnel, data stewardship, protected time, training, and shared infrastructure. The pain-specific ENTRUST-PE framework provides a useful lifecycle model by considering responsible governance, rigorous and transparent methods, applicability to intended populations, relevance of questions and outcomes, balanced communication, and well-documented data (O'Connell et al., 2025).

Positive incentives and field-led initiatives can translate rigor principles into practical changes in research culture. Professional societies can contribute by adapting these principles to their disciplines. For example, USASP has used NINDS-developed rigor icons at its Annual Scientific Meetings to help presenters communicate key design features. NIH could also build upon the NINDS Rigor Champions

Prize as a positive-incentive model (NINDS, 2026). Challenge prizes can recognize investigators, trainees, research staff, and teams while identifying promising practices implemented beyond routine requirements. Successful approaches should be eligible for follow-on support to evaluate, refine, disseminate, and sustain them.

NIH should partner with societies, community-based organizations, and other stakeholders to determine whether tools and funded interventions meaningfully improve research, but also of equal importance is consideration of the practices and quality of clinical care. Such approaches should be thoughtful enough to support planning, reflection, and cultural change rather than becoming certification systems or additional checklists. USASP strongly recommends that NIH collect data and feedback on the effectiveness, burden, and feasibility of rigor interventions and disseminate the findings not only to the research community but the general community on whom it will have an impact. This evidence should guide decisions about broader implementation or necessary refinements to improve feasibility and effectiveness.

2. Data, Software, and Model Sharing: USASP supports NIH's efforts to incentivize the sharing of scientific data, software, models, and other research resources. Successful sharing should be defined by whether prospective users can understand how a resource was generated, evaluate its quality and limitations, and reuse or combine it appropriately.

Supporting Curation and Infrastructure. Effective data sharing depends on expert curation and sustained infrastructure. Even within coordinated research networks, investigators may struggle to standardize metadata, reconcile variable definitions, document provenance, complete quality-control requirements, and satisfy repository expectations. These challenges are compounded when submissions are infrequent and staff turnover limits retention of specialized knowledge. We recommend that NIH provide sustained support for repository curators and data coordinators who can guide investigators through preparation and submission, preserve institutional knowledge, and improve the quality and usability of shared resources. For large consortia, each data-generating laboratory could designate a trained data steward and develop a data-management SOP in coordination with the repository or data coordinating center. Dedicated budget categories, administrative supplements, shared curation cores, and continued support beyond the original award period would prevent these activities from competing with core research costs. Together, these investments would reduce submission inefficiencies and ensure that shared resources remain well documented, interoperable, and reusable over time.

Promoting Quality and Harmonization. Harmonization should begin during study design rather than being imposed retrospectively. Common data elements, structured metadata, controlled vocabularies, data dictionaries, and transparent protocols can support cross-study comparison, pooled analyses, and machine-assisted reuse. The HEAL Data Ecosystem illustrates the value of coordinated standards when they are scientifically appropriate. NIH could encourage conformance with established standards while allowing justified variation across study designs, populations, methods, and data types. Standardization cannot repair biased sampling, inadequate power, invalid measures, or weak analysis; NIH should therefore assess the quality, provenance, documentation, and limitations of shared resources, not merely their technical compliance. Uses involving artificial intelligence also require clear provenance, licensing, versioning, validation, documentation of limitations, and appropriate protection of participant information.

Promoting Responsible Reuse. Data availability does not ensure that investigators understand how shared resources may be used. Misconceptions persist about whether public data can support grant applications, hypothesis development, pooled analyses, experimental troubleshooting, or subsequent publications. NIH should coordinate with journals, repositories, and institutional libraries to provide clear guidance and examples demonstrating that responsible reuse is legitimate and encouraged when consistent with consent, access, attribution, and data-use requirements. Addressing these misconceptions would increase the scientific return on existing data investments.

Measuring and Rewarding Reuse. NIH should evaluate shared resources based on demonstrated reuse and downstream scientific value, not merely whether they were deposited or made available. Evidence could include formal citation, verified incorporation into new studies, independent validation, external adoption, development of derivative tools, educational or clinical applications, and research that would otherwise have been difficult or costly. Evaluation should reflect the type of resource involved. Software may require documentation, versioning, testing, and maintenance, while computational and experimental models require appropriate validation, characterization, provenance, and disclosure of intended uses and limitations. To make these contributions traceable, USASP recommends that NIH work with journals and repositories to promote persistent identifiers, formal resource citation, and bidirectional links among grants, publications, datasets, software, models, and contributors.

Resources demonstrating substantial downstream value should be eligible for competitive supplements supporting continued curation, harmonization, expansion, maintenance, validation, and user assistance. Recognition and support should extend to curators, data managers, research software engineers, tool developers, and coordinating-center personnel. This combination of visible attribution and reinvestment would reward meaningful reuse while preserving high-value resources for future discovery.

3. Training and Mentorship: Training and mentorship should be evaluated by the capabilities, independence, and sustainable careers they foster, rather than simply by participation or conventional academic outputs. Publications, grants, appointments, and trainee counts provide useful context but do not fully capture growth in rigorous research practices, methodological expertise, communication, leadership, interdisciplinary collaboration, or team-science skills. USASP therefore, recommends that NIH consider a broader portfolio of outcomes, including access to professional networks and sponsorship, successful career transitions, sustained participation in research, and subsequent contributions to science, health and the community at large.

Training outcomes should be assessed over time and interpreted in relation to the program, career stage, and trainee's goals. Including training on methods for increasing the impact of science research and communication beyond the research community will substantially improve our ability to assess the importance of the work promoted by our training program. (See Haroutounian, S. et al. IMMPACT recommended considerations (2023). For interdisciplinary pain researchers, developing foundational knowledge across fields, establishing durable collaborations, or remaining engaged in pain research may represent important early outcomes before publications or independent funding emerge. Therefore, we recommend that NIH use existing data systems and follow-up surveys wherever possible to evaluate longer-term outcomes without creating duplicative reporting requirements.

Recognizing Mentorship Quality and Effort. Mentorship quality should be evaluated independently from a trainee's eventual publication or funding record, which is influenced by institutional resources, funding conditions, career goals, and other factors beyond the mentoring relationship. NIH could use validated, confidential mentee-reported assessments addressing communication, accessibility, constructive feedback, career guidance, support for increasing independence, and creation of a respectful research environment. These measures should support program improvement rather than rank individual mentors, and reporting must protect trainees when programs or mentoring relationships whenever possible.

NIH should also recognize mentorship occurring outside formal training and career-development awards, including team mentorship, peer mentorship, sponsorship, and cross-institutional mentorship. Investigators could document significant mentoring contributions through a concise narrative or structured contribution statement. Because high-quality mentorship requires time and sustained engagement, NIH should permit reasonable mentor effort on training awards and consider broader mechanisms providing protected time or salary support for substantial mentoring responsibilities. Recognition programs such as the NINDS Landis Award can highlight exemplary mentorship, but selective awards should complement—not substitute for—routine support of mentoring effort.

Expanding Access to Mentorship. NIH should assess the complete mentoring environment rather than relying solely on an individual investigator's prior mentoring record. Relevant evidence may include mentoring teams, institutional resources, plans for mentor development, and access to complementary scientific and career expertise. This approach would allow early-career investigators to develop as mentors while ensuring appropriate support for trainees, and it would recognize high-quality mentorship at institutions that have fewer formal NIH training programs.

Professional societies can complement institutional mentoring by providing cross-institutional networks, interdisciplinary engagement, and leadership development. For example, the USASP Leadership Academy pairs established pain researchers and clinicians with midcareer investigators to develop leadership and professional skills that may not be available within their home institutions. NIH could partner with professional societies to evaluate and expand approaches of this kind while preserving institutional responsibility for mentorship and career development.

Supporting Sustainable Career Pathways. Training programs should recognize successful careers in clinical practice, industry, government, nonprofit organizations, research administration, communication, and other sectors—not only tenure-track appointments or NIH-funded faculty positions. NIH could consider whether its indicators inadvertently encourage mentors to select trainees based on their predicted likelihood of achieving a narrowly defined academic outcome. NIH could also consider regularly assessing whether NRSA stipends and related support remain adequate relative to inflation, regional living costs, and institutional compensation requirements. Adequate and predictable support is necessary to retain talented researchers and realize the long-term value of NIH's training investments. Recognizing and sustaining varied career pathways would extend the benefits of NIH training across the broader research enterprise and strengthen the workforce needed to advance science and health.

4. Collaboration: USASP recommends that NIH assess collaboration by the scientific integration and added value it produces, rather than by the size or visibility of the team. Meaningful team science

combines complementary expertise, methods, perspectives, and resources to address questions that investigators could not answer as effectively on their own. This approach would reward substantive collaboration rather than the appearance of interdisciplinarity.

Funding Integrated Team Science. We recommend that NIH expand upon its opportunities for investigator-initiated multidisciplinary research through U19 and comparable multi-project or cooperative mechanisms when scientific objectives require interdependent projects, shared cores, coordinated methods, and sustained collaboration. Planning awards, collaborative pilot funding, administrative supplements, and coordinating centers could support smaller or emerging teams. Allowable costs should recognize the infrastructure required for collaboration, including project management, team-science facilitation, shared communication and data platforms, methodological consultation, standards development, evaluation, and appropriate compensation for external partners.

Policies designed around individual investigators should not inadvertently discourage genuine multiple-PI projects. If NIH limits the number or value of awards held by an investigator, it should consider the investigator's actual effort, authority, and share of project leadership rather than treating participation in an integrated MPI team as equivalent to directing the project alone. Any exception should require evidence of substantive leadership to discourage nominal MPI designations.

Integrating Training with Team Science. Large, milestone-driven programs are not automatically effective training environments. Trainees may contribute substantially to predetermined deliverables without gaining experience identifying research gaps, developing hypotheses, or designing studies. NIH should encourage team-science awards to include trainee pilot funds, exploratory subprojects, mentored proposal development, and opportunities to lead cross-disciplinary working groups or propose questions arising from consortium resources.

The HEAL PAIN Cohort T90/R90 and NIDA T32 programs provides a useful model by combining interdisciplinary mentoring, authentic collaborative projects, career development, and scientific training across the spectrum of disciplines relevant to pain research. Comparable features could be incorporated into research consortia and multi-project awards, including programs not primarily designed as training mechanisms. This would allow trainees to develop both team-science skills and intellectual independence.

Assessing Collaboration Quality. Relevant indicators could include whether team members jointly shaped the research question and design; integrated distinct methods or disciplinary perspectives; established clear governance, communication, decision-making, authorship, and conflict-resolution practices; and produced knowledge, resources, or capabilities that would have been difficult to achieve independently. NIH could also consider the durability of relationships, development of shared methods or datasets, creation of new interdisciplinary directions, and dissemination of expertise beyond the original team. Contributions to community standards, metadata, protocols, and interoperability should be recognized when they enable collaboration across a field.

Recognizing Individual Contributions. Principal-investigator status, authorship order, and consortium authorship often obscure essential contributions from data curators, software developers, statisticians,

project managers, research coordinators, standards developers, and domain experts. Structured contributor-role frameworks offer a useful foundation but may need greater specificity for metadata design, standards development, maintenance of shared tools, use-case development, and other enabling work. NIH should encourage structured, machine-readable contribution records across publications, datasets, software, models, and standards, supplemented, when necessary, by brief descriptions of the significance of each contribution.

Within consortia, funding and governance plans should prospectively recognize laboratories and investigators contributing data, validation, use cases, domain expertise, or standards development even when they do not build or publish the final resource. Appropriate subaward support, protected effort, and formal credit would reduce friction and ensure that essential collaborative work is not treated as invisible service.

5. Entrepreneurship and Translation: Defining NIH's Role. NIH can most effectively advance translation by reducing the scientific, technical, and coordination risks that prevent credible discoveries from reaching capable developers and users. Its role should be to support validation, development, training, and connections to appropriate expertise—not to presume that every discovery should become a commercial product or that NIH should operate as an entrepreneur. Support should reflect the type and maturity of the innovation and connect investigators with relevant regulatory, manufacturing, clinical, implementation, and commercialization expertise.

Matching Support to Development Requirements. Therapeutic development often requires more time and capital than conventional small-business or milestone-driven awards provide. Validation, toxicology, manufacturing, regulatory engagement, and clinical studies may be required before private investment, or an industry partnership becomes feasible. NIH should evaluate whether SBIR/STTR, UG3/UH3, and related mechanisms provide realistic budgets, timelines, and continuity for the development stages they are intended to support. Where persistent gaps exist, NIH could provide larger or longer awards, bridge support between development stages, or complementary mechanisms extending beyond conventional limits. Continued funding should remain tied to clearly defined scientific, technical, regulatory, and development milestones, with independent decisions to continue, revise, or discontinue support.

NIH should also expand access to training and technical assistance in regulatory strategy, manufacturing, clinical development, reimbursement, intellectual property, and commercialization planning. These resources may be particularly valuable for academic investigators and first-time entrepreneurs who have strong scientific expertise but limited product-development experience.

Designing for Adoption. Technical quality does not ensure that a product, tool, standard, or infrastructure resource will be used. NIH should encourage translation-focused projects to identify intended users and potential adopting organizations early enough for them to help define requirements, test usability, establish implementation milestones, and plan for the distribution of knowledge into the community of potential users. Including affected communities and users early would help to ensure that the presentation of data is made understandable to non-researchers. Joint funding or shared milestones between developers and adopting partners could create accountability for both development and implementation. Expectations should vary by project maturity so that early engagement demonstrates a credible need without requiring a fully committed commercial partner before an innovation is

sufficiently developed.

Improving University-to-Startup Translation. The time, cost, and uncertainty involved in licensing university-owned technologies can prevent promising discoveries from reaching qualified startups. NIH-funded institutions should be encouraged to use transparent licensing processes, reasonable timelines, standardized startup agreements, proportionate financial terms, and procedures for resolving stalled negotiations. More predictable terms would allow early-stage companies to invest limited resources in validation and development while preserving appropriate institutional and public interests in federally supported discoveries.

Measuring Translational Contribution. Translational impact should reflect whether an innovation responsibly advanced toward practical application, not simply the number of patents, licenses, startup companies, or dollars raised. Relevant evidence may include completion of scientific, regulatory, manufacturing, or clinical milestones; engagement of qualified development or adoption partners; integration into independent research or clinical workflows; and appropriate follow-on support. Unprompted adoption by organizations outside the originally funded program will provide especially meaningful evidence that a product, tool, or standard addressed a broader need.

Indicators should account for differences among therapeutics, devices, diagnostics, software, research tools, communication into the general community, and implementation strategies. NIH should also recognize well-conducted work demonstrating that a product is ineffective, unsafe, infeasible, or not ready for further development. Timely discontinuation based on credible evidence can prevent greater downstream losses and should not automatically be treated as failure.

6. Foundational Scientific Exploration: Basic research and high-risk, high-reward research are both essential to scientific progress but should not be treated as interchangeable. Basic research builds the knowledge, methods, and conceptual foundations upon which future advances depend; much of it is incremental and cumulative rather than inherently high-risk. High-risk research deliberately tests unconventional ideas whose probability of success is uncertain, but whose potential scientific effect is substantial. These forms of exploration require distinct funding and review strategies.

Sustaining Foundational Basic Research. Foundational research should not be required to demonstrate an immediate path to a product, intervention, or clinical outcome. Its value may become apparent only after multiple discoveries converge, sometimes many years later. Research on incretin physiology and glucagon-like peptides ultimately enabled GLP-1–based therapies, while studies of bacterial immune systems provided the foundation for CRISPR-Cas9 gene editing (NIDDK, 2021; NIGMS, 2024). Neither trajectory could have been fully predicted when the underlying observations were first investigated.

NIH should maintain stable support for investigator-initiated basic research alongside goal-directed, translational, and clinical programs. Tightly defined initiatives can mobilize research around urgent needs, but excessive emphasis on predetermined outcomes may narrow the questions being investigated and reduce opportunities for unexpected discovery. NIH should transparently monitor its investments across these categories and ensure that every institute and center sustains the foundational science needed for future progress.

Foundational science should also include careful incremental research that validates methods, resolves inconsistencies, characterizes mechanisms, refines models, or establishes the boundaries of a finding. NIH should not equate innovation solely with novelty or dramatic claims. Relevant indicators of foundational contribution may include creation of new concepts, methods, measures, models, datasets, or research directions; resolution of scientific uncertainty; or eventual uptake across disciplines. Because these effects may emerge unpredictably, investigators should not be required to forecast a specific clinical or commercial impact.

Supporting High-Risk, High-Reward Research. High-risk research requires review processes that tolerate genuine uncertainty without relaxing methodological standards. Although NIH's R21 and High-Risk, High-Reward programs state that preliminary data are not required (NIH, 2026a; NIH, 2026b), applicants may still perceive that reviewers expect conventional evidence of feasibility. NIH should examine reviewer critiques, scoring patterns, and funding decisions to determine whether preliminary-data expectations are being reintroduced in practice or whether projects described as innovative remain comparatively conventional.

Reviewer training should distinguish the uncertainty inherent in testing an unconventional idea from avoidable weaknesses in study design. Review criteria could separately consider the importance of the question, degree of conceptual departure, potential magnitude of the advance, credibility of the scientific rationale, rigor of the approach, and value of the knowledge generated even if the central hypothesis is not confirmed. NIH should recruit reviewers experienced in evaluating unconventional or cross-disciplinary research while ensuring that high-risk mechanisms remain accessible to early-career investigators and researchers entering new fields.

Funding for Learning. High-risk programs should be structured around learning and decision-making rather than the expectation that every aim will succeed. Staged awards could use learning milestones, flexible follow-on funding, and opportunities to modify direction when early findings challenge the original premise. NIH should evaluate these mechanisms as portfolios by asking whether they support ideas unlikely to succeed in conventional review, generate new concepts or methods, and occasionally produce unusually substantial advances. Projects that disprove plausible hypotheses, identify unworkable approaches, or establish unexpected limitations can still provide a meaningful return by preventing unproductive investment and informing future research.

7. Public Impact: USASP supports NIH's efforts to recognize the many ways biomedical research benefits the public. Public impact is multidimensional, often collective, and may emerge long after an award ends. Relevant evidence could include improvements in health outcomes or clinical practice; incorporation into guidelines, policy, or health-system operations; development of accessible tools and educational resources; meaningful use by people affected by health conditions, clinicians, educators, or community organizations; economic or workforce benefits; and contributions to public understanding of science. Public visibility, social-media reach, or favorable attention alone should not be treated as evidence of meaningful impact.

Building Capacity for Dissemination. Public impact rarely follows from publication alone. Researchers may lack the time, expertise, partnerships, or resources needed to communicate findings to those who could use them. We appreciate efforts like NIH ENGAGE that focus on integrating people with lived

experience into research from early stages through to translation. But with an evolution in practice, capacity building is essential. NIH should provide training and dedicated support for plain-language writing, visual communication, responsible use of social media, and dissemination to people living with health conditions, clinicians, community health workers, educators, policymakers, and other intended users. These skills should be incorporated into training and career-development programs and project dissemination plans. Grant funds should also be available to support communication specialists and compensate external partners who help adapt and disseminate findings.

Creating Accessible Scientific Resources. Well-curated repositories can extend public impact by offering accessible pathways to NIH-supported research. Where privacy, consent, and other protections permit, repositories could provide plain-language study summaries, public-facing explanations connecting data to research questions, educational materials grounded in active research, appropriately deidentified classroom datasets, and channels through which patient and community organizations can ask questions or identify areas of interest. Evidence of educational use, adoption by public-serving organizations, or incorporation into accessible tools may help demonstrate impact more meaningfully than website traffic or download counts alone.

Recognizing and Sharing Effective Practices. NIH could establish an annual recognition program honoring investigators, research teams, research staff, communicators, and community partners whose work exemplifies meaningful public impact. Awards could be named for distinguished former NIH leaders whose careers reflected public service and the application of scientific knowledge for societal benefit. Recognition need not include monetary support; an opportunity to present the work publicly and dissemination of the recipient's approach as a case study could provide meaningful visibility.

Selection should focus on documented contribution rather than institutional reputation, publication metrics, or public prominence. Publishing recipients' strategies, challenges, and lessons learned would make the program more than an award by helping NIH identify and disseminate effective approaches throughout the biomedical research community.

Re: NOT-OD-26-087 — Request for Information on Measuring and Rewarding Scientific Impact

Dear NIH Office of Science Policy Colleagues:

On behalf of the United States Association for the Study of Pain (USASP), thank you for the opportunity to respond to NIH's Request for Information on Measuring and Rewarding Scientific Impact. USASP brings together researchers, clinicians, people with lived experience of pain, and other partners committed to advancing science that reduces the burden of pain.

Because pain research spans basic, preclinical, clinical, behavioral, rehabilitative, translational, and implementation science, measures of impact must remain appropriate to the goals, methods, and settings involved. Across all topic areas, NIH should use context-sensitive portfolios of evidence rather than universal scores or rankings. Indicators should inform, not replace, expert judgment and should be piloted before broad implementation. NIH should evaluate their validity, administrative burden, privacy implications, susceptibility to gaming, and effects across disciplines, institutions, and career stages. New expectations should also be accompanied by the funding, personnel, training, and infrastructure necessary for meaningful implementation.

Rigor and Reproducibility

USASP supports NIH's efforts to strengthen rigor, transparency, reproducibility, and replicability as related but distinct dimensions of trustworthy research. Findings may be reproduced across studies that share the same biases, for example, while differences among studies may reveal meaningful variation across populations, methods, models, or settings. USASP recommends that NIH evaluate reproducibility within a broader framework that rewards rigorous design, transparent reporting, appropriate interpretation of uncertainty, independent validation, and communication of null and negative findings.

Prioritizing Replication and Validation. Replication investments should focus on findings whose failure would carry substantial scientific, clinical, or public consequences. Relevant considerations include uncertainty or conflict in the existing evidence; reliance of subsequent research or clinical decisions on the finding; burden of illness or disability; and the importance of the question and outcomes to people affected by the condition. Replication need not mean repeating a study identically. Conceptual replication, multisite validation, reanalysis, and evaluation across populations, methods, models, or real-world settings may provide greater

scientific value and clarify generalizability—an especially important consideration in heterogeneous fields such as pain research.

Strengthening Review and Reporting. USASP recommends that NIH ensure reviewers have access to the methodological expertise and training needed to determine whether a study can credibly answer its research question. Review should address field-relevant considerations such as sample-size justification, safeguards against bias, measurement validity, predefined data-handling decisions, relevant biological variables, authentication of key resources, and alignment between the research question and analytic plan. For causal claims, reviewers should assess whether the design, assumptions, comparison groups, and analyses support causal inference and whether the conclusions appropriately distinguish causation from association. Existing initiatives, including the Landis reporting principles and IMI-Europain recommendations, demonstrate how consequential design decisions can be made visible while allowing standards to vary across research contexts (Landis et al., 2012; Knopp et al., 2015).

Potential Indicators. Indicators of rigor and reproducibility should make consequential research decisions and evidence of independent validation visible while preserving expert assessment of quality. Relevant evidence could include transparent reporting of design and analytic decisions; protocol availability when appropriate; documentation of deviations and limitations; responsible availability of methods, data, software, and code; independent validation; and dissemination of rigorous null, negative, and replication findings. NIH could also identify subsequent studies that independently confirm, extend, refine, or challenge NIH-supported findings and allow investigators to document verified examples of downstream validation. Citation context may help identify these relationships, but a supportive citation should not be considered replication unless the citing study tests the relevant finding. NIH should address publication bias by supporting prospective registration and registered reports where appropriate, encouraging publication or repository pathways for rigorous null and negative findings, and recognizing complete reporting as a scientific contribution. No indicator should be treated as proof of research quality. Indicators must be interpreted in context to determine whether the methods were appropriate and the conclusions supported.

Measuring Scientific Contribution. Journal prestige, publication volume, citation counts, and researcher-level indices such as the h-index are poor proxies for methodological rigor or scientific contribution. Macleod et al. found no relationship between journal impact factor and reported safeguards against bias in preclinical research (2015). NIH should instead consider what research changes or enables, including whether it clarifies uncertainty, redirects subsequent work, improves methods or shared resources, enables discovery, influences health or practice, or prevents unproductive investment. These contributions may take years to emerge and should not be collapsed into another universal numerical “impact factor.”

Consideration of impact beyond medical researchers is important. This includes ensuring that the presentation of data always strives to provide easily understood graphs (and tables) of results and careful explanation of the implications in language understandable to non-scientists and other affected communities. The inclusion of community members in the conduct, presentation, and publication of research can help to ensure that presentation of results will be more impactful on the people impacted by the findings. Quantifying impact into additional

areas such as clinical, community, economic, and policy domains as described as part of the Translational Science Benefits Model (TSBM), helps to expand the influence of funded research. Researchers should be trained to be part of research training programs.

Building a Culture of Trustworthy Research. Sustainable improvement requires aligned action by NIH, research institutions and centers, journals, investigators, and professional societies. NIH should pair its expectations with support for replication, methodological expertise, research personnel, data stewardship, protected time, training, and shared infrastructure. The pain-specific ENTRUST-PE framework provides a useful lifecycle model by considering responsible governance, rigorous and transparent methods, applicability to intended populations, relevance of questions and outcomes, balanced communication, and well-documented data (O'Connell et al., 2025).

Positive incentives and field-led initiatives can translate rigor principles into practical changes in research culture. Professional societies can contribute by adapting these principles to their disciplines. For example, USASP has used NINDS-developed rigor icons at its Annual Scientific Meetings to help presenters communicate key design features. NIH could also build upon the NINDS Rigor Champions Prize as a positive-incentive model (NINDS, 2026). Challenge prizes can recognize investigators, trainees, research staff, and teams while identifying promising practices implemented beyond routine requirements. Successful approaches should be eligible for follow-on support to evaluate, refine, disseminate, and sustain them.

NIH should partner with societies, community-based organizations, and other stakeholders to determine whether tools and funded interventions meaningfully improve research, but also of equal importance is consideration of the practices and quality of clinical care. Such approaches should be thoughtful enough to support planning, reflection, and cultural change rather than becoming certification systems or additional checklists. USASP strongly recommends that NIH collect data and feedback on the effectiveness, burden, and feasibility of rigor interventions and disseminate the findings not only to the research community but the general community on whom it will have an impact. This evidence should guide decisions about broader implementation or necessary refinements to improve feasibility and effectiveness.

Data, Software, and Model Sharing

USASP supports NIH's efforts to incentivize the sharing of scientific data, software, models, and other research resources. Successful sharing should be defined by whether prospective users can understand how a resource was generated, evaluate its quality and limitations, and reuse or combine it appropriately.

Supporting Curation and Infrastructure. Effective data sharing depends on expert curation and sustained infrastructure. Even within coordinated research networks, investigators may struggle to standardize metadata, reconcile variable definitions, document provenance, complete quality-control requirements, and satisfy repository expectations. These challenges are compounded when submissions are infrequent and staff turnover limits retention of specialized knowledge. We recommend that NIH provide sustained support for repository curators and data coordinators who can guide investigators through preparation and

submission, preserve institutional knowledge, and improve the quality and usability of shared resources. For large consortia, each data-generating laboratory could designate a trained data steward and develop a data-management SOP in coordination with the repository or data coordinating center. Dedicated budget categories, administrative supplements, shared curation cores, and continued support beyond the original award period would prevent these activities from competing with core research costs. Together, these investments would reduce submission inefficiencies and ensure that shared resources remain well documented, interoperable, and reusable over time.

Promoting Quality and Harmonization. Harmonization should begin during study design rather than being imposed retrospectively. Common data elements, structured metadata, controlled vocabularies, data dictionaries, and transparent protocols can support cross-study comparison, pooled analyses, and machine-assisted reuse. The HEAL Data Ecosystem illustrates the value of coordinated standards when they are scientifically appropriate. NIH could encourage conformance with established standards while allowing justified variation across study designs, populations, methods, and data types. Standardization cannot repair biased sampling, inadequate power, invalid measures, or weak analysis; NIH should therefore assess the quality, provenance, documentation, and limitations of shared resources, not merely their technical compliance. Uses involving artificial intelligence also require clear provenance, licensing, versioning, validation, documentation of limitations, and appropriate protection of participant information.

Promoting Responsible Reuse. Data availability does not ensure that investigators understand how shared resources may be used. Misconceptions persist about whether public data can support grant applications, hypothesis development, pooled analyses, experimental troubleshooting, or subsequent publications. NIH should coordinate with journals, repositories, and institutional libraries to provide clear guidance and examples demonstrating that responsible reuse is legitimate and encouraged when consistent with consent, access, attribution, and data-use requirements. Addressing these misconceptions would increase the scientific return on existing data investments.

Measuring and Rewarding Reuse. NIH should evaluate shared resources based on demonstrated reuse and downstream scientific value, not merely whether they were deposited or made available. Evidence could include formal citation, verified incorporation into new studies, independent validation, external adoption, development of derivative tools, educational or clinical applications, and research that would otherwise have been difficult or costly. Evaluation should reflect the type of resource involved. Software may require documentation, versioning, testing, and maintenance, while computational and experimental models require appropriate validation, characterization, provenance, and disclosure of intended uses and limitations. To make these contributions traceable, USASP recommends that NIH work with journals and repositories to promote persistent identifiers, formal resource citation, and bidirectional links among grants, publications, datasets, software, models, and contributors.

Resources demonstrating substantial downstream value should be eligible for competitive supplements supporting continued curation, harmonization, expansion, maintenance,

validation, and user assistance. Recognition and support should extend to curators, data managers, research software engineers, tool developers, and coordinating-center personnel. This combination of visible attribution and reinvestment would reward meaningful reuse while preserving high-value resources for future discovery.

Training and Mentorship

Training and mentorship should be evaluated by the capabilities, independence, and sustainable careers they foster, rather than simply by participation or conventional academic outputs. Publications, grants, appointments, and trainee counts provide useful context but do not fully capture growth in rigorous research practices, methodological expertise, communication, leadership, interdisciplinary collaboration, or team-science skills. USASP therefore, recommends that NIH consider a broader portfolio of outcomes, including access to professional networks and sponsorship, successful career transitions, sustained participation in research, and subsequent contributions to science, health and the community at large.

Training outcomes should be assessed over time and interpreted in relation to the program, career stage, and trainee's goals. Including training on methods for increasing the impact of science research and communication beyond the research community will substantially improve our ability to assess the importance of the work promoted by our training program. (*See* Haroutounian, S. et al. IMMPACT recommended considerations (2023). For interdisciplinary pain researchers, developing foundational knowledge across fields, establishing durable collaborations, or remaining engaged in pain research may represent important early outcomes before publications or independent funding emerge. Therefore, we recommend that NIH use existing data systems and follow-up surveys wherever possible to evaluate longer-term outcomes without creating duplicative reporting requirements.

Recognizing Mentorship Quality and Effort. Mentorship quality should be evaluated independently from a trainee's eventual publication or funding record, which is influenced by institutional resources, funding conditions, career goals, and other factors beyond the mentoring relationship. NIH could use validated, confidential mentee-reported assessments addressing communication, accessibility, constructive feedback, career guidance, support for increasing independence, and creation of a respectful research environment. These measures should support program improvement rather than rank individual mentors, and reporting must protect trainees when programs or mentoring relationships whenever possible.

NIH should also recognize mentorship occurring outside formal training and career-development awards, including team mentorship, peer mentorship, sponsorship, and cross-institutional mentorship. Investigators could document significant mentoring contributions through a concise narrative or structured contribution statement. Because high-quality mentorship requires time and sustained engagement, NIH should permit reasonable mentor effort on training awards and consider broader mechanisms providing protected time or salary support for substantial mentoring responsibilities. Recognition programs such as the NINDS Landis Award can highlight exemplary mentorship, but selective awards should complement—not substitute for—routine support of mentoring effort.

Expanding Access to Mentorship. NIH should assess the complete mentoring environment rather than relying solely on an individual investigator's prior mentoring record. Relevant evidence may include mentoring teams, institutional resources, plans for mentor development, and access to complementary scientific and career expertise. This approach would allow early-career investigators to develop as mentors while ensuring appropriate support for trainees, and it would recognize high-quality mentorship at institutions that have fewer formal NIH training programs.

Professional societies can complement institutional mentoring by providing cross-institutional networks, interdisciplinary engagement, and leadership development. For example, the USASP Leadership Academy pairs established pain researchers and clinicians with midcareer investigators to develop leadership and professional skills that may not be available within their home institutions. NIH could partner with professional societies to evaluate and expand approaches of this kind while preserving institutional responsibility for mentorship and career development.

Supporting Sustainable Career Pathways. Training programs should recognize successful careers in clinical practice, industry, government, nonprofit organizations, research administration, communication, and other sectors—not only tenure-track appointments or NIH-funded faculty positions. NIH could consider whether its indicators inadvertently encourage mentors to select trainees based on their predicted likelihood of achieving a narrowly defined academic outcome. NIH could also consider regularly assessing whether NRSA stipends and related support remain adequate relative to inflation, regional living costs, and institutional compensation requirements. Adequate and predictable support is necessary to retain talented researchers and realize the long-term value of NIH's training investments. Recognizing and sustaining varied career pathways would extend the benefits of NIH training across the broader research enterprise and strengthen the workforce needed to advance science and health.

Collaboration and Team-Based Science

USASP recommends that NIH assess collaboration by the scientific integration and added value it produces, rather than by the size or visibility of the team. Meaningful team science combines complementary expertise, methods, perspectives, and resources to address questions that investigators could not answer as effectively on their own. This approach would reward substantive collaboration rather than the appearance of interdisciplinarity.

Funding Integrated Team Science. We recommend that NIH expand upon its opportunities for investigator-initiated multidisciplinary research through U19 and comparable multi-project or cooperative mechanisms when scientific objectives require interdependent projects, shared cores, coordinated methods, and sustained collaboration. Planning awards, collaborative pilot funding, administrative supplements, and coordinating centers could support smaller or emerging teams. Allowable costs should recognize the infrastructure required for collaboration, including project management, team-science facilitation, shared communication and data platforms, methodological consultation, standards development, evaluation, and appropriate compensation for external partners.

Policies designed around individual investigators should not inadvertently discourage genuine multiple-PI projects. If NIH limits the number or value of awards held by an investigator, it should consider the investigator's actual effort, authority, and share of project leadership rather than treating participation in an integrated MPI team as equivalent to directing the project alone. Any exception should require evidence of substantive leadership to discourage nominal MPI designations.

Integrating Training with Team Science. Large, milestone-driven programs are not automatically effective training environments. Trainees may contribute substantially to predetermined deliverables without gaining experience identifying research gaps, developing hypotheses, or designing studies. NIH should encourage team-science awards to include trainee pilot funds, exploratory subprojects, mentored proposal development, and opportunities to lead cross-disciplinary working groups or propose questions arising from consortium resources.

The HEAL PAIN Cohort T90/R90 and NIDA T32 programs provides a useful model by combining interdisciplinary mentoring, authentic collaborative projects, career development, and scientific training across the spectrum of disciplines relevant to pain research. Comparable features could be incorporated into research consortia and multi-project awards, including programs not primarily designed as training mechanisms. This would allow trainees to develop both team-science skills and intellectual independence.

Assessing Collaboration Quality. Relevant indicators could include whether team members jointly shaped the research question and design; integrated distinct methods or disciplinary perspectives; established clear governance, communication, decision-making, authorship, and conflict-resolution practices; and produced knowledge, resources, or capabilities that would have been difficult to achieve independently. NIH could also consider the durability of relationships, development of shared methods or datasets, creation of new interdisciplinary directions, and dissemination of expertise beyond the original team. Contributions to community standards, metadata, protocols, and interoperability should be recognized when they enable collaboration across a field.

Recognizing Individual Contributions. Principal-investigator status, authorship order, and consortium authorship often obscure essential contributions from data curators, software developers, statisticians, project managers, research coordinators, standards developers, and domain experts. Structured contributor-role frameworks offer a useful foundation but may need greater specificity for metadata design, standards development, maintenance of shared tools, use-case development, and other enabling work. NIH should encourage structured, machine-readable contribution records across publications, datasets, software, models, and standards, supplemented, when necessary, by brief descriptions of the significance of each contribution.

Within consortia, funding and governance plans should prospectively recognize laboratories and investigators contributing data, validation, use cases, domain expertise, or standards development even when they do not build or publish the final resource. Appropriate subaward support, protected effort, and formal credit would reduce friction and ensure that essential collaborative work is not treated as invisible service.

Entrepreneurship and Translation

Defining NIH's Role. NIH can most effectively advance translation by reducing the scientific, technical, and coordination risks that prevent credible discoveries from reaching capable developers and users. Its role should be to support validation, development, training, and connections to appropriate expertise—not to presume that every discovery should become a commercial product or that NIH should operate as an entrepreneur. Support should reflect the type and maturity of the innovation and connect investigators with relevant regulatory, manufacturing, clinical, implementation, and commercialization expertise.

Matching Support to Development Requirements. Therapeutic development often requires more time and capital than conventional small-business or milestone-driven awards provide. Validation, toxicology, manufacturing, regulatory engagement, and clinical studies may be required before private investment, or an industry partnership becomes feasible. NIH should evaluate whether SBIR/STTR, UG3/UH3, and related mechanisms provide realistic budgets, timelines, and continuity for the development stages they are intended to support. Where persistent gaps exist, NIH could provide larger or longer awards, bridge support between development stages, or complementary mechanisms extending beyond conventional limits. Continued funding should remain tied to clearly defined scientific, technical, regulatory, and development milestones, with independent decisions to continue, revise, or discontinue support.

NIH should also expand access to training and technical assistance in regulatory strategy, manufacturing, clinical development, reimbursement, intellectual property, and commercialization planning. These resources may be particularly valuable for academic investigators and first-time entrepreneurs who have strong scientific expertise but limited product-development experience.

Designing for Adoption. Technical quality does not ensure that a product, tool, standard, or infrastructure resource will be used. NIH should encourage translation-focused projects to identify intended users and potential adopting organizations early enough for them to help define requirements, test usability, establish implementation milestones, and plan for the distribution of knowledge into the community of potential users. Including affected communities and users early would help to ensure that the presentation of data is made understandable to non-researchers. Joint funding or shared milestones between developers and adopting partners could create accountability for both development and implementation. Expectations should vary by project maturity so that early engagement demonstrates a credible need without requiring a fully committed commercial partner before an innovation is sufficiently developed.

Improving University-to-Startup Translation. The time, cost, and uncertainty involved in licensing university-owned technologies can prevent promising discoveries from reaching qualified startups. NIH-funded institutions should be encouraged to use transparent licensing processes, reasonable timelines, standardized startup agreements, proportionate financial terms, and procedures for resolving stalled negotiations. More predictable terms would allow

early-stage companies to invest limited resources in validation and development while preserving appropriate institutional and public interests in federally supported discoveries.

Measuring Translational Contribution. Translational impact should reflect whether an innovation responsibly advanced toward practical application, not simply the number of patents, licenses, startup companies, or dollars raised. Relevant evidence may include completion of scientific, regulatory, manufacturing, or clinical milestones; engagement of qualified development or adoption partners; integration into independent research or clinical workflows; and appropriate follow-on support. Unprompted adoption by organizations outside the originally funded program will provide especially meaningful evidence that a product, tool, or standard addressed a broader need.

Indicators should account for differences among therapeutics, devices, diagnostics, software, research tools, communication into the general community, and implementation strategies. NIH should also recognize well-conducted work demonstrating that a product is ineffective, unsafe, infeasible, or not ready for further development. Timely discontinuation based on credible evidence can prevent greater downstream losses and should not automatically be treated as failure.

Foundational Scientific Exploration

Basic research and high-risk, high-reward research are both essential to scientific progress but should not be treated as interchangeable. Basic research builds the knowledge, methods, and conceptual foundations upon which future advances depend; much of it is incremental and cumulative rather than inherently high-risk. High-risk research deliberately tests unconventional ideas whose probability of success is uncertain, but whose potential scientific effect is substantial. These forms of exploration require distinct funding and review strategies.

Sustaining Foundational Basic Research. Foundational research should not be required to demonstrate an immediate path to a product, intervention, or clinical outcome. Its value may become apparent only after multiple discoveries converge, sometimes many years later. Research on incretin physiology and glucagon-like peptides ultimately enabled GLP-1–based therapies, while studies of bacterial immune systems provided the foundation for CRISPR-Cas9 gene editing (NIDDK, 2021; NIGMS, 2024). Neither trajectory could have been fully predicted when the underlying observations were first investigated.

NIH should maintain stable support for investigator-initiated basic research alongside goal-directed, translational, and clinical programs. Tightly defined initiatives can mobilize research around urgent needs, but excessive emphasis on predetermined outcomes may narrow the questions being investigated and reduce opportunities for unexpected discovery. NIH should transparently monitor its investments across these categories and ensure that every institute and center sustains the foundational science needed for future progress.

Foundational science should also include careful incremental research that validates methods, resolves inconsistencies, characterizes mechanisms, refines models, or establishes the boundaries of a finding. NIH should not equate innovation solely with novelty or dramatic claims. Relevant indicators of foundational contribution may include creation of new concepts,

methods, measures, models, datasets, or research directions; resolution of scientific uncertainty; or eventual uptake across disciplines. Because these effects may emerge unpredictably, investigators should not be required to forecast a specific clinical or commercial impact.

Supporting High-Risk, High-Reward Research. High-risk research requires review processes that tolerate genuine uncertainty without relaxing methodological standards. Although NIH's R21 and High-Risk, High-Reward programs state that preliminary data are not required (NIH, 2026a; NIH, 2026b), applicants may still perceive that reviewers expect conventional evidence of feasibility. NIH should examine reviewer critiques, scoring patterns, and funding decisions to determine whether preliminary-data expectations are being reintroduced in practice or whether projects described as innovative remain comparatively conventional.

Reviewer training should distinguish the uncertainty inherent in testing an unconventional idea from avoidable weaknesses in study design. Review criteria could separately consider the importance of the question, degree of conceptual departure, potential magnitude of the advance, credibility of the scientific rationale, rigor of the approach, and value of the knowledge generated even if the central hypothesis is not confirmed. NIH should recruit reviewers experienced in evaluating unconventional or cross-disciplinary research while ensuring that high-risk mechanisms remain accessible to early-career investigators and researchers entering new fields.

Funding for Learning. High-risk programs should be structured around learning and decision-making rather than the expectation that every aim will succeed. Staged awards could use learning milestones, flexible follow-on funding, and opportunities to modify direction when early findings challenge the original premise. NIH should evaluate these mechanisms as portfolios by asking whether they support ideas unlikely to succeed in conventional review, generate new concepts or methods, and occasionally produce unusually substantial advances. Projects that disprove plausible hypotheses, identify unworkable approaches, or establish unexpected limitations can still provide a meaningful return by preventing unproductive investment and informing future research.

Public Impact

USASP supports NIH's efforts to recognize the many ways biomedical research benefits the public. Public impact is multidimensional, often collective, and may emerge long after an award ends. Relevant evidence could include improvements in health outcomes or clinical practice; incorporation into guidelines, policy, or health-system operations; development of accessible tools and educational resources; meaningful use by people affected by health conditions, clinicians, educators, or community organizations; economic or workforce benefits; and contributions to public understanding of science. Public visibility, social-media reach, or favorable attention alone should not be treated as evidence of meaningful impact.

Building Capacity for Dissemination. Public impact rarely follows from publication alone. Researchers may lack the time, expertise, partnerships, or resources needed to communicate findings to those who could use them. We appreciate efforts like NIH ENGAGE that focus on

integrating people with lived experience into research from early stages through to translation. But with an evolution in practice, capacity building is essential. NIH should provide training and dedicated support for plain-language writing, visual communication, responsible use of social media, and dissemination to people living with health conditions, clinicians, community health workers, educators, policymakers, and other intended users. These skills should be incorporated into training and career-development programs and project dissemination plans. Grant funds should also be available to support communication specialists and compensate external partners who help adapt and disseminate findings.

Creating Accessible Scientific Resources. Well-curated repositories can extend public impact by offering accessible pathways to NIH-supported research. Where privacy, consent, and other protections permit, repositories could provide plain-language study summaries, public-facing explanations connecting data to research questions, educational materials grounded in active research, appropriately deidentified classroom datasets, and channels through which patient and community organizations can ask questions or identify areas of interest. Evidence of educational use, adoption by public-serving organizations, or incorporation into accessible tools may help demonstrate impact more meaningfully than website traffic or download counts alone.

Recognizing and Sharing Effective Practices. NIH could establish an annual recognition program honoring investigators, research teams, research staff, communicators, and community partners whose work exemplifies meaningful public impact. Awards could be named for distinguished former NIH leaders whose careers reflected public service and the application of scientific knowledge for societal benefit. Recognition need not include monetary support; an opportunity to present the work publicly and dissemination of the recipient's approach as a case study could provide meaningful visibility.

Selection should focus on documented contribution rather than institutional reputation, publication metrics, or public prominence. Publishing recipients' strategies, challenges, and lessons learned would make the program more than an award by helping NIH identify and disseminate effective approaches throughout the biomedical research community.

Conclusion

USASP appreciates NIH's consideration of these recommendations. We encourage NIH to develop context-sensitive measures that recognize varied scientific contributions, preserve expert judgment, and are adequately resourced and evaluated before broad implementation.

Sincerely,

[redacted]

Re: NOT-OD-26-087: Request for Information on Measuring and Rewarding Scientific Impact

Submitted via comment form: https://osp.od.nih.gov/comment-form-measuring-and-rewarding-scientific-impact/

Dear Director Jorgenson:

We are writing on behalf of the Coalition to Illuminate and Address Animal Methods Bias (COLAAB) in response to the National Institutes of Health (NIH) request for information on measuring and rewarding scientific impact. Thank you for the opportunity to provide input.

The COLAAB is an international collaboration of researchers and advocates working to develop strategies to address the phenomenon of "animal methods bias," when research is unfairly evaluated because it does not include animal-based experiments.[1] As recognized by NIH's initiative to prioritize human-based research technologies and reduce animal use, nonanimal biomedical research methods like tissue chips and organoids are increasingly effective and available for disease modeling and drug development, but peer review remains one barrier to their broader uptake.[2] Members of the COLAAB have personally experienced animal methods bias, and empirical evidence gathered by our team demonstrates that it can cause delays in publication or rejection of manuscripts or grant applications, negatively impacting scientists' productivity and effectively disincentivizing the use of nonanimal approaches.[3]

To incentivize and reward rigorous, translatable, impactful research that delivers value to the American public, human-based research should continue to be prioritized agency-wide, and further action should be taken to mitigate animal methods bias. As requested, below, we provide specific recommendations for measurable indicators and incentives of NIH-funded research that is collaborative, rigorous, and mission-driven.

1. RIGOR AND REPRODUCIBILITY

Recommendations to incentivize rigor and reproducibility:

A. Implement grant application review criteria to assess proposals for adherence to NIH priorities, human relevance, context of use, and translatability. Animal methods bias undermines evaluations of rigor by allowing the methodological familiarity or gaps in reviewer expertise to unfairly influence assessments of scientific rigor. We urge the agency to recognize that methodological suitability is a key factor of rigorous and reliable science. A method should be fit for its intended purpose, regardless of its historical prominence or familiarity. NIH should distinguish successful replication from evidence of external validity, human relevance, or translational value. A finding can be reproducible within a particular experimental model without that model accurately representing human biology or predicting human outcomes. Furthermore, NIH should encourage reviewers to be critical of applicants' claims about the necessity and past contribution of an animal-based method. Correlation is no measure of necessity or validity (animals' involvement in successful drug development does not mean success depended on their involvement).[4]

B. Require reviewers to provide substantive, referenced reasoning if they argue that lacking animal experiments is a weakness of any particular proposal.[5] A study should not be considered *more* rigorous because it includes animal use, nor *less* rigorous because it does not.

C. Continue to evaluate reviewer performance for evidence of methodological bias.[6]

---

survey to evaluate animal methods bias experienced by India-based researchers in the peer review of manuscripts and grant applications. *NAM Journal*. Published online August 6, 2025:100042. doi:10.1016/j.namjnl.2025.100042

[5] Vinken M. Advancing toxicology through new approach methodologies. *Toxicology*. 2026;526:154546. doi:10.1016/j.tox.2026.154546

[6] Yee LM and Olufokunbi Sam D. CSR Advisory Council Reviewer Evaluation Working Group Update. *Center for Scientific Review Advisory Council Meeting.* September 23, 2024. Accessed August 13, 2026. https://public.csr.nih.gov/sites/default/files/2024-08/Update_on_CSRAC_Working_Groups_Reviewer_Evaluation.pdf

D. Incentivize replication in human-based systems, including with human cells, organoids, organ chips, computational models, clinical datasets, or convergent evidence across complementary human-based approaches.[7]
E. Encourage and reward researchers to follow best practice guidelines for reporting *in vitro* studies.[8]

Recommendations to measure rigor and reproducibility:

A. Measure the proportion of individuals with expertise in human-based and nonanimal methods within study sections, advisory committees, and review staff.
B. Track and investigate reviewer comments that judge lacking animal experiments as a weakness.
C. Track rates of methodological bias within reviewer evaluations.
D. Track funding rates of proposals with animal- and nonanimal-based methodological approaches, and evaluate the relationship of those findings with review group composition.

2. DATA, SOFTWARE, AND MODEL SHARING

Recommendations to incentivize data, software, and model sharing:

A. Incentivize and reward open science practices, such as open access publishing, systematic reviews, data sharing, and preregistration of studies. This will foster transparency, rigor, and reproducibility, helping to build confidence in nonanimal methods and mitigate animal methods bias by addressing the hesitancy of some reviewers to embrace nonanimal methods.
B. Incentivize and reward data, software, and model sharing to help researchers validate findings without conducting new animal experiments. One of the primary drivers of animal methods bias is the reviewer expectation that nonanimal findings must be "validated" using animals. On August 4th, the National Cancer Institute (NCI) published new Guidance on Applications for Studies with Animal Models and included a requirement that grant applicants should include human-based validation for animal experiment findings.[9] NIH

Guidance document on Good Cell and Tissue Culture Practice 2.0 (GCCP 2.0). *ALTEX - Alternatives to Animal Experimentation*. 2022;39(1):1. doi:10.14573/altex.2111011

[9] Letai A. Guidance on studies with Animal Models. National Cancer Institute. August 4, 2026. Accessed August 14, 2026. https://www.cancer.gov/grants-training/nci-bottom-line-blog/2026/guidance-animal-models

should implement NCI's requirement agency-wide, encourage researchers to use clinically relevant forms of validation, and enable this by incentivizing the sharing of high-quality human datasets, computational tools, and experimental models.

C. Incentivize and reward publishing null (or inconsistent) results through measures like requirements to report negative results and de-emphasis of journal-based metrics in evaluations of investigator capabilities. Publication bias against null studies has resulted in the scientific literature being dominated by studies that reject the null hypothesis, an absence of complete data in the scientific record, and—consequently—a threat to the rigor of systematic reviews. This jeopardizes the accurate assessment of interventions and model validity. Existing scientific literature may present an inaccurately positive portrayal of experiments on animals, where studies demonstrating the failure of those experiments to answer research questions or replicate human biology have been excluded from the record. Bias against null studies can therefore distort interpretations and opinions of experiments on animals, particularly regarding their precision and translatability, thus contributing to animal methods bias in the form of reviewers' expectations or requests for animal studies—including ones that have already been carried out but never published.[10]

Recommendations to measure data, software, and model sharing:

A. Measure open access publishing and preregistration rates of NIH-funded research.
B. Track null result publications associated with grants.

3. TRAINING AND MENTORSHIP

Recommendations to incentivize training and mentorship:

A. Continue requiring bias mitigation training for all reviewers that includes information on methodological biases.
B. Incentivize training in nonanimal approaches.
C. Continue to support and promote the Early Career Reviewers (ECR) Program and make a special effort to recruit ECRs who have experience in human-based technologies.

Recommendations to measure training and mentorship:

A. Track funds toward training in nonanimal approaches.
B. Track early-career researcher participation in review groups.
C. Survey early-career researchers about any experiences where they felt pressure to conduct animal experiments—from reviewers, advisors, mentors, peers, or other sources—to understand the needs of trainees to overcome animal methods bias. The time cost of grant

[10] Trunnell ER and Krebs CE. Chapter 15 Overcoming animal methods bias and its impacts on nonanimal research assessments. In: *Moving Toward Nonanimal Approaches in Medical Research and Testing*. Elsevier, 2026 (In press). ISBN: 9780443265143

and manuscript rejection and resubmission associated with animal methods bias can have especially severe consequences on early career researchers. Furthermore, although the intersection of animal methods bias and person-based biases (including related to age or seniority) has yet to be directly studied, the hierarchical structure of academic research could mean that early career researchers may experience animal methods bias in a compounded manner. When confronted with the pressure to use animals because of institutional inertia, expectation to obtain funding and publish, or direct requests from advisors, reviewers, or others, early career researchers may be less empowered to push back on these directives or requests, making them more susceptible to their harmful effects.

4. COLLABORATION

Recommendation to incentivize collaboration:
To develop and sustain an interdisciplinary research workforce capable of advancing the development, usability, qualification, and application of nonanimal, human-based technologies, NIH should incentivize and reward interdisciplinary training, research teams, research programs, research centers, and core facilities. Skills across fields such as medicine, clinical research, bioengineering (including microfabrication and microfluidics), pharmacology, toxicology, computational biology, and AI will be crucial.[11]

Recommendation to measure collaboration:
Measure not just disciplinary diversity but also methodological diversity of collaborative science.

5. ENTREPRENEURSHIP AND TRANSLATION

Recommendation to incentivize entrepreneurship and translation:
Translatability is a key component of rigorous, reproducible, and reliable methods and should be evaluated and rewarded (see response to 1. Rigor and Reproducibility).

Recommendations to measure entrepreneurship and translation:
A. Measure translation rates and contributing factors through systematic reviews and meta-analyses.
B. Track funding, uptake, and replication of translatable nonanimal systems.
C. Track the application of nonanimal systems to preclinical, clinical, and regulatory workflows, as well as the evidence that they contributed to decisions, products, policies, or improvements in human health.

[11] Moruzzi A, Shroff T, Keller S, Loskill P, Cipriano M. Training the Next Generation of Researchers in the Organ-on-Chip Field. *Education Sciences*. 2023;13(2):2. doi:10.3390/educsci13020144

6. FOUNDATIONAL SCIENTIFIC EXPLORATION

Recommendation to incentivize foundational scientific exploration:
When innovative human-based technologies are used for foundational scientific exploration, they should be supported and stand on their own, not subjected to animal methods bias. For some, confidence in these approaches is still being established, an inherently high-risk, high-reward process. They must, therefore, be further embedded within the academic enterprise to build evidence, familiarity, and ensure continued support for bold and innovative research directions.

Recommendations to measure foundational scientific exploration:
Track the use of human-based technologies for basic research.

7. PUBLIC IMPACT

Recommendation to incentivize public impact:
Encourage the practice of researcher assessment to move away from journal-based metrics like impact factors and toward scientific content, merit, and real-world impact on medical practice, health outcomes, societal benefit, and public policy.[12] COLAAB studies have found that researchers who use nonanimal approaches feel pressure to add animal experiments to their studies to ensure publication, especially from journals with high impact factors; and when authors do not comply with reviewer requests for animal experiments, they report publishing in lower impact journals among other consequences. The narrow focus of research assessments on journal-based metrics like impact factors penalizes research that counters the status quo, including the animal experimentation paradigm that is upheld by decades of embedded preference, infrastructure, and culture, as well as entire industries with vested interests in maintaining it.

Recommendation to measure public impact:
Investigate animal methods bias by assessing reviews and funding rates of projects with animal- and human-based methods. Based on preliminary evidence from a pilot study and workshop we conducted, at least some NIH grant application reviews may be impacted by animal methods bias.[13] However, the full extent of this impact, including how it affects funding rates of

[12] Allen L, Barbour V, Borrell-Damián L, Cobey K, Dube N, Firth C, et al. A Practical Guide to Implementing Responsible Research Assessment at Research Funding Organizations. Declaration on Research Assessment (DORA). May 2026. doi:10.5281/zenodo.18402271

[13] Trunnell ER, Roe KV. Predominance of animal-based expertise may bias NIH neuroscience grant review: A pilot study with implications for non-animal methodologies. *bioRxiv*. Preprint posted online March 2, 2025:2025.02.28.640877. doi:10.1101/2025.02.28.640877; Krebs CE, Geissler S, Herrmann K, et al. Exploring

animal- and human-based projects, remains to be determined. Understanding the breadth of this issue and its specific characteristics in the NIH context will be helpful for addressing it appropriately and holistically. We therefore recommend assessing review reports and reviewer comments during study section meetings for evidence of bias toward animal use and the resulting impacts on funding rates. Having already performed similar analyses with the aid of AI methods, the COLAAB would be pleased to assist with this effort. We have found large language models (LLMs) to be very useful for screening review reports for potential animal methods bias. However, a locally hosted LLM or cloud environment with privacy and confidentiality agreements may be needed to use such an approach for grant application reviews due to confidentiality restrictions; the compute power available will determine how large a reasoning model can be queried.

Thank you for your attention to these recommendations. We welcome further collaboration to ensure their implementation.

Sincerely,

[redacted]

People for the Ethical Treatment of Animals

animal methods bias in biomedical research funding: Workshop proceedings and action steps. *NAM Journal*. 2025;1:100004. doi:10.1016/j.namjnl.2024.100004

232. People for the Ethical Treatment of Animals

I am responding: On behalf of an organization

Name: Emily R. Trunnell, Ph.D.

Name of Organization: People for the Ethical Treatment of Animals

Type of Organization: Non-Profit Research Organization

Role: Bioethicist

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: Experiments on animals have long been recognized as a major contributor to the reproducibility crisis in biomedical research. Former NIH leadership acknowledged that "[p]reclinical research, especially work that uses animal models, seems to be the area that is currently most susceptible to reproducibility issues" (https://doi.org/10.1038/505612a).

In addition to the harms inflicted on animals and poor translation, irreproducible experiments impose substantial costs on science and the public. Failed attempts to replicate findings can consume years of effort and millions of dollars while delaying the development of effective interventions. Importantly, irreproducibility is an indicator that certain approaches are not generating sufficiently reliable knowledge to justify continued investment.

NIH must prioritize metrics that identify, evaluate, and replace methods that fail to produce reproducible, translatable, and clinically meaningful results.

NIH should establish dedicated funding mechanisms for evidence synthesis and comparative assessments of research methods, such as that which can be generated through systematic reviews. Systematic reviews can assess whether methods are scientifically valid, translatable, and relevant to human biology (https://brill.com/edcollbook-oa/title/35072; https://ntp.niehs.nih.gov/sites/default/files/2024-03/VWG_Report_27Feb2024_FD_508.pdf; https://doi.org/10.1177/01410768221093551).

Extensive data already exist without the need to reproduce every experiment at the benchtop. Researchers who identify ineffective approaches and facilitate their replacement should be recognized and rewarded for these important scientific contributions.

Reproducibility is also influenced by the quality and consistency of the biological reagents used in research. Antibodies and cell culture media can be significant sources of experimental variability when they are derived from irreproducible sources or are poorly characterized. NIH should support efforts to improve the adoption and characterization of reliable research reagents, including sequence-defined non-animal recombinant antibodies and chemically-defined cell culture media. NIH already recognizes the importance of this issue through its requirements that grant applicants address the authentication of key biological and chemical resources used in proposed research. However, beyond requiring researchers

to describe authentication plans, NIH should establish targeted funding opportunities, incentives, and reporting metrics that promote the development, validation, characterization, and adoption of more reliable reagents. Measurable indicators could include increased funding and use of sequence-defined antibodies and chemically-defined cell culture medium.

2. Data, Software, and Model Sharing: In addition to the sharing of data and software, NIH should reward investigators and institutions for sharing information that enables the scientific community to identify superior research approaches and discontinue ineffective ones. This could include creating databases that catalog human-based research methods, sharing data on the predictive performance and validation of human-based models, or developing data, tissue, cell, and other model-related repositories that facilitate the replacement of experiments on animals. NIH's Standardized Organoid Modeling Center is an excellent start, and efforts like this must be expanded for other human-based technologies.

NIH should incentivize the creation of openly accessible resources that help researchers identify and adopt non-animal methods. Making data on model performance publicly available would enable more informed funding decisions, facilitate meta-research, and accelerate the replacement of experiments on animals, which fail to advance human health.

3. Training and Mentorship: NIH should reward mentors and institutions that prepare researchers to use the most rigorous, reproducible, and human-relevant approaches available. Metrics such as publication output and grant success do not assess whether trainees are equipped to advance biomedical research using methods that are predictive of human biology.

NIH should incentivize training programs that support the development and adoption of non-animal methods, including organoids, organs-on-chips, computational models, artificial intelligence tools, and other human-based approaches. Indicators of successful training and mentorship could include participation in cross-disciplinary programs, acquisition of skills in emerging technologies, and transition from experiments on animals to human-based methods.

Mentors who help trainees critically evaluate the strengths and limitations of existing research methods should also be recognized for advancing scientific rigor and training future scientists in the important discipline of meta-research. Likewise, institutions should receive credit for providing researchers with the knowledge, infrastructure, and support needed to replace experiments on animals with modern human-based approaches.

As part of efforts to build institutional capacity, NIH should support educational opportunities for individuals involved in research oversight, including Institutional Animal Care and Use Committee (IACUC) and Institutional Review Board (IRB) members. Online training programs focused on non-animal methods, emerging human-relevant technologies, and the scientific and regulatory limitations of animal models would help to better equip IACUCs to evaluate animal use proposals in light of available non-animal methods and advances in biomedical science.

NIH should also support retraining opportunities for established investigators whose careers have been built around animal experimentation. Providing scientists with the resources and incentives needed to adopt human-relevant methods would strengthen the biomedical workforce and accelerate the

transition away from experiments on animals.

For more information on this topic, see “Developing a global education hub for animal-free innovation,” by Janssens et al. (https://doi.org/10.14573/altex.2411251).

4. Collaboration: Replacing experiments on animals will be most successful when we combine expertise that spans multiple disciplines, including cell biology, omics, bioengineering, materials science, computational biology, data science, and artificial intelligence. Advances such as organoids, organs-on-chips, digital twins, and AI-enabled drug discovery depend on the integration of knowledge, tools, and datasets across these fields. NIH should therefore recognize and reward collaborative projects that bring together diverse scientific expertise to further develop and apply human-based approaches. Particular recognition should be given to collaborative efforts that generate shared resources or produce evidence demonstrating that human-based methods can replace experiments on animals and facilitate the transition away from them.

5. Entrepreneurship and Translation: Translation should be measured by whether a research approach improves prediction of human outcomes.

Drug candidates typically progress through a development pipeline in which experiments on animals remain the norm. Basic and translational research often involve animal experiments, the most commonly used models of human disease are not human, and preclinical development has historically required extensive animal testing. The result of this status quo has been 95% of novel drugs failing in clinical trials (https://ncats.nih.gov/research/research-activities/ntu). After decades of dependence on animal use, such a failure rate cannot reasonably be described as a successful translational paradigm. The failure of this system to deliver translational impact, and the need for it to change, are clear.

Entrepreneurial and translational impact should be assessed based on the development, validation, and adoption of better methods that improve the prediction of human responses. Researchers, institutions, and companies that develop approaches capable of replacing experiments on animals should be recognized for advancing more effective pathways from discovery to clinical application. NIH should also reward innovations that reduce the cost, time, and high attrition rates that have long stymied drug development.

6. Foundational Scientific Exploration: Human-based technologies such as organoids, organs-on-chips, advanced imaging, computational modeling, and AI are enabling researchers to study human biology directly, capture patient-specific variation, and answer questions that experiments on animals cannot. These approaches have the potential to transform basic research itself by providing unprecedented insight into human development, disease, and physiology and should be prioritized when considering foundational research applications.

Expanding the scientific community's ability to study human biology directly should also be recognized as a paradigm-shifting contribution to basic research and the biomedical research enterprise. NIH should therefore consider projects that develop, improve, or apply these technologies as essential to foundational scientific exploration. Scientific impact should be measured not only by discoveries made using existing research tools, but also by the creation of new capabilities that expand what biomedical research can achieve.

7. Public Impact: Public impact should include transparency, accountability, and alignment with public expectations regarding how taxpayer-funded research is conducted. The public reasonably expects that federally funded research adheres to the public's views on morality, uses the most scientifically advanced approaches available, and that research investments are regularly evaluated to ensure they continue to serve the public interest. In terms of the public's views on morality, opposition to the use of animals in experiments has increased steadily. In 2026, Gallup reported that only 45% of Americans felt that medical testing on animals was morally acceptable, down from 65% in 2001 (https://news.gallup.com/poll/710981/moral-acceptability-falls-several-behaviors.aspx; https://news.gallup.com/opinion/polling-matters/694550/trends-adults-acceptance-moral-values-behaviors.aspx).

NIH must recognize that improving public impact requires discontinuing practices that no longer meet scientific and ethical standards. Research that identifies areas where experiments on animals can be ended and provides evidence-based pathways for modernization can help ensure that public funds are directed toward approaches most likely to benefit human health.

NIH should also recognize efforts to increase transparency regarding the methods it funds and the outcomes those methods produce. This should include public reporting on research portfolios, assessments of the scientific value and human relevance of funded approaches, and measures of progress toward reducing experiments on animals, including quantitative tracking of the number of animals used in NIH-supported research and the purposes for which they are used.

Public impact should also encompass activities that increase public confidence in the biomedical research enterprise. Scientists who openly evaluate the strengths and limitations of existing research methods, engage with public concerns, and/or facilitate the transition from experiments on animals to human-based methods provide a valuable service to both science and society.

A meaningful indicator of public impact would be whether NIH-funded research becomes more transparent, more accountable to taxpayers, and more responsive to scientific advances. Efforts to replace experiments on animals with modern human-based approaches can advance all three goals by aligning research practices with both scientific progress and growing public expectations.

8. Other Areas: Animal methods bias occurs when research is judged less favorably because it does not include animal experiments, regardless of whether animal use is scientifically necessary. As human-based approaches such as organoids, organs-on-chips, computational models, and AI become increasingly capable of addressing biomedical research questions, researchers continue to report pressure from reviewers, funders, and mentors to conduct experiments on animals to secure funding.

Animal methods bias can distort scientific evaluation by conflating the inclusion of animal experiments with rigor, validity, or translational relevance. A research method should be assessed based on its fitness for purpose and ability to answer the research question at hand, not on its familiarity or historical prominence. Bias toward animal use may disadvantage innovative human-based approaches and discourage researchers from pursuing methods that are directly relevant to human biology.

NIH should recognize animal methods bias as a potential barrier to scientific progress and research

modernization. Understanding the extent to which bias influences peer review, funding decisions, publication outcomes, and career advancement would help ensure that researchers are rewarded for scientific merit and impact rather than adherence to established methodologies. Mitigating animal methods bias would support innovation, accelerate the adoption of human-relevant approaches, and better align research incentives with NIH's goal of advancing rigorous and impactful science. On this matter, NIH should consult the Coalition to Illuminate and Address Animal Methods Bias (www.animalmethodsbias.org).

233. American Chemical Society

I am responding: On behalf of an organization

Name: John P. Ochs

Name of Organization: American Chemical Society

Type of Organization: Other

Type of Organization - Other: Scholarly Society

Role: Organizational Official

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: The American Chemical Society (ACS) is a congressionally chartered nonprofit organization representing a global community of more than 262,000 individuals across academia, industry, and government. Guided by its vision of a world built on science, ACS advances scientific knowledge and research impact through programs and activities that serve educational and government institutions, businesses, and the broader public.

As a socially responsible organization deeply rooted in the scholarly community, ACS appreciates the opportunity to respond to NIH's request for information on broadening the ways scientific impact is measured and rewarded. We support efforts to identify and incentivize the characteristics of modern scientific research that most effectively advance discovery and societal benefit.

One of the most important features of 21st-century science that should continue to be measured, recognized, and incentivized is the publication of research findings as a clear, measurable output of scientific activity. We are concerned, however, that the RFI suggests publication and citation counts may not be well aligned with NIH's core mission to generate knowledge that enhances health, lengthens life, and reduces illness and disability.

We agree that no single metric can fully capture scientific impact, and publication and citation counts are no exception. Practices such as fragmenting research findings into multiple publications solely to increase publication counts should not benefit researchers and are explicitly discouraged by the ACS Ethical Guidelines to Publication of Chemical Research. However, it would be a disservice to the research

community to allow concerns about isolated misuse to diminish the value of publications as evidence of sustained scientific productivity and knowledge generation.

Similarly, citation counts have certain limitations. In some instances, citations may reflect narrow networks of scholarly acknowledgement. More commonly, however, they provide a meaningful indication that research findings are being used, evaluated, and extended by others. Citations often signal that new knowledge is influencing subsequent advances that contribute to human health and welfare, economic growth, and innovation.

Publication and citation metrics remain important because publication itself is fundamental to the scientific enterprise and directly supports NIH's mission to generate and disseminate knowledge in multiple ways.

First, scholarly journals provide a trusted and effective forum for the vetting, exchange, and dissemination of scientific ideas and discoveries. They enable researchers across academia, industry, and government to share knowledge, evaluate emerging findings, and identify new directions for research. Journals also serve as one of the primary mechanisms through which the data underlying scientific advances become accessible to the scientific community, American businesses, policymakers, and the public. These functions accelerate future discoveries, support innovation, and fuel U.S. scientific and economic leadership.

The value of research publications is already recognized by both federal agencies and the private sector. Articles published in ACS journals were downloaded 5.6 million times during 2024 and 2025 by federal agency staff in support of agency missions and evidence-based decision-making. ACS articles acknowledging federal funding were downloaded more than 293,000 times by U.S. corporations during the same period, demonstrating the role of published research in driving innovation and economic competitiveness. Researchers at U.S. academic institutions downloaded these articles more than 4.8 million times, further illustrating the importance of broad access to high-quality scientific information.

Second, rigorous peer review remains a cornerstone of scientific quality and integrity. The peer review process helps ensure that published research findings meet recognized standards of validity, transparency, and reliability. This provides scientists with a trusted body of knowledge upon which to build, reducing unnecessary duplication of effort and enabling more efficient progress. Peer-reviewed literature also plays an important role in fostering public confidence in science and in supporting evidence-based policymaking in areas of national importance, including those funded by NIH.

Third, scientific publications serve as a critical source of research and development knowledge for small and medium-sized enterprises that often lack substantial internal R&D capabilities. Access to rigorously reviewed scientific literature enables these organizations to benefit from advances generated across the research ecosystem and to translate scientific discoveries into products, services, and innovations that improve human health, create jobs, and contribute to economic growth.

For these reasons, publication and citation metrics should not be discounted as indicators of scientific impact. While they should not be the only standards used, they provide valuable signals regarding the

production, dissemination, and use of new knowledge. NIH should therefore adopt a balanced and nuanced approach that considers publication and citation data alongside other measures of impact when evaluating whether federally funded research is achieving its intended outcomes.

Such complementary measures may include indicators related to individual articles, journals, policy influence, data sharing, public engagement, technology transfer, clinical implementation, or other pathways through which scientific knowledge creates value.

Importantly, many of the additional indicators referenced in the RFI are already enabled by and embedded within the scholarly communication ecosystem. The competitive scholarly publishing community plays a critical role in ensuring that scientific information is rigorously evaluated, corrected when necessary, validated, preserved, interrelated, and disseminated. Scientific progress depends on a robust ecosystem that supports expert peer review, access to the scientific record, discovery of relationships between studies, and effective communication of research findings.

Knowledge cannot improve health, lengthen life, or reduce illness unless it is communicated, preserved, and made discoverable. The scholarly publishing ecosystem creates an organized, durable, and accessible scholarly record that enables current and future research and supports the scientific discoveries and interrelationships that drive societal progress. While publication and citation metrics should not be viewed as the sole indicators of impact, they provide objective evidence that knowledge is being generated, shared, utilized, and built upon by the broader research community.

Efforts to expand the measurement and recognition of scientific impact should build upon this foundation. NIH should work collaboratively with other federal funding agencies, research institutions, investigators, and the scholarly publishing community to develop additional standards that complement existing measures while preserving appropriate recognition of the central role that publication and scholarly communication play in advancing science and delivering public benefit.

INTRODUCTION AND SUMMARY

The Information Technology and Innovation Foundation (ITIF) is pleased to submit the following comments in response to the National Institutes of Health's (NIH's) Request for Information on Measuring and Rewarding Scientific Impact. ITIF is an independent, nonprofit, nonpartisan research and educational institute focusing on the intersection of technological innovation and public policy.

The biomedical industry is one of the most critical advanced industries in the world, supporting the development of biologics, pharmaceuticals, and medical devices to improve human health. The United States has been the world leader in the biotechnology industry, with the highest levels of new drug development, medical device production and exports, and the largest share of global output in the industry. But, as ITIF has written extensively, the People's Republic of China (PRC) is rapidly closing the gap with the United States, with the goal of becoming the world leader in life sciences, specifically in areas such as innovative drug development.[1] China has utilized every policy lever possible to eclipse the United States as the global leader in biomedical innovation and development, including legitimate practices such as research and development (R&D) investments, tax incentives, and talent development programs; as well as a number of illegitimate or illegal tools, according to international trade law, all of which have aided in China's goal of becoming a genuine competitor in the industry.

As the United States attempts to fight back against China's growing push for dominance in this industry (and many other high-tech sectors), much needs to change. But to understand which policy levers must be pulled and where the United States needs to advance, the ways the United States stimulates and measures innovation must change as well.[2]

[2] Robert D. Atkinson, "Testimony to the US Senate Subcommittee on Science, Manufacturing, and Competitiveness on "Measuring What Matters: Science, Standards, and Strategic Competition" (ITIF, July 21, 2026),

ITIF commends the administration and the NIH for seeking to improve the American scientific enterprise. In the United States, research productivity has continued to decline since the 1980s, with studies showing that scientific research has become increasingly consolidated while papers and patents have become less disruptive since 1980.[3] Moreover, though budgets in areas such as biomedical and pharmaceutical sciences have increased in the past several decades, progress has not been commensurate, with new drug approvals in the United States slowing.[4]

While these issues are concerning and demand change, ITIF first urges the administration not to make any rash decisions that could negatively impact the state of American science. One such adverse action would be the Office of Management and Budget's (OMB's) Proposed Rule to Revise the Guidance for Federal Financial Assistance. This rule would greatly expand the authority of OMB and the executive branch, giving them and agencies the authority to terminate grants, or entire classes of awards, mid-award if they are viewed as inconsistent with the goals of the agency or program that is funding them. Moreover, the language used in the proposed rule is incredibly vague, including a provision that allows the termination of a grant if it "is in the interest of the Federal agency," giving agencies near-unfettered power to revoke grants at will.[5] This proposed rule should be withdrawn from consideration to avoid the unintended consequences that would surely be realized under its implementation.

These comments will present a series of options for how the NIH and other agencies throughout the government can accurately measure scientific advancement and innovation, including measuring new drug development, total industry funding of R&D, translational research, international scientific collaboration, and bolstering the American scientific workforce over the next generation. It will also present several policy proposals for how agencies can increase scientific advancement and innovation in the United States based on these new metrics.

NEW DRUG DEVELOPMENT

Undoubtedly, the most important and relevant indicator of success in biomedical research impact is the total number of new medicines a country creates. Over the past two decades, the United States has been the leader in new drug development, as measured by the number of new chemical and biological entities produced. (See Figure 1.) However, this measure also shows how rapidly China is rising to compete with the United States. Between 2019 and 2023, China produced 71 new chemical or biological entities, a booming increase compared to the four it produced between 2014 and 2018. Over that same period, the number of new entities produced by the United States increased from just 125 to 148.[6] And China has continued to increase

INDUSTRY FUNDING OF UNIVERSITY R&D

A key feature of the American innovation and research engine is the strong interconnection and collaboration between government, private enterprise, and universities. Universities have historically been one of the innovation labs for private enterprise, conducting the basic research that industry builds upon in applied research. Unfortunately, the private sector contributes just a small percentage of research funding to universities. For example, in 2023, the business sector contributed only $3.3 billion, or just 5 percent, of the higher education sector's total R&D spending on basic research.[7] And this rate differs dramatically from state to state. For example, North Carolina, Georgia, and Kansas led in the share of university research funded by industry, and Nebraska, Rhode Island, and Nevada were last. Among institutions, Duke, MIT, and Ohio State led, while University of Maryland, Michigan State, and Pitt were last.[8]

Robust industry funding for universities pays off economically. There are small, positive correlations between the share of a state's university research supported by industry and its strength on key innovation variables

Entities (2004-2023)," accessed August 12, 2026, https://www.efpia.eu/publications/data-center/the-pharma-industry-in-figures-rd/new-chemical-or-biological-entities/.

[7] Trelysa Long, "Why University Research Is Crucia to US Competitiveness" (ITIF, April 22, 2025), https://itif.org/publications/2025/04/22/why-university-research-is-crucial-to-us-competitiveness/.

[8] Robert Atkinson, "Industry Funding of University Research: Which States Lead?" (ITIF, January 2018), https://itif.org/publications/2018/01/08/industry-funding-university-research-which-states-lead/.

such as venture capital (a correlation coefficient of 0.28), scientists and engineers (0.19), high-tech startups (0.15), and high-tech jobs (0.14).[9] Industry research funding is also associated with stronger university technology output, with a correlation of 0.26 between industry investment and academic patents.[10] Moreover, interaction with industry as a STEM graduate student is associated with a significantly greater likelihood of producing intellectual property ("IP", e.g., patents, invention disclosure, etc.).[11]

Congress can and should make the following changes to incentivize and catalyze industry investment into university R&D.

- Require programs such as NSF's Engineering Research Center (ERC) to have at least some matching funds from industry as a condition of being awarded funding. In practice, for instance, this could require the University of Minnesota's ERC for Advanced Technologies for Preservation of Biological Systems to receive at least 10 percent of its funding from firms in the biotechnology or biomedical industry.[12]
- Require a number of actions in the tax code to stimulate industry support of university R&D.
    - Expand the R&D credit for companies that fund university research and eliminate language that restricts the definition of basic research to projects "not having a specific commercial objective."[13]
    - Broaden the tax credit for energy research consortia to include all research consortia.
    - Make all business funding of university and federal lab research eligible for a 40 percent flat tax credit.
    - Restore the Orphan Drug Tax Credit (ODTC) to 50 percent. To incentivize R&D of drugs for rare diseases, which are those that typically affect fewer than 200,000 people in the United States, in 1983 Congress created an orphan drug tax credit equal to 50 percent of qualified clinical trial costs and also offered a seven-year period of orphan drug exclusivity.[14]

A 2015 study by the National Organization for Rare Disorders found that at least one-third fewer new orphan drugs would have been developed to treat rare diseases over the preceding 30 years had the act not been implemented.[15] Unfortunately, the 2017 Tax Cuts and Jobs Act halved the ODTC to just 25 percent.[16] This should be restored to 50 percent.

TRANSLATIONAL RESEARCH

Since the end of WWII, U.S. science policy has followed a path of disciplinary neutrality and openness, allowing principal researchers to conduct curiosity-driven research with generous levels of federal funding and little overt incentive for turning discoveries into marketable IP.[17] This strategy was successful in leading to the development of several critical technologies, including the touchscreen and the Internet, and when coupled with a focus on international competitiveness and complemented by policies such as the Bayh-Dole Act, supported U.S. economic and industrial strength for many decades.[18]

But never in the history of the United States has the country faced a threat to global techno-economic leadership as significant as China poses, requiring a responsive shift in U.S. science policy. Several changes are of the highest importance.

1. U.S. science and research funding should not be cut under any circumstances. Unfortunately, the Trump administration's proposed FY 2027 budget calls for a 12 percent proposed cut to NIH funding, this coming after an effort to cut NIH funding by 40 percent in FY 2026.[19] If the goal of this RFI is to understand how to maximize scientific impact from federal funding of biomedical research, then policymakers should recognize that the American public enjoys a tremendous return from the federal government's investments in basic biomedical scientific research. In fact, each NIH dollar invested yields roughly $2.50 in short-term economic returns and stimulates an additional $8.30 in long-term private-sector R&D investment, underscoring the strong multiplier effect of public science funding.[20]

2. U.S. research funding can no longer be technology- or discipline-agnostic. Instead, it must be directed toward the critical and emerging technologies most essential for economic and national power. This means more focus on biology, physics, engineering, and computer science.[21]

This can be measured through the number of discoveries transferred to the commercial marketplace, similar to the statistics reported by the Association of University Technology Managers (AUTM) every year.[22] AUTM publishes data on the economic output, number of patents issued, licenses executed, and start-ups formed from academic technology transfer since 1996, giving a sense of how successful R&D investment has been over the past several decades. It also publishes the number of drugs and vaccines developed through public-private partnerships since the enactment of the Bayh-Dole Act, a critical indicator of success for the biomedical industry.[23]

The Bayh-Dole Act has had a significant impact on technology transfer and commercialization in the United States since its enactment in 1980.[24] The legislation, which allows universities, small businesses, and nonprofit institutions to take ownership of IP rights stemming from discoveries made from federally funded research. *The Economist* has called the Bayh-Dole Act "Possibly the most inspired piece of legislation to be enacted in America over the past half-century" noting "more than anything, this single policy measure helped to reverse America's precipitous slide into industrial irrelevance" as it made impact from "all the inventions and discoveries that had been made in laboratories throughout the United States with the help of taxpayers' money."[25] In the aftermath of its passage, the Bayh-Dole Act had an almost immediate impact on invention and discovery, with the number of patents awarded to universities ballooning from 390 in 1980 to 3,088 in 2009 and 6,680 in 2015.[26]

Given the profound success of the Bayh-Dole Act in catalyzing technology transfer and economic growth, it's critical that the legislation be maintained and not misused. Namely, policymakers should refrain from using the Act's march-in rights to control or ensure "reasonable prices" for drugs. March-in rights were included in the law to ensure that patent owners commercialized their inventions, with the intent to never use the provision to manipulate the pricing of a product.

Despite this, some policymakers have proposed otherwise. For instance, Senator Angus King (I-ME) has proposed legislation that would require the Department of War to issue compulsory licenses under Bayh-Dole "whenever the price of a drug, vaccine, or other medical technology is higher in the U.S. than the median price charged in the seven largest economies that have a per capita income at least half the per capita income

of the U.S."[27] The Trump administration should act to protect Bayh-Dole and its original intent by affirmatively declaring that price is not a legitimate basis for the exercise of Bayh-Dole march-in rights.[28]

U.S. universities should also collect better data on the new business start-ups coming out of U.S. universities to better understand which universities are excelling at commercializing research. This could be done through a directive from Congress directing NSF to develop a metric by which universities report such information annually. In addition, the Department of Commerce could use data available through the ES-202 form (unemployment insurance tax records), which tracks how many employees an establishment has every quarter. If the form noted the university that the founder of the organization attended, it could reveal which colleges and universities have graduates who are founding and running high-growth businesses.[29]

Federal funding agencies, such as the NIH, can take several further steps to aid and incentivize greater technology transfer and commercialization at universities.

- Federal agencies should use data on indicators of technology transfer commercialization at universities, including the number of start-ups founded or the extent of technology licensing, to reward universities that exhibit high levels of entrepreneurship. For example, agencies could give these universities bonus points on research grant proposals.
- Agencies should begin allocating a small share of university R&D funding—about 5 percent—based on how well universities commercialize research, including the number of start-ups founded from universities or the extent of technology licensing. (Here, agencies could refer to the 11 federal agencies that provide Small Business Innovation Research funding.)[30] This is similar to what other countries have done, including Finland, which allocates 25 percent of the research budgets of Finnish universities based on "quality and efficacy," including the universities ability to attract research investment from businesses. Similarly, Sweden's national government allocates 10 percent of regular research funds to universities based on performance indicators.[31]

  Similarly, Australia's engagement and impact assessment system scores universities on industry engagement, income from industry, and impact case studies. The United Kingdom's Research Excellence Framework includes an "impact" component that assesses commercial and societal impact of research, including patents, spinouts, and industry partnerships. And Chinese university funding and researcher evaluation increasingly weight patents, technology transfer, and enterprise partnerships.

[30] U.S. Department of the Interior, "Small Business Innovation Research Programs (SBIR)," https://www.doi.gov/pmb/osdbu/small-business-innovation-research-programs-sbir.

[31] Ibid.

- The NIH should establish an entrepreneur-in-residence (EIR) program at universities that receive NIH research funding. Universities and academic medical centers that receive funding from NIH often follow the narrow and traditional path to commercializing research that revolves around patenting and licensing. The technology transfer office at the universities/medical centers then take these patents and licenses to biotechnology and pharmaceutical firms for the development of products. While this model can be an appropriate vehicle for commercialization, it often lacks strong connections between firms and research organizations. Successfully scaling a life-sciences startup requires social and capital networks, mentorship, public-private partnerships, and access to both scientific and managerial talent. The EIR program would help universities identify, support, and grow the research efforts best positioned to become high-growth companies.
- Congress should provide financial incentives to universities that develop technology accelerators/incubators to commercialize faculty and student research. For example, Stanford University created StartX and Johns Hopkins created Fast Forward, both of which assist university students and faculty in establishing entrepreneurial ventures seeking to move university-developed discoveries and inventions into the commercial sector. These types of programs are increasingly proliferating throughout the U.S. university system, but additional support from the federal government would support the development through a wider set of universities and colleges, particularly those without large endowments or wealthy alumni to self-fund such programs.

Finally, the federal government needs to prioritize commercialization activities at federal labs and research institutes. America's federal laboratories are insufficiently incentivized to invest time, energy, and resources in facilitating technology transfer. For instance, Department of Energy (DOE) lab planning guidance includes a dedicated "Technology Transitions, Commercialization, and Partnership Strategy" section asking labs to describe their Cooperative Research and Development Agreement (CRADA), Agreements for Commercializing Technology (ACT), and Strategic Partnerships Projects activities and how these tie into lab strategy. But that's a planning-narrative requirement, not a scored performance criterion on par with the eight goals**.** It needs to be an enforced performance requirement tied to funding. Further, the federal government should require that applications for federally funded research at labs, research institutes, and universities include a one-page summary of the potential commercial applications of the research being funded.

EXPAND AND MODIFY SBIR AND STTR

Billed as "America's Seed Fund," the Small Business Innovation Research (SBIR) and Small Business Technology Transfer (STTR) programs provide over $2 billion per year to qualified small businesses to fund R&D activities through multiple federal agencies, acting as a key conduit to brining scientific innovations to market. While SBIR accounts for only 3.4 percent of federal extramural research funding, the program punches well above its weight, with as much as 22 percent of America's top innovations (as reflected by studies of previous winners of R&D Magazine's R&D 100 innovation awards) coming from companies that received SBIR grants at some point in their history.[32]

[32] Fred Block and Matthew Keller, "Where Do Innovations Come From? Transformations in the U.S. National Innovation System, 1970-2006" (Washington: Information Technology and Innovation Foundation, 2008), http://www.itif.org/files/Where_do_innovations_come_from.pdf.

Yet SBIR's impact could be even greater, particularly if certain facets of the program were slightly more strongly geared toward commercialization.

- SBIR awardees should be permitted to expend up to 5 percent of their award funds for commercialization-oriented activities. Awardees are currently limited in using grant funds to support critical commercialization activities such as building product or service prototypes, acquiring commercial customers, attracting private capital, or accelerating market entry. These activities span the gamut of important commercial activities, including IP development and prosecution, marketing and market development, and the recruitment of key team members associated with customer acquisition, thereby preventing awardees from taking important steps to commercialize innovations.[33]
- All participating agencies in the SBIR and STTR programs consider commercialization potential and plans in their grant funding decisions. However, agencies differ in the weight or emphasis they place on commercialization. In agencies where the intended customers are external, a greater portion of the merit review evaluation criteria and scoring should include commercialization factors, such as the company's understanding of market opportunity, product development timelines, and needed resources. Further, to evaluate these important criteria, the composition of SBIR/STIR review panels at these agencies should include industry experts, investors with relevant industry or technology expertise, and/or representatives from commercialization intermediary organizations.

INTERNATIONAL SCIENTIFIC COLLABORATION

The China challenge is so large that the United States cannot hope to succeed without partnering with allies. Congress and federal agencies need to expand joint research initiatives with allies in critical technology areas, such as biomedical research, and develop a shared network of advanced-industry centers in which firms from both countries can participate in each other's programs. International cooperation among national technology agencies, such as the NIH, presents an opportunity for technological innovation and information sharing between the United States and allied countries at potentially lower cost. Such programs have been undertaken by the National Science Foundation's (NSF) Technology Innovation and Partnership (TIP) Directorate, which conducts both basic and translational, market-ready research.[34]

For example, the Verticals-enabling Intelligent Network Systems (VINES) is a funding opportunity that supports research to enhance wireless communication networks, specifically to advance next-generation network systems. A global network of agencies and industry partners supports VINES, including NSF, Department of Homeland Security, Qualcomm, Ericsson, Intel, and international partners from Finland, India, Japan, and Sweden.[35] Congress should encourage federal agencies to seek out and invest in initiative such as this. NSF TIP has stated that it intends to invest $50 million into VINES when it is allocated its full funding from Congress.[36]

---

[33] Ezell and Andes, ""Localizing the Economic Impact of Research and Development."

[34] Robert D. Atkinson and Meghan Ostertag, "Congress Should Fully Fund NSF's TIP Directorate to Make America More Competitive Versus China" (ITIF, June 30, 2025), https://itif.org/publications/2025/06/30/congress-should-fully-fund-nsf-tip-directorate/.

[35] "Verticals-enabling Intelligent Network Systems (VINES)," U.S. National Science Foundation, June 2025, https://www.nsf.gov/funding/opportunities/vines-verticals-enabling-intelligent-network-systems.

[36] Robert D. Atkinson and Meghan Ostertag, "Congress Should Fully Fund NSF's TIP Directorate to Make America

The federal government should not only measure the amount of international collaboration between international partners and federal agencies, such as the NIH, and their outcomes, but also actively encourage these partnerships. One way it can facilitate these is through reducing the bureaucratic barriers to collaboration. Navigating diplomatic and congressional bureaucracy can slow down or even fully prevent these partnerships from materializing. The Department of State should identify countries that are automatically approved for scientific engagement, thus streamlining the path to partnership. The nations identified would be countries with which the United States is closely allied and those that possess the human and infrastructural resources necessary to make the partnership mutually beneficial.

PRODUCTION OF STEM TALENT

NIH plays a central role not only in funding research but also in sustaining the nation's biomedical workforce. It supports graduate education, postdoctoral training, and career pathways for more than 300,000 researchers through nearly 50,000 competitive grants across 2,500 universities and research institutions.[37] In FY2024, 34,000 R01-equivalent investigators applied for NIH funding, with about 9,655 receiving awards.[38]

This talent pipeline represents a strategic national asset. A steady flow of skilled biomedical researchers is essential to respond to pandemics, biothreats, and health security challenges. Without sustained federal investment, this talent will be lost to other countries or diverted to different fields, weakening U.S. capacity for innovation and response. Initiatives such as France's Choose France for Science campaign and the European Union's Horizon Europe Strategic Plan 2021–2024, which have been explicitly designed to attract top international talent, especially from the United States, pose a risk to the United States' ability to attract and retain talent.[39] In this competitive environment, sustained NIH support is critical to maintaining the United States as an attractive global hub for world-class biomedical science and to ensuring that the nation can meet both public health and national security needs.

A COMPREHENSIVE COMPETITIVENESS ASSESSMENT FOR AMERICA'S BIOPHARMACEUTICAL INDUSTRY

These comments contain several policy recommendations for how the NIH and other federal agencies can better record and incentivize innovation and scientific success. But ultimately, any effective policy needs to be backed by ongoing institutional, analytical, and intergovernmental capacity, which appears to be lacking in the United States. The NIH should establish a committee of industry experts and government officials to assess the competitiveness of the U.S. biopharmaceutical industry and issue a biannual report on its state of

competitiveness. The report should include all of the metrics we've outlined in these comments as well as others, including but not limited to:

- Domestic and global industry share of value-added output;
- Share of active pharmaceutical ingredients and key starting materials produced in the United States;
- Trade balances in the sector;
- Foreign direct investment in the sector;
- Productivity per worker and total factor productivity;
- Annual number of clinical trials for each type of drug;
- Global and domestic sales;
- Location quotients.

CONCLUSION

As global competition in biomedical innovation intensifies, particularly from China's state-directed push for dominance, the metrics the United States uses to gauge scientific progress can no longer rely on outdated measures. NIH and other federal agencies must adopt a more comprehensive framework for measuring scientific impact, one that captures industry outputs such as new drug development, industry investment in university research, the translation of discoveries into commercial and clinical outcomes, the depth of international scientific partnerships, and the strength of the biomedical talent pipeline. These diagnostics will enable policymakers to better understand where U.S. policy is currently insufficient and where targeted actions are warranted.

Pairing smarter metrics with the policy recommendations outlined above, the United States can ensure that its biomedical research enterprise, and greater scientific enterprise as a whole, remains positioned to maintain the economic competitiveness of the United States for years to come.

Thank you for your consideration.

Role - Other: Science Policy Manager

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: Rigorous and reproducible research begins at the experimental design phase of each grant application. Researchers carefully plan experiments so that they have adequate statistical power to accurately answer the scientific questions at hand. When research involves either human or animal research subjects, it is essential that experiments are designed to include a sufficient number of participants to ensure that the data generated is statistically significant. When requested funds are reduced, investigators are forced to amend their experimental design from the original rigorous research design. This may involve reducing or eliminating the number of human or animal subjects that would otherwise be needed to test the influence of sex on outcome variables with adequate power. To support rigorous and reproducible research, and to ensure that the investigators have the resources to meet the NIH mandated focus on sex as a biological variable, grants must be fully funded at the requested level.

2. Data, Software, and Model Sharing: Rapidly changing requirements for research security have left researchers with questions about how to meet data sharing requirements while also complying with research security policies. As research security policies change, NIH should review and update data sharing expectations. Ensuring that data sharing expectations are compatible with security concerns is an essential part of promoting data sharing within and outside of the NIH community.

NIH should recognize or reward demonstrated adoption or reuse of shared resources by the broader scientific community. Activities related to developing, maintaining, and using shared data resources involve a significant investment of time and resources that may not be adequately reflected in traditional measures of research output. One way that NIH might enable this is by allowing grant funds to be used for costs related to shipping or sharing samples or data. Additionally, NIH could create a data depository, similar to PubMed. If NIH hosts the data, then the barriers are lowered on the investigators. Investigators could then more easily ensure that data are deposited in a timely fashion.

3. Training and Mentorship: To maximize training and mentorship opportunities, NIH must understand what their trainees are seeking. While it is often assumed that postdoctoral training is intended to prepare scientists for tenure-track faculty positions, only 1 in 4 postdocs will be in a tenure-track academic position after 5–6 years post-graduation (Denton et al., 2022). NIH should assess the quality of mentorship, not merely trainee outcomes. For example: trainee progression and independence,

individualized development plans, successful transition into scientifically relevant careers, opportunities for authorship and intellectual leadership, mentorship of trainees from different career stages, sustained mentoring relationships, etc. This is particularly important because simply counting how many trainees become faculty could create the wrong incentive. Training and mentorship opportunities for postdocs vary widely at the discretion of the mentor. Essential elements of this training include grant writing, publishing, experimental design, scientific communication, etc. If all elements of training are adequately addressed, NIH supported graduate students and postdocs should be well positioned for a variety of careers both inside and outside of academia. NIH should examine current trainee offerings and ensure that they provide and require experience in skills that will translate well into both academic and industry-related careers. NIH should periodically review what are considered "successful" outcomes on training grants to fully encompass and reward alternative/non-tenure track careers.

NIH should consider incorporating public-private partnerships into their mentoring activities to ensure that trainees who pursue industry careers have adequate access to mentorship in those areas of interest.

NIH should recognize the significance of the commitment to mentoring by allowing effort for this mentoring to be an allowable cost.

Denton, M., Borrego, M., & Knight, D. B. (2022). U.S. postdoctoral careers in life sciences, physical sciences and engineering: Government, industry, and academia. PLoS ONE, 17(2 February). https://doi.org/10.1371/journal.pone.0263185

4. Collaboration: Science has always been a collaborative effort. Diversity, innovation, and creativity have long been essential elements in team-based science.

The recent proposal to cap Research Project Grants (RPGs) per Principal Investigator (PI), if finalized in its current form, will likely have a negative impact on collaboration by disincentivizing multi-PI grants.

In May of 2026, NIH reaffirmed definitions of foreign components. One of these components is "collaborations with investigators at a foreign site that result in co-authorship." This policy disincentivizes collaborations that might benefit the health of the American people etc. by increasing administrative burden on relationships with foreign entities, some of whom do not receive NIH funding. Existing policies and export control regulations are sufficient to protect against intellectual property theft and to ensure that sensitive data are not misused.

5. Entrepreneurship and Translation: Over the past 18 months NIH has emphasized its goal of prioritizing "human-based research technologies." The newly formed Office of Research Innovation, Validation, and Application (ORIVA) embraces this as an essential goal. We would caution NIH that "human-based" research does not exclude animal models. Animal models have been fundamental to modeling human physiology and disease and have consistently laid the scientific foundation leading to therapeutic advances. NIH fosters the maturation of discoveries from bench to bedside, and these opportunities for innovation would stall by excluding any type of model, including animal models. As new technologies are developed that reduce reliance on traditional animal models, we encourage NIH not to discount the role that traditional animal models of human disease play in the development of scientific concepts and the testing of hypotheses and therapies. Instead, NIH should look for fit-for-

purpose experimental systems. NIH should evaluate scientific impact based on whether investigators employ the most appropriate and rigorously validated model system for the biological question, including human-based models, computational approaches, organoids, animal models, or integrated combinations of these approaches.

6. Foundational Scientific Exploration: Transformative scientific advancements often arise from curiosity-driven, investigator-initiated research. Many of the most important breakthroughs in physiology and medicine have emerged from efforts that were not originally directed toward a specific translational goal. We encourage NIH not to lose sight of the foundational, basic exploratory science. These discoveries, which do not always have an immediate translational goal, lay the groundwork for the future of scientific advancement. We encourage NIH to avoid overemphasizing short-term or immediately measurable outcomes at the cost of high risk endeavors, and to value contributions that enable future discoveries, even when direct applications are not yet apparent. It can take decades before basic science observations can be linked to others to form a transformational discovery. This interconnected network of basic observations forms the basis of science and should not be discounted. A balanced research portfolio requires support for both basic and translational science. These initiatives would also benefit from periodic training and retraining of the NIH staff (e.g. SROs) as well as the reviewers on study sections to make a clear distinction between high-risk high-reward applications and the ones that also address key knowledge gaps, but which may not fit the high-risk high-reward criterion.

7. Public Impact: APS encourages NIH to explore existing resources regarding the broader public impact of biomedical research, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit. Scientific societies and advocacy organizations have long used these resources, including United for Medical Research's report on "NIH's Role in Sustaining the U.S. Economy"

NIH should consider recognizing contributions related to public engagement and science communication, dissemination of research findings to non-scientific audiences, educational outreach activities, and contributions that enhance public trust in science and scientific institutions. These activities should complement, not replace, measures of scientific excellence and rigor. NIH may consider how these activities, and others related to civic science, might be considered at the funding level. NIH could also acknowledge that some grant funds can or should be used in civic outreach.

8. Other Areas: APS encourages NIH to pilot and evaluate any proposed metrics before widespread implementation. New measures should each be assessed with the involvement of the scientific community for feasibility, reliability, and potential unintended consequences. NIH should specifically aim to minimize burden on investigators, maintain flexibility across disciplines and career stages, and continue to incorporate expert peer review alongside other measures.

Name:

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: '-Create dedicated funding streams or high-status journal tracks specifically for publishing well-powered replication studies and negative results.
-Treat shared datasets, software code, and open-source hardware as first-class research outputs with distinct Digital Object Identifiers (DOIs) that must be cited.
-Federal open-access mandates have created a cost barrier that threatens scientific equity. Top-tier journals now charge prohibitive fees that grants rarely cover and individual labs cannot absorb. Many researchers are effectively excluded from the highest-impact venues, undermining rigorous peer review and visibility. Sustainable solutions to open-access costs are essential to ensure equitable access to premier publication venues.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: '-Structure major grants so that multi-disciplinary co-PIs receive equal institutional and funding credit, removing the "sole leader" prestige bias.
-Track and reward scientists who build or maintain vital research infrastructure, biobanks, or community data repositories used by thousands of other researchers.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: '-Quantify contribution to public literacy by measuring community engagement events, activities, and workshops and media contributions.

1. Rigor and Reproducibility: Gene expression level is one of the most important biomedical data as it links to whether a gene's function is robust in a living body or not. Messenger RNA (mRNA) profiling has long been used as biomarkers in diagnostic, prognostic, and predictive assays. Four major platforms have been developed for RNA profiling. Listed in time order, they are RT-qPCR, microarray, next-generation sequencing (NGS) and NanoString nCounter. Digital PCR (dPCR) has been developed based on RT-PCR mechanism, but separately amplify each gene copy and detect the result. All those four technologies are matured and have received clearances from the Food and Drug Administration (FDA) for some of their products although none of them are perfect. In order to further improve the rigor and reproducibility of RNA expression data, we must understand the differences between two types of quantification: relative quantification and absolute quantification.

Relative quantification measures relative change in RNA expression levels. These data determine the changes in steady-state RNA levels of a gene across multiple samples and express it relative to the levels of another RNA (1) or a group of RNAs, such as housekeeping genes (2). However, there is a problem with this assumption, because it is nearly impossible to find a reference gene expression that does not change when the biological condition changes. Without a standard normalization reference(s), the data of relative quantification are literally unable to be integrated together and have difficulties to freely perform comparisons among different samples/experiments. This is because the normalization reference itself of relative quantification is NOT a fixed value, but also variables. Unfortunately, relative quantification is the "default" quantification method in gene expression measurement. Despite NGS's data can be output as absolute number of reads, without proper normalization, it is no different from microarray's data of fold change in the term of relative quantification. Thus, data generated in different experiments, no matter by microarray or NGS, cannot be directly integrated together or compared with each other. Although Nanostring nCounter's counts may equal RNA copy numbers during ideal experimental conditions, practically, this method also requires normalization to adjust the data integrity (3,4). The spiked-in RNA is suggested to be a normalization method for NanoString nCounter too (5). NanoString nCounter does not immune from random errors and systematic errors, and the accuracy and reliability of its gene expression results is also dependent on the proper normalization of the data against reference genes (3-7). Consequently, the counts provided by current Nanostring nCounter are data of relative quantification as well since those counts are not normalized to standard known copy numbers.

Absolute quantification measures the exact number of molecules, for mRNA is copy number because it

fits the First Principles for gene expression quantification. Such measurement ensures precise and reproducible results because “copy number” to RNA expression is equivalent to “gram” to weight and “liter” to liquid volume. All measures are universal definitions and never change. Scientific researchers have been trying to establish better normalization methods for gene expression profiling. However, most of the researchers have not pursued innovation of technology to output absolute quantification data, but have depended on pure mathematical methods to solve the problem of the incomparable data. The mathematical “deconvolution methods” ended up in the impossibility of obtaining absolute measurement with universal value (8). Therefore, it is the time to pursue technology innovation to output absolute quantification data to provide gene expression data with rigor and reproducibility.

For technology innovation, please see the “Entrepreneurship and Translation” section.

2. Data, Software, and Model Sharing: Besides a software is needed to be developed to perform the calculation of measured RNA copy numbers, a centralized database and comprehensive software may be developed to fully utilize the power that standardized absolute RNA copy number data can provide. Both software and mathematics are very advanced and have no problem crunching big data. One of major obstacles that drag epigenetics research is gene expression profiling data are relative quantification data. Feeding big data with relative quantification data, the result is sort of “garbage in, garbage out.”

Absolute quantification data, mRNA copy number / nanogram RNA, are clean/clear data with a standard unit. Thus, absolutely quantified mRNA copy number of different experiments can be freely integrated together no matter from different times or different locations. Therefore, data sharing, reuse and accumulation become realistic. Which in return will dramatically increase data power and accelerate

biomedical research discovery only if there are enough researchers participating in contributing their quality controlled absolute quantification data to establish a central database.

3. Training and Mentorship: Training is needed. Mentorship is great. I'd like to applaud, particularly, NIH also practice Request for Information. If it is okay, may I boldly further suggest that a two-way communication is feasible in uncharted territory? Either training/mentorship or information submission often end up in a one-way direction. I believe that constructive dialogue and creative discussion may elevate one-way information flow to a higher and more fruitful level. If such a two-way communication mechanism is available, please forgive my ignorance.

4. Collaboration: Traditionally, the model of research and discovery depends on experimental design that may be conducted in a laboratory or collaborated among many groups. Research results are concluded within the designed experiments. This model may be fundamentally shaped when switching data from relative quantification to absolute quantification. Absolute quantification data stored with character descriptions will provide researchers the opportunity to "collaborate" with all data contributors because all accumulated data can be freely reused to answer new questions. For example, there are 3000 sets of mouse gene expression profiling data stored historically from 3000 different labs of different experiment purposes. By chance, they used the same mouse strain, but different ages. Let's assume a scientist who is studying the relevance of gene X and development. The scientist may easily pull the related data from the database to perform further analysis. In that way, organized absolute quantification data of gene expression profiling may provide unlimited scientific collaboration globally.

5. Entrepreneurship and Translation: If we can upgrade the matured gene expression profiling platforms from current relative quantification to absolute quantification, it would be an ideal innovation. The way to fix the problem is to establish a normalization method that includes defined calibration curve(s) or other standards - the key attribute of absolute quantification (1, 2). Standard curve is the traditional and most used method to perform absolute quantification. In this approach, a series of known concentrations of the target molecule is prepared to generate a standard curve. The unknown sample is then compared to this curve to determine its absolute quantity. This method is used in quantitative PCR (qPCR), where the cycle threshold (CT) values of the unknown are matched against the standard curve to calculate the exact copy number. However, qPCR is unable to meet the needs of thousands gene expression profiling. Microarray and NGS are the two most powerful high-throughput platforms, which one should be our chosen for the innovation?

The comparative study on different platforms revealed that the reproducibility of microarrays can be higher than NGS (3). Moreover, it is my understanding that it is not feasible to include RNAs at known abundances for use as quantification standards during manufacturing process based on the platform mechanisms of NGS and NanoString nCounter. It is, however, experimentally proved that standard curves can be generated on microarray platform (4,5). The next question is how we can add a reliable "scale" on microarry platform to measure gene copy number? To answer this question, let's first have a brief review of the basic mechanism of microarray technology. Microarray technology is based on nucleic acid hybridization. Sample RNA, called target, binds to probe that is immobilized on microarray chip. Labeled target RNA binds to probe that is immobilized on microarray chip. Labeled target's signal intensity bound on probe is scanned to estimate the RNA amount as it is illustrated in Figure 1 (See uploaded file).

While microarray is a dependable technology, it cannot output standard absolute quantification data

because of the labeling and hybridization variations of each experiment and the sequence-dependent labeling and hybridization efficiencies of RNAs (4, 6-10). To upgrade the microarray platform from relative to absolute quantification, two challenges must be overcome --

The number one challenge is to identify reference(s) to normalize the labeling and the hybridization variations of each experiment. The spike-in method was developed to satisfy the need of canceling biases related to labeling and hybridization of each experiment (4, 10). The spike-in is the most notable and widely used method. It is suggested to be a fundamental need for virtually all genome-wide analyses, including sequencing (11-13). One of the milestones of the spike-in is the National Institute of Standards and Technology (NIST) hosted project of the industry-initiated External RNA Controls Consortium (ERCC) (14) . ERCC partners from industry, government, and academia, were attempting to develop RNA spike-in controls and establish analytical methods for bringing reproducible gene expression measurements into routine, high-quality practice. Developed for microarray platform, ERCC was used in RNA-seq to estimate RNA copy numbers as well (15). Should we fully utilize the valuable ERCC metrology products, Standard Reference Material (SRM) 2374 (16), we can be on a fast track to achieve the goal of absolute quantification on gene expression profiling with an innovative approach.

The second challenge is to resolve sequence-dependent labeling and subsequent hybridization efficiencies of RNAs. The traditional spike-in has two shortcomings. The first shortcoming is incredibly difficult to spike-in precise amounts across all the samples (17,18). Thus, very few people have used spike-in to perform absolute quantification. Another shortcoming is that one spike-in control sequence only generates one intensity data point on an array. A standard curve can only be made on a combination of control sequences as illustrated in Figure 1. The red circle on the top indicates that a set of RNAs are needed to be spiked-in to generate different signal intensities on the chip (the red circle at the bottom). Representing individual RNA character using a standard curve can be challenging.

The innovation and mechanism of absolute quantification microarray technology:
Figure 2 (See uploaded file) shows an innovative spike-in, named S-pike-in. The core of this invention (19,20) is the fundamental principle of 1:1 hybridization ratio between probe and target. This hybridization principle is the theory that allows us to advance the current spike-in method to be able to manufacture built-in standards on a chip via controlling immobile probe(s) instead of spike-in free target(s). Fixed probe concentrations/copy numbers on a chip allow us to use one control sequence to generate one standard curve. In Figure 2, the red circle on the top indicates that one S-spike-in sequence can generate different signal intensities on the chip (the red circle at the bottom), which can generate a standard curve. So, the amount of S-spike-in does not affect the accuracy of standard curve as spike-in does. This method erases the variations caused by individually added different spike-in concentrations. This method also allows for many standard curves to be built on one array. It also means that different standard curves may be established to represent different RNA characters. Thus, the S-spike-in provides potential solutions to overcome the shortcomings of traditional spike-in, while maintaining the function of canceling biases related to labeling and hybridization intact.

Once the inherited microarray platform problems are solved and external standard copy number curves are able to build on microarray chips, the following computational work, including determining original copy number that is before amplification, are much easier. The signal intensities obtained from the

arrays will be subjected to regular background subtraction and quality inspection. Linear regression analysis on each S-spike-in reference probe can be used to generate algorithms of linear correlations of the signal intensities and mRNA copy numbers for standard curves. Finally, the linear regression formula generated by the standard curve will be used to translate signal intensities of target mRNAs into copy numbers.

6. Foundational Scientific Exploration: It is quite encouraging that NIH is committed to foundational scientific exploration and willing to take risk of failure but the potential for paradigm-shifting breakthroughs. In my humble opinion, a paradigm-shifting is needed to speed up epigenetics research/discovery/clinical application. The current relative quantification of gene expression modules satisfies the conclusion that answers a specific question between control and treatment. Relative quantification data generated within one experiment are a closed set of data. Such data are not open to freely interact with each other, therefore, Big Data to Knowledge is difficult to reach. While absolute quantification data determined in RNA copy number/ng RNA allow data freely to interact with each other to speed up Big Data to Knowledge, another beauty of the upgraded absolute quantification microarray platform is that it can keep the function of the relative quantification. This is because the innovation described in the “Entrepreneurship and Translation” section is through adding a “scale” – standard curve on the original chip and upgraded computational software to achieve. Thus, the original relative quantification function can be intact on the absolute quantification platform. Which will provide a smooth process of paradigm-shifting. Researchers may continue their research in the way they are familiar with, simultaneously, the data can also be extracted as RNA copy number/ng RNA. Should the NIH lead the new direction of absolute quantification, there is no abrupt interruption to the current gene expression field, but open unlimited potential for the future.

Another advantage of absolute quantification is whenever a better method emerges to replace an old one, any data generated by absolute quantification including the microarray method can be easily transferred and integrated into another absolute quantification data pool generated by another platform(s). This is because each absolute quantification data is generated on a fixed value. The difference between two fixed values can be easily determined by a ratio.

7. Public Impact: Since gene expression of absolute quantification of copy number in a defined amount of biological material is a quantification with universal value, the impact of its success cannot be overemphasized. First of all, there is no doubt that it can dramatically speed up research discovery. Secondly, research results can fit clinical application seamlessly because the gene expression defined as “X gene copy number/ng RNA” is equivalent to blood pressure defined as “mmHg.” Thirdly, it is economical and cost-saving as the absolute quantification does not need the concurrent control for each

test as the relative quantification does. Fourthly, an absolutely quantified gene expression database will be a powerful tool when facing unexpected health emergency situations, pandemic COVID-19 is used as an example to explain how significant such a database would be below.

The world-wide response to COVID-19 was quite passive with struggle from diagnosis to treatment. Let's reshape the thinking model from targeting diagnosis and treatment separately to focus on one goal: restore health conditions. Health depends on each gene function normally. A pathogenic invasion damages health through altering gene expression profile. This is not only a theory, but published data showed that COVID-19 patients' transcriptomic pattern demonstrated responses to the viral infection (1). Another study, based on the swine experiment, showed that the response of transcriptome profiles of peripheral blood mononuclear cells could be detected 24h after porcine reproductive and respiratory syndrome (PRRS) vaccination. PRRS is caused by a positive-sense single-stranded RNA virus as well (2). These findings demonstrate that measuring transcriptome can be performed as a quick check on whether a person is infected and whether a person's body has generated a good immune response. Now, the question is how do we translate transcriptome data into knowledge in fighting COVID-19? It would be of tremendous value if we were to develop method(s) that are ready to test any unknown pathogenic invasion and provide essential information for treatment. Is such a goal achievable? The answer "Yes" lies in an established standardized gene expression profile database. If there was such a database available, gene expression profiles of COVID-19 patients could be compared to database stored data. Which would provide the guidance and information needed to design/select/evaluate treatments. The principle is similar to the diagnosis and treatment evaluation of anemia. The diagnosis and treatment evaluation of anemia depend on the hemoglobin range of grams per deciliter (g/dL). Changes in gene expression profiles can serve as a reference for the diagnosis and treatment assessment of COVID-19.

Needless to say, whoever owns such an absolute quantification database would have a dynamic molecular base for data-driven decision-making for health-related issues and be in an advanced position on functional genomics and precision medicine.

8. Other Areas: I'm aware that I'm submitting a huge project and unpopular idea. Once an entrepreneur colleague said to me "you are against the mainstream." Besides relative quantification is the "default" quantification method in gene expression measurement, sequencing technology will replace microarray has been a common view for more than a decade. However, microarray is still being widely used today (1-7). Regarding those two platforms' strength and weakness, three groups published solid comparison studies (7-9). The FDA group's recent conclusion clearly stated microarray is a viable method for transcriptomic applications (7). Moreover, researchers even innovatively combined microarray and sequencing technologies together for scalable spatial transcriptomics (6).

I am not interested in being in or against any stream, but having a strong desire to solve problems. I submitted the similar material in last year's Replication and Reproducibility tract 1 and tract 2 submission without success. I could not obtain the reviewers' review. Therefore, I do not know what the reviewers' opinions are. Nevertheless, I believe that careful argumentation and thorough consideration are the first steps toward the success of a project, especially aimed at paradigm-shifting. If absolute quantification of gene expression profiling is an interest of NIH, I'd like to suggest that NIH summit some top scientists in related field, let's sit down to freely discuss, debate, and brainstorm together –

1) Is absolute quantification of RNA expression profiling worth pursuing? If "Yes" –

2) Is it acceptable to add the function on an old technology platform? If "Yes" –

3) Which high-throughput platform we should choose, NGS or microarray? It would be fair that let scientists of both technology platforms to present their expert opinions on: a) the possibility of mechanism that allow absolute quantification on the two platforms; b) the comparison of strengths and weaknesses of the two platforms with considering that how much money has been poured into sequencing technology and the possible improving room of microarray; c) the cost effectiveness of the two platforms including data size and storage space. I only have very limited knowledge on sequencing technology. I would not be envious if the conclusion is that sequencing is the choice. But if microarray is the choice –

4) It would be ideal to have experts in industry join the endeavor to explore the opportunity to improve the microarray platform, such as whether 3D printing technology can be used to better fit a higher requirement to the microarray chip? It is also wise to have biomedical researchers' input on quality control such as RNA purity and accuracy of RNA amount of each experiment.

5) Biological experts and software engineers may work together to design the frame of the database storage and link to various functions for external research use.

All the best.

238. Federation of Associations in Behavioral and Brain Sciences

I am responding: On behalf of an organization

Name: Lindsey Leary

Name of Organization: Federation of Associations in Behavioral and Brain Sciences

Type of Organization: Non-Profit Research Organization

Role: Organizational Official

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: Behavioral and brain scientists have and continue to actively work to develop practices and norms to improve replicability. The field has scrutinized their journals and standard tools and made significant improvements to the statistical analyses and methodology. The Center for Open Science (COS) has provided critical infrastructure to enable rigorous and open practices. Scientific society publishers have changed journal standards and incentivized open science (OS) practices, including preregistration and sharing data/materials. These can improve rigor by making replication research easier and requiring scientists to think very deliberately about their research choices and how they might affect study findings. The American Psychological Association (APA), which publishes nearly 90 peer-reviewed journals, developed its Journal Article Reporting Standards (JARS), offering guidance on what information should be included in articles reporting quantitative, qualitative, and mixed methods research.

NIH might also lean on existing journals that explicitly welcome replication studies (e.g., Collabra: Psychology) or use Registered Replication Reports (RRRs; e.g., Advances in Methods and Practices in Psychological Science). In addition to looking at the publication count, it is important to consider where a paper was published.

According to COS, over 300 journals are tackling publication bias by offering a two-stage review process through the Registered Reports (RR) format. This approach prioritizes research quality over results in publishing decisions, which are made before the research is conducted. The Journal of Articles in Support of the Null Hypothesis only publishes research that does not have positive results.

In order to incentivize these changes and institutionalize replication and reproducibility efforts at the agency, NIH needs to fund these activities and tools with new calls. Some of this work, such as establishing new standard practices, may be best accomplished by scientific societies. By way of example, the FABBS Open Science Statement articulates norms for sharing data and research findings while protecting privacy of research participants. When evaluating grant proposals, NIH should reward researchers who not only follow these rigorous practices, but also researchers that devote their time and energy to reproducing the work of others.

2. Data, Software, and Model Sharing: In concert with COS, many journals use badges to signal when researchers participate in OS practices, including sharing data, study protocols, and analysis strategies. PubMed currently does not use the badge system itself; adopting it would make it easier to see which researchers have a history of data, software, and model sharing—something that could be considered in a grant application review. PubMed could track how often a dataset or protocol is reused, a clear

additional value.
Depositing data is only one step in strong open science practice. In order to be truly usable by colleagues, researchers must provide clear and detailed information for others to be able to reproduce or replicate their findings. FABBS urges NIH to carefully consider when certain datasets might not be feasible to share due to privacy concerns.
Science Tracking Across the Project Lifespan (STAPLE) is another example of the behavioral science community proactively improving open science practice. STAPLE is a science focused project management tool that not only helps with the unique challenges of project management of research, but includes open and transparent documentation of data and metadata.

3. Training and Mentorship: FABBS applauds the inclusion of training and mentorship as NIH considers broadening the measures of impact, albeit complicated. Behavioral and cognitive scientists have contributed to an evidence base for understanding and developing effective training and mentorship. We urge NIH to consider NASEM's The Science of Effective Mentorship in STEMM (2019); Chapter 6 is specifically devoted to assessment and evaluation.
The quality and impact of training and mentorship efforts can be measured in a number of ways. Primary investigators (PIs) could be required to submit detailed mentoring plans for any grants that involve recruiting research assistants, post-docs, or similar trainees who might benefit from the research experience, even if they are not funded by the grant. Following this, those trainees could report on their mentoring experiences with their PIs. Relying on just the number of mentees and trainees could provide incentives to maximize the number reported over the quality of the engagement.
Additionally, NIH grant PIs can track their mentees in several ways: replication efforts, grants awarded, and career outcomes. FABBS encourages NIH to consider not just mentees who stay in research, but also those who go into other fields and, nevertheless, have an important impact on public health.

4. Collaboration: FABBS applauds NIH's efforts to measure and reward collaboration. Team-based science is essential for maximizing the cumulative nature of science and the potential impact of the research. Furthermore, this research can be time consuming and not as conducive to acceptance in peer review journal articles that tend to be discipline specific. Indeed, a whole field of research exists on team science. In 2025, the National Academy of Sciences published Research and Application in Team Science. FABBS also encourages the agency to take into account a scientist's community-engaged research, considering how the program involves non-scientists in the research process.

5. Entrepreneurship and Translation: Pharmaceuticals and medical devices have clear pathways from basic research to product development. Industry is motivated to bring NIH-funded discoveries to scale when they are able to recoup their expenses and gain a financial profit. Unfortunately, the NIH-funded research and discoveries regarding prevention and reducing chronic diseases do not have the same financial incentives for being taken to scale.
FABBS encourages NIH to consider how to best measure the physical and financial benefits of prevention efforts — how can we measure the money saved and the lives improved when individuals avoid disease and disability thanks to healthy lifestyles and decisions?
NIH can also consider the impact a research program has had on clinical practice. For example, when an oversight body such as APA makes recommendations for how therapists treat certain patients or the American Psychiatric Association revises the Diagnostic and Statistical Manual of Mental Disorders (DSM), what research are they relying on? Can researchers be credited with contributing to clinical practice guidelines if their work is cited by oversight organizations?

NIH has made important advances with implementation science, with credit to behavioral scientists. FABBS encourages NIH to support additional work in implementation science as a key to effectively translating knowledge into health benefits.

6. Foundational Scientific Exploration: NIH recently released several notices of funding opportunities (NOFOs) for high-risk, high-reward (HRHR) projects. FABBS noted a significant change in the NOFOs: the reference to behavioral and social science had been systematically removed throughout, including in the routing code used to determine reviewers. This removal narrows the disciplinary range of scientists likely to respond to these NOFOs. FABBS encourages NIH to restore 'behavioral and social' science throughout the NOFOs and most definitely within the list of routing codes.

7. Public Impact: To date, the federal health ecosystem has fallen short in translating fundamental knowledge about health into practices and policies that reduce the burdens of illness and disease. NIH is only one part of the federal health infrastructure, yet plays a critical role. NIH could better incentivize researchers to consider and actively engage with the practitioners and policymakers in positions to incorporate knowledge and improve outcomes. Other federal agencies in the health delivery space who benefit greatly from leveraging insights and knowledge made possible by NIH-funded research. FABBS encourages NIH to recognize, measure, and value the impact of its research, as it serves the mission of sister agencies.
New tools exist to capture how governments, think tanks, and policymakers use relevant research to inform their decisions:
Sage Policy Profiles allows researchers to look up their own research and discover how their work has been used in policy decisions.
Altmetrics tracks online engagement.
There are also journals dedicated to the policy impact of science (e.g., Policy Insights from the Behavioral and Brain Sciences). We urge NIH to consider how other federal agencies use NIH-funded research in their work.

8. Other Areas: N/A

File Upload: https://osp.od.nih.gov/wp-content/uploads/ninja-forms/77/FABBS-Comment-on-NIH-RFI-Measuring-Impact.pdf

FABBS Response to NIH Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Date: August 19, 2026

The Federation of Associations in Behavioral & Brain Sciences (FABBS) represents 35 scientific societies and 60 academic departments in the psychological, cognitive, and behavioral sciences. We advance the sciences of mind, brain, and behavior; promote evidence-based policymaking; and advance the integrity and impact of the federal scientific enterprise. With support from federal agencies, including NIH, FABBS scientists study critical health challenges such as maternal mortality, youth mental health, and chronic diseases.

FABBS values the opportunity to provide feedback on measuring and rewarding scientific impact. We agree that current indicators of scientific success, mainly publication counts and citation metrics, do not fully capture the scope of the impact of NIH funded research. In particular, these limited measures fail to assess the degree to which behavioral and cognitive research impacts well being, clinical practice, and policies. Furthermore, reliance on publications and citations can focus researchers on these measures and actually disincentivize meaningful scientific engagement with the potential to provide the greatest societal benefits. Below, we offer seven suggestions for how to improve measures of scientific rigor and impact.

(1) Rigor and Reproducibility.

Behavioral and brain scientists have and continue to actively work to develop practices and norms to improve replicability. The field has scrutinized their journals and standard tools and made significant improvements to the statistical analyses and methodology. The Center for Open Science (COS) has provided critical infrastructure to enable rigorous and open practices.

Scientific society publishers have changed journal standards and incentivized open science (OS) practices, including preregistration and sharing data/materials. These can improve rigor by making replication research easier and requiring scientists to think very deliberately about their research choices and how they might affect study findings. The American Psychological Association (APA), which publishes nearly 90 peer-reviewed journals, developed its Journal Article Reporting Standards (JARS), offering guidance on what information should be included in articles reporting quantitative, qualitative, and mixed methods research.

NIH might also lean on existing journals that explicitly welcome replication studies (e.g., *Collabra: Psychology*) or use Registered Replication Reports (RRRs; e.g., *Advances in Methods and Practices in Psychological Science*). In addition to looking at the publication count, it is important to consider where a paper was published.

According to COS, over 300 journals are tackling publication bias by offering a two-stage review process through the Registered Reports (RR) format. This approach prioritizes research quality over results in publishing decisions, which are made before the research is conducted. The

Journal of Articles in Support of the Null Hypothesis only publishes research that does not have positive results.

In order to incentivize these changes and institutionalize replication and reproducibility efforts at the agency, NIH needs to fund these activities and tools with new calls. Some of this work, such as establishing new standard practices, may be best accomplished by scientific societies. By way of example, the FABBS Open Science Statement articulates norms for sharing data and research findings while protecting privacy of research participants. When evaluating grant proposals, NIH should reward researchers who not only follow these rigorous practices, but also researchers that devote their time and energy to reproducing the work of others.

(2) ***Data, Software, and Model Sharing****.*

In concert with COS, many journals use badges to signal when researchers participate in OS practices, including sharing data, study protocols, and analysis strategies. PubMed currently does not use the badge system itself; adopting it would make it easier to see which researchers have a history of data, software, and model sharing—something that could be considered in a grant application review. PubMed could track how often a dataset or protocol is reused, a clear additional value.

Depositing data is only one step in strong open science practice. In order to be truly usable by colleagues, researchers must provide clear and detailed information for others to be able to reproduce or replicate their findings. FABBS urges NIH to carefully consider when certain datasets might not be feasible to share due to privacy concerns.

Science Tracking Across the Project Lifespan (STAPLE) is another example of the behavioral science community proactively improving open science practice. STAPLE is a science focused project management tool that not only helps with the unique challenges of project management of research, but includes open and transparent documentation of data and metadata.

(3) ***Training and Mentorship****.*

FABBS applauds the inclusion of training and mentorship as NIH considers broadening the measures of impact, albeit complicated. Behavioral and cognitive scientists have contributed to an evidence base for understanding and developing effective training and mentorship. We urge NIH to consider NASEM's The Science of Effective Mentorship in STEMM (2019); Chapter 6 is specifically devoted to assessment and evaluation.

The and impact of training and mentorship efforts can be measured in a number of ways. Primary investigators (PIs) could be required to submit detailed mentoring plans for any grants that involve recruiting research assistants, post-docs, or similar trainees who might benefit from the research experience, even if they are not funded by the grant. Following this, those trainees could report on their mentoring experiences with their PIs. Relying on just the number of mentees and trainees could provide incentives to maximize the number reported over the quality of the engagement.

Additionally, NIH grant PIs can track their mentees in several ways: replication efforts, grants awarded, and career outcomes. FABBS encourages NIH to consider not just mentees who stay in research, but also those who go into other fields and, nevertheless, have an important impact on public health.

(4) ***Collaboration.***

FABBS applauds NIH's efforts to measure and reward collaboration. Team-based science is essential for maximizing the cumulative nature of science and the potential impact of the research. Furthermore, this research can be time consuming and not as conducive to acceptance in peer review journal articles that tend to be discipline specific. Indeed, a whole field of research exists on team science. In 2025, the National Academy of Sciences published Research and Application in Team Science.

FABBS also encourages the agency to take into account a scientist's community-engaged research, considering how the program involves non-scientists in the research process.

(5) ***Entrepreneurship and Translation.***

Pharmaceuticals and medical devices have clear pathways from basic research to product development. Industry is motivated to bring NIH-funded discoveries to scale when they are able to recoup their expenses and gain a financial profit. Unfortunately, the NIH-funded research and discoveries regarding prevention and reducing chronic diseases do not have the same financial incentives for being taken to scale.

FABBS encourages NIH to consider how to best measure the physical and financial benefits of prevention efforts — how can we measure the money saved and the lives improved when individuals avoid disease and disability thanks to healthy lifestyles and decisions?

NIH can also consider the impact a research program has had on clinical practice. For example, when an oversight body such as APA makes recommendations for how therapists treat certain patients or the American Psychiatric Association revises the Diagnostic and Statistical Manual of Mental Disorders (DSM), what research are they relying on? Can researchers be credited with contributing to clinical practice guidelines if their work is cited by oversight organizations?

NIH has made important advances with implementation science, with credit to behavioral scientists. FABBS encourages NIH to support additional work in implementation science as a key to effectively translating knowledge into health benefits.

(6) ***Foundational Scientific Exploration.***

NIH recently released several notices of funding opportunities (NOFOs) for high-risk, high-reward (HRHR) projects. FABBS noted a significant change in the NOFOs: the reference to behavioral and social science had been systematically removed throughout, including in the routing code used to determine reviewers. This removal narrows the disciplinary range of scientists likely to respond to these NOFOs. FABBS encourages NIH to restore 'behavioral and social' science throughout the NOFOs and most definitely within the list of routing codes.

(7) ***Public Impact.***

To date, the federal health ecosystem has fallen short in translating fundamental knowledge about health into practices and policies that reduce the burdens of illness and disease. NIH is only one part of the federal health infrastructure, yet plays a critical role. NIH could better incentivize researchers to consider and actively engage with the practitioners and policymakers in positions to incorporate knowledge and improve outcomes. Other federal agencies in the health delivery space who benefit greatly from leveraging insights and knowledge made possible by NIH-funded research. FABBS encourages NIH to recognize, measure, and value the impact of its research, as it serves the mission of sister agencies.

New tools exist to capture how governments, think tanks, and policymakers use relevant research to inform their decisions:

- Sage Policy Profiles allows researchers to look up their own research and discover how their work has been used in policy decisions.
- Altmetrics tracks online engagement.

There are also journals dedicated to the policy impact of science (e.g., *Policy Insights from the Behavioral and Brain Sciences*). We urge NIH to consider how other federal agencies use NIH-funded research in their work.

In closing, FABBS strongly supports expanding efforts to measure and reward scientific impact and appreciates the opportunity to comment on these initial categories. As NIH moves forward developing new measures for impact, we encourage the agency to carefully consider how — given the breadth and depth of NIH-funded research — there may be considerable differences across disciplines and research questions. Accordingly, FABBS encourages NIH to continue to engage with the scientific community. We look forward to seeing your progress and providing feedback on the next step in the process.

Thank you again for the opportunity to comment. FABBS would be delighted to be a resource.

Sincerely,

Juliane Baron, Executive Director

239. Springer Nature

I am responding: On behalf of an organization

Name: Kaia Motter

Name of Organization: Springer Nature

Type of Organization: Publisher

Role: Organizational Official

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: Springer Nature welcomes NIH's agency-wide focus on strengthening rigor, reproducibility, and replication as the foundation for gold standard biomedical science. NIH has emphasized that replication and reproducibility are essential to scientific progress, public trust, and the ability of research findings to benefit patients and communities. Springer Nature supports this commitment with infrastructure and peer review services, open access, and insight into researcher motivations and community norms.

Springer Nature already has the necessary infrastructure to ensure that NIH-funded findings are rigorously evaluated, clearly reported, openly accessible where possible, and linked to the underlying research objects. By publishing the results of NIH funded research in our journals, researchers ensure that they are properly archived and preserved as part of a trustworthy scholarly record that can be scrutinized, reused, and built upon over time. We offer analytical capabilities to help NIH identify trends in the literature and measure impact. Public access to NIH funded research, including all research outputs, allows for broader replication, reproducibility, and re-use, and is enabled with centralized open access funding models and proper licensing and attribution. Building on the lessons learned and best practices from fields like social and behavioral science, that have been focused on the replication, robustness and reproducibility of results for many years, saves time and effort. Learning from researchers directly about their motivations and barriers to participation can help shape the NIH's incentive structure and ensure compliance.

Infrastructure
Springer Nature's publishing infrastructure directly supports trustworthy, reproducible biomedical research through editorial oversight, independent peer review, research integrity screening and post publication correction and retraction processes, standardized competing interest and funding disclosure, adherence to the relevant biomedical reporting standards, and mandatory publication of data availability statements. Publication of the Version of Record (VoR) supports NIH's goals because it provides the context necessary to validate the results and ultimately accelerates future replication efforts.

The ability to reproduce and replicate results is enabled by access to clear and informative protocols and methods. In addition to Springer Nature's journal publishing infrastructure, we host the world's large collection of protocols and methods, available on SN Experiments (https://experiments.springernature.com/), which provides a resource for any researcher engaged in

replicating and reproducing research across all subject areas. NIH funded researchers can also benefit from recording their own protocols on protocols.io, which provides institutional plans for funders who wish to collate their efforts in a dedicated repository.

The flagship Nature Portfolio has a history of pioneering reporting initiatives to improve the reproducibility and replication of the research it publishes. In 2013, following a wide-reaching community consultation, that included workshops organized by institutes within the NIH, Nature Portfolio journals mandated authors in the life sciences to provide a checklist (https://www.nature.com/articles/496398a) that reported the key technical and statistical information necessary for referees and readers to assess the reproducibility of their work. Independent analysis by Macleod et al (https://access.portico.org/Portico/auView?auId=ark:%2F27927%2Fphzq8gmxdp1) concluded that this had an immediate and measurable effect on the reproducibility of published research. These requirements were subsequently extended (https://www.nature.com/nature-portfolio/editorial-policies/reporting-standards) to the behavioral and social sciences, evolution and environmental sciences, ecology, and to specific claims in the physical sciences regarding the performance of materials and devices such as lasers and solar cells.

Springer Nature has long advocated for preregistration and the use of the Registered Reports format that prioritize rigorous experimental design over the specific implications of the results those experiments lead to. This approach seeks to address concerns about so-called publication bias in which papers that report seemingly interesting results are more likely to be published than papers whose methodologies are rigorous. The use of this format has historically been limited to behavioral and social sciences as well as the life sciences. Recently, Nature expanded the scope of the format (https://www.nature.com/articles/d41586-026-01629-y) to allow them to be submitted from any scientific discipline.

As NIH considers strategies for identifying new areas to expand replication and reproducibility efforts, the Agency can look to evidence from the increased adoption of reporting tools such as registered reports or checklists beyond the behavioral and social sciences to review any discipline specific modifications they may need to be made.

Public Access
53% of the primary research published at Springer Nature is now open access (https://stories.springernature.com/oa-report-2025/index.html). Open access publication continues to deliver impact through unrestricted engagement and licensed re-use of our machine-readable research publications. Open access delivers higher rates of citations (policy, patent, and article citations) and expanded media references. Public access is an essential component of all reproducibility and replication work and increasingly AI tools can be applied to investigate citations that have been supported or contradicted by later research, e.g. tools like scite.ai.

NIH can accelerate progress towards greater reproducibility and replication by treating scholarly communication, research integrity workflows, and long-term stewardship of the scientific record as a necessary part of the national biomedical research infrastructure and making results publicly accessible. However, peer review services are an essential component of the validation of results and without the

necessary funding, trust and integrity are compromised. Grant policies and budgets should allow researchers to plan and pay for high-quality peer reviewed publication, data and code curation, protocol sharing, and preservation in ways that advance rigor, transparency, and reuse.

Behavior and Incentives

To create incentives, NIH should recognize replication studies, null hypotheses, preregistration, reusable datasets, software, protocols, and other open science contributions as valued research outputs. Springer Nature already provides publication platforms and infrastructure to support many of these practices, including journals that publish null hypotheses and replication studies, dedicated data journals such as Scientific Data and BMC Research Notes, as well as data article formats. DOI assignment to a broad range of research outputs ensures NIH researchers receive the credit and acknowledgement they deserve. These mechanisms can help NIH reward researchers who strengthen the reliability of the biomedical evidence base, not only those who produce novel positive findings.

Springer Nature publishes over 3,000 peer reviewed scholarly research journals, working with 180,000 + academic editors to publish over 500,000 articles per year. For nearly two centuries, Springer Nature has supported the communication and dissemination of American science and over time we have learned a lot about author behavior. Springer Nature has always been at the forefront of open science innovation and has piloted many open science initiatives. These initiatives have helped us to better understand the impact of funder policy on compliance, the motivation of researchers to adopt the open sharing of research artefacts across disciplines, and barriers to participation and adoption. In addition, we periodically conduct large scale surveys of the researchers who publish with us to better understand their attitudes related to open science policy, research assessment, and research integrity training and practices. If NIH wants to develop incentives to support the reproduction and replication of existing findings, there are valuable insights to be gained from collaboration with the publishers who support researchers in the dissemination of the research outputs. Recent results from our State of Research Assessment survey (https://stories.springernature.com/state-of-research-assessment/index.html) and our 2026 Research Leaders survey (https://www.nature.com/nature-index/about-research-leaders-survey-2026) as well as our State of Open Data report (https://stateofopendata.com/) and State of Null Results report (https://stories.springernature.com/the-state-of-null-results-white-paper/index.html), contain insights into what motivates researchers, what they value, but also about what is preventing them from fully participating in the advancement of science and sharing of results. This could help inform the way NIH structures its approach to incentives.

In terms of community norms and disciplinary trends, NIH could learn from work that has been done within key subject disciplines that advance the Agency's understanding of the impact of policy interventions and best practices. Springer Nature explored progress in replication and reproducibility in the field of social and behavioral science earlier this year, publishing a collection of articles that shed insight on the challenges that exist and how we can address them. The journal Nature Human Behaviour recently partnered with the Institute for Replication (https://www.nature.com/articles/s41562-024-01818-7) to attempt the reproduction and replication of papers published in the journal from 2023 onward, at scale. This effort is currently underway, but we would be happy to share the results as soon as they're available.

We recognize the benefits of highlighting replication efforts, which are often buried amongst other research findings, to amplify individual contributions and enhance recognition and reward. We do this by aggregating research findings and hosting them on an accessible, discoverable platform. Our most recent example can be found here. Platforms that recognize individual efforts encourage researchers to share their results which is a powerful incentive.

Springer Nature is well positioned to partner with NIH to drive, incentivize, and institutionalize replication and reproducibility across the biomedical research enterprise. Through sustained investment in the infrastructure that supports trustworthy scholarly communication, Springer Nature can help NIH reduce administrative burden, scale good practices, and embed reproducibility throughout the research lifecycle.

A partnership with NIH would build on existing infrastructure and experience rather than duplicating it, helping NIH maximize the reliability, reach, and public impact of the research it funds.

2. Data, Software, and Model Sharing: Springer Nature is committed to providing a variety of high-quality, peer-reviewed journals that offer immediate, free public access to the final published article—the Version of Record (VoR).

Access to the VoR enables access to the research artefacts generated throughout a study and strengthens confidence in research results and conclusions through transparency and openness—the cornerstones of Gold Standard Science. We are well equipped to support immediate access to the full spectrum of NIH-funded research results in the following ways:

- Open access article publication in our hybrid and fully open access journals provides immediate public access, impact, and discoverability for the VoR, while enabling immediate deposit of the VoR to Agency repositories.
- Automated submission integrations with Research Square (preprints), Figshare (data), protocols.io (protocols), and Code Ocean (code) connect research outputs from every stage of the research lifecycle to the VoR and allow researchers to receive credit for their work. Linking the VoR to related data, code, protocols, and other outputs supports trust and effective reuse.
- Introduction of a standard Research Data policy for journals and books that requires publication of a Data Availability Statement. We are currently piloting cutting-edge automation to help authors develop statements that include the context needed to support reproducibility and replication. In addition, our AI-assisted data deposition workflow, currently being piloted on Nature Communications and Scientific Reports, will remove a significant administrative burden for authors who need data deposition support.
- Outlets for “sound science” publication outputs, including null hypotheses and preliminary results, through the BMC Series, Scientific Reports, and the recently launched Discover and Cureus journals.
- Publication and citation of high-value research data through dedicated data journals and data articles, including Scientific Data and BMC Research Notes, help address the credit gap for data sharing.

Together, these integrations, tools, and publication platforms provide resources that facilitate reproducibility and replication, where provenance and trust indicators must be reliable, interlinked, and machine-readable.

Springer Nature provides the infrastructure and services that enable NIH-funded researchers to share

scientific results with the necessary context and validation. Persistent identifiers, uniform data and software citation practices, and metadata standards set by industry bodies like NISO, RDA, and others allow NIH to track compliance consistently while expanding opportunities for attribution and recognition of individual research contributions. Repository and database integrations, along with bidirectional linking through the VoR, support version control and uphold trust in the integrity of the scientific record. Publishers have spent years investing in infrastructure to support interlinked research objects, as well as technologies that automate deposition activities and reduce administrative burdens. We are committed to FAIR principles and to licensing agreements that accelerate discovery while ensuring that necessary legal and ethical guardrails are in place.

Springer Nature's State of Open Data report outlines many of the barriers that prevent researchers from sharing all of their research outputs. NIH could help remove some of these obstacles by directing its attention to the administrative burdens that policy mandates impose on researchers and authors across the system, while also supporting appropriate incentive structures.

3. Training and Mentorship: In 2019, Nature hosted a meeting of stakeholders from across the Australian research community—including representatives from business, government bodies, universities, research institutes, and funding organizations—to discuss research integrity and good research practices. One of the most striking outcomes of the meeting was the recognition that little was known about researchers' level of understanding of research integrity, the training available to them, or the data needed to assess that training. This led Springer Nature to launch a series of surveys of researchers in different parts of the world to address this knowledge gap. These surveys were also intended to provide a baseline for the level of support researchers currently have access to at a time when improving research integrity is an increasing priority for stakeholders across the research ecosystem.

Between 2021 and 2024, Springer Nature surveyed (https://doi.org/10.6084/m9.figshare.29100596.v1) 7,871 researchers across Australia (993), the UK (1,078), the U.S. (1,962), India (659), Japan (1,190), China (1,008), and Brazil (981). Respondents in China (79%), Japan (73%), and Australia (68%) reported the greatest access to research integrity training. In Brazil, the proportion of respondents reporting access to training was substantially lower (27%). Just over half of respondents in the U.S. (56%), India (53%), and the UK (51%) reported having access to research integrity training.

Across countries, the overwhelming majority of respondents (84–94%) supported mandatory research integrity training at some point in a researcher's career. In many countries—particularly Australia, the U.S., the UK, and Brazil—researchers expressed interest in additional training on the curation and sharing of research data. Many respondents also expressed concern that the training they received was not tailored to the immediate needs of their research practice and functioned more as a box-ticking exercise for their institutions.

Springer Nature has used these results to open conversations with stakeholders across the research community about how to better support researchers in understanding best practices and conducting research with integrity. This work has led to the development of a suite of courses offered at no cost to editors, referees, and researchers, including a course on the fundamentals of research integrity (https://www.springernature.com/gp/authors/campaigns/research-integrity-course) and a course in publication ethics (https://www.nature.com/masterclasses/publication-ethics/52046828).

Since 2005, the annual Nature Awards for Mentoring in Science (https://www.nature.com/nature/awards/mentorship) have recognized and celebrated outstanding contributions by those who support early-career researchers in their scientific development.

NIH might consider the results of our survey as the Agency evaluates its current training program, especially as they to research integrity and data curation, and supplement its internal training program with externally available resources.

4. Collaboration: Not all collaborations result in publications, and not all publications include every contributor to a collaboration. However, publications provide one approach for assessing and recognizing both individual and team-based scientific contributions.

Springer Nature journals support both consortia authorship and team-based scientific collaborations, as well as individual author contribution statements, in ways that ensure roles and responsibilities are clearly and transparently acknowledged, and credit is assigned where credit is due.

The CRediT (Contributor Roles Taxonomy) offers another way to list author contributions across various research outputs, including preprints, data sets, and peer-reviewed journal articles. There are numerous tools that can help organize and record the methods and results of collaboration, including electronic lab notebooks and protocols.io, which allow researchers to be more productive, improve collaboration and recordkeeping, and foster a culture of transparency and accountability. NIH should encourage the use of these tools and taxonomies to track and acknowledge research collaborations resulting from NIH funding.

New forms of cross-sector and community-engaged research will drive local and regional public impact, workforce development, and commercial innovation. The results of these collaborations should be documented, preserved in the scholarly record, and made publicly accessible for the benefit of society. These collaborations may take more time to develop and execute to ensure that all participants endorse the terms of the collaboration and plans for disseminating the results, but documenting this process and its outcomes will ultimately uphold trust in the scientific enterprise.

NIH can encourage and reward team science and other forms of community-engaged research by creating funding models that specifically incentivize this type of research and require publication of results. This would help build a corpus of work that supports best practices and smooths the pathway to replication and reproducibility.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: NIH has an important opportunity to broaden how it assesses and recognizes the public impact of biomedical research. Rather than relying primarily on traditional impact metrics, such as the Impact Factor, NIH could adopt a more holistic, evidence-based framework that captures how research improves health, informs clinical practice, strengthens public trust, supports economic growth, and delivers societal benefit. This is not an easy task, as many of these outcomes are difficult to measure

quantitatively. However, journal and article-level impact analysis can offer useful insights.

For NIH-funded research to have public impact, findings must be rigorous, trusted, discoverable, accessible, reusable, and connected to the broader evidence base. Public benefit is realized not simply when research is completed, but when validated findings can be linked to real-world outcomes, such as improved quality of life, health policy, successful drug development, and informed patients. NIH should assess impact throughout every stage of the research lifecycle, including post-publication application and reuse.

The published Version of Record (VoR) is the foundation of trust on which impact is built. It allows the public to access and verify research results, understand the peer-review model, examine competing interests and sources of funding, and confirm that appropriate ethical and reporting standards were followed. These features are critical trust signals for clinicians, policymakers, researchers, patients, journalists, AI systems, and the public. Without them, it becomes harder to distinguish validated biomedical knowledge from unverified claims, increasing the risk that inaccurate or incomplete information will be amplified as evidence.

Metrics and Measurement

NIH should develop an impact framework that combines quantitative indicators with qualitative impact narratives. Traditional citation measures remain useful for understanding scholarly uptake, but they should be complemented by indicators that better reflect real-world impact. Quantitative measures might include replication and reproducibility outcomes; citations in clinical guidelines, patents, or policy documents; clinical trial registrations; media references; or other citation-based metrics that can be measured in a standardized way across the published scholarly record. Qualitative measures, or real-world outcomes, are more difficult to assess and fall outside the realm of our expertise, but we would encourage NIH to explore options with local and community leaders, patient advocacy groups, and other key stakeholders who can help expand qualitative measurement of NIH-funded research. NIH should look for evidence of downstream health outcomes, economic activity, workforce development, community benefit, or improved public understanding. At the same time, NIH should recognize that public impact is not always immediately quantifiable. Some impacts are immediate, such as public access to findings or reuse of a dataset. Others may take years to emerge, such as changes in clinical practice or policy, development of a therapeutic application, or measurable improvements in population health. NIH should therefore avoid a one-size-fits-all metric and instead use field-appropriate indicators, transparent evaluation criteria, and flexible narrative reporting that allows investigators to describe the pathway from research output to public benefit.

Traditionally, research impact in academic environments has been measured through journal citation metrics. However, Springer Nature recognizes the need for a more holistic approach to impact analysis, one that includes measures of engagement, patent and policy citation, and other metrics that allow funders and institutions to quantify socio-economic impact.

Springer Nature is well positioned to support NIH in developing and piloting expanded measures of impact. As a publishing partner for biomedical and related research, Springer Nature's experience with impact analysis—including approaches that examine engagement, patent and policy citation, open data

sharing, and impact narratives—could help NIH develop practical models for assessing returns on public research investments without relying narrowly on publication counts or journal-level metrics.
Our Impact Solutions team is developing bespoke impact narrative reporting and tools for funders and institutions to help them measure the impact of the research they have funded and their return on investment (ROI). An example of a recent project measuring socio-economic impact through article-level analysis can be found in our "From Publications to Policy" report (https://stories.springernature.com/sdg-impact-report/executive-summary/index.html), produced in collaboration with Overton. In 2024, we conducted a similar exercise (https://doi.org/10.6084/m9.figshare.27337476.v2) in partnership with Digital Science, using analysis of open data sharing to quantify policy impact.

To better align with DORA principles, Springer Nature publishes up-to-date article-level metrics, including citations and other engagement metrics. Authors can reference this data in grant applications, and funders can use it to track research impact.

Science Communication
Clear, targeted scientific and medical communication is essential to achieving public impact. When research is communicated appropriately to the relevant audience, it is more likely to be understood and trusted. Peer-reviewed scientific and medical literature is often not accessible, or easily understandable, to the public, patients, journalists, policymakers, or even non-specialist healthcare professionals who could benefit from the information. Springer Nature has recognized this challenge and taken steps to make research more accessible to the broader community. We have developed several models that improve the communication of biomedical results by synthesizing key findings and making them accessible to patients, practitioners, and members of the public who wish to better understand the science. Within our medical and health science journals, including the Adis journals, we encourage the publication of Plain Language Summaries (PLS) and Summaries of Research Articles (SRA) (https://link.springer.com/collections/bfgfdabjig). PLSs are peer reviewed as part of the source article and are subsequently indexed in PubMed. SRAs are standalone summaries of the source article that are assigned a DOI and indexed in PubMed. They are intended to be read quickly and understood by a wider, non-specialist audience, primarily healthcare professionals (HCPs). These publications are curated in collections that increase discoverability, access, and visibility for the authors who produce them, which encourages participation and broader recognition. SRAs also increase engagement with the source article. In addition, we have been experimenting with AI-generated video summaries that ensure scientific accuracy through an essential author validation process. Our experience thus far is that these initiatives have had a strong impact on article engagement—usage, citations, and Altmetric references—all meaningful indicators of broader impact.

Many researchers and clinicians are experimenting with alternative modes of communication and article types that translate complex scientific results and make them accessible through podcasts, vodcasts, blog posts, and social media posts. Many Springer Nature publications support these forms of communication, including targeted Patient/Physician Perspectives. Several of our journals include patient authors who incorporate evidence of public impact through real-world, lived patient experience. Policymakers are another important stakeholder in the research funding ecosystem, but they may require a narrative style that differs from communication intended for journalists or patients, for

example. With this in mind, several Nature journals have developed a document type called the Policy Brief, which is specifically designed for policymakers and contains the key information needed to communicate effectively and clearly with that audience. Examples are available here in Nature Energy. Springer Nature has also developed new AI tools to make science more accessible to non-specialist readers. The Nature Research Assistant (https://natureresearchassistant.com/), a reading assistant currently in beta, allows readers to quickly understand material, chat in real time, and obtain detailed descriptions of each figure. We are also piloting a "Chat with Article" feature across some of the Discover journals (open access), which allows users to ask questions, explore key concepts, and summarize findings directly alongside the full-text source article.

While there is no replacement for the peer-reviewed journal article as the foundation of scientific communication, NIH could consider recognizing and rewarding researchers who successfully communicate their research beyond the biomedical community and achieve public impact through expanded modes of communication. These may include approaches that incorporate the perspectives of patients, for example, or tailor communication to specific target audiences. NIH-funded researchers would receive credit and acknowledgement through DOI assignment, which enables article types such as SRAs to be linked to VoR and the author's profile. NIH can also easily track these outputs through indexing in PubMed and the use of persistent identifiers.

Our research assessment survey results indicate that researchers would like greater recognition for work that has societal and public impact. NIH is well positioned to recognize and reward these activities through the proper incentive structure.

NIH's replication and reproducibility efforts should be treated as central to public impact assessment. Reliable biomedical research is foundational to public trust and to ensuring that findings can ultimately benefit patients and communities.

NIH should also ensure that public impact measures account for the range of outputs from biomedical research. Foundational, preclinical, translational, clinical, population health, behavioral, data science, and implementation research may produce different forms of impact over different time horizons.

Finally, NIH should align recognition and funding mechanisms with the behaviors it seeks to encourage. If NIH wants publicly funded biomedical research to be trusted, accessible, reproducible, and useful, then grant policies, review criteria, progress reporting, and career incentives should recognize the full range of contributions that make impact possible. This includes not only novel and groundbreaking discoveries, but also data stewardship, replication studies, null hypotheses, methods development, and community or patient engagement. By treating these activities as essential to public impact rather than as ancillary dissemination costs, NIH can strengthen public trust, improve the reliability of biomedical evidence, accelerate translation into practice, and maximize the return on taxpayer investment in medical research.

8. Other Areas: Springer Nature appreciates the opportunity to comment on NIH's Request for Information on Measuring and Rewarding Scientific Impact. Research assessment reform and expanded measures of impact are key priorities for us, and we are eager to support NIH in this effort.

We encourage NIH to consider the following three high-level recommendations as the Agency takes steps to address the areas outlined in this RFI:

• Springer Nature urges NIH to partner with academic institutions, publishers, and community stakeholders, rather than acting in isolation. We encourage NIH to learn from best practices and feedback from the research community and to take advantage of existing infrastructure, analytical capabilities, and industry standards that can ensure consistency and reduce administrative burden.
• We encourage NIH to develop incentive structures that reward a broader range of research outputs in addition to rewarding behaviors and practices that support the ethical sharing of results, stakeholder consultation, openness, transparency, and cross-border and cross-sector collaboration with trusted allies and industry partners. These collaborations should respect copyright frameworks.
• The NIH recognizes the benefits of public access to taxpayer funded results, but this should come with a commensurate recognition of the need for adequate funding to support peer review, quality control services, and trust in the scientific record. Publication of the peer-reviewed Version of Record helps mitigate version-control issues and provides a hub for interlinked research outputs across the research lifecycle.

Cultivating a healthy and productive research culture requires a shared and unified commitment from stakeholders across the U.S. research ecosystem. We look forward to partnering with NIH and working with NIH-funded researchers who publish in our books and journals to help achieve the Agency's goals.

240. The Alliance for Longevity Initiatives (A4LI)

I am responding: On behalf of an organization

Name: Brenda Eap

Name of Organization: The Alliance for Longevity Initiatives (A4LI)

Type of Organization: Non-Profit Research Organization

Role: Research Participant/Patient/Advocate/Caregiver

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: A. Key Bottlenecks
1) Publication Saturation vs. Translational Reality: Standard metrics reward publication volume in hyper-explored pathways (>1,000 papers in 5 years) while actively penalizing underexplored, high-risk research questions and deep mechanistic characterization.

2) Systemic Bias Against Null/Negative Results: Academic publishing imposes a substantially higher barrier to publication for null findings in aging biology and disease-modifying assays compared to positive outcomes. Researchers face demands for disproportionate secondary validation, lower impact venues, and prolonged review cycles for negative data—creating a strong structural disincentive to report null outcomes and leading to the costly, wasteful duplication of unviable experiments across labs.

B. Measurable Indicators & Recommendations

1) Mandatory Public Negative Results Archive: Establish a central, publicly accessible, and searchable NIH repository requiring grantees to archive negative and null experimental outcomes. To incentivize adoption, NIH must formally recognize documented repository submissions as valid, citable scientific contributions equivalent to traditional journal publications. Additionally, instruct the Center for Scientific Review (CSR) to award positive scoring modifiers under "Investigator" and "Environment" criteria for PIs who routinely deposit pre-registered protocols, negative findings, and open-access datasets.

2) RPPR Modernization for Non-Traditional Scientific Outputs: Update annual Research Performance Progress Report (RPPR) reporting guidelines—specifically under Section C (Products) and Section B (Accomplishments) to explicitly instruct grantees on how to report pre-registered protocols, published null/negative results, and open-access dataset depositions. Program Officers should be directed to evaluate these documented rigor outputs as formal metrics of scientific success during annual progress reviews and grant renewals, ensuring PIs receive official credit even before or in lieu of traditional journal publication.

3) Standard Pre-Registered Verification Tracks: Create explicit, ring-fenced funding mechanisms—such as a dedicated "R-Verify" grant track (R21 or U-series variants)—for independent protocol replication. Expand multi-site animal and cellular intervention pipelines (modeled after the NIA ITP, CITP, and Nathan Shock Centers of Excellence) that evaluate studies based on the translational importance of the original

claim and statistical power rather than novelty.

4) T32 "Hands-On Replication Modules": Modernize institutional training grants by incorporating mandatory "Hands-On Replication Modules," requiring trainees to execute and archive pre-registered replication studies of core field findings. Evaluate T32 renewal applications based on program open-data deposition rates and trainee-led null/replication publications to align institutional incentives with scientific integrity.

5) Career Development for Rigor Specialists: Establish specialized career transition awards (K99/R00 alternatives) dedicated to early-career researchers who specialize in quantitative validation, cross-lab verification, methodology development, and open-dataset curation.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: A. Key Bottleneck: Academic training pathways over-emphasize traditional publication metrics while under-preparing trainees for the full career ecosystem of biomedical translation—including science policy, regulatory affairs, technology transfer, public health, and entrepreneurship.

B. Measurable Indicators & Recommendations

1) Translational & Policy Summer Experiential Grants: Expand institutional training and short-term research education grants (e.g., R25, T35, or administrative supplements to T32s) to fund 8- to 12-week off-site summer immersion fellowships. Modeled on successful programs like the NIA Summer Training in Aging Research (STAR) program, these funded tracks would place graduate and postdoctoral trainees directly inside federal policy offices (e.g., OSTP, FDA, Congressional committees), venture funds, regulatory consulting firms, or biotech startups to gain hands-on translational competencies outside traditional academic labs.

2) Intramural Research Program (IRP) Modernization: Restructure the Intramural Research Program by shifting from indefinite tenure models toward fixed-term, high-impact appointments. IRP scientists should be measured on landmark, risk-tolerant scientific advances and trainee placement into interdisciplinary translational leadership roles.

4. Collaboration: A. Key Bottleneck: Institutional & Review Barriers to Team Science: NIH scoring frameworks remain optimized for isolated single-PI or parallel sub-award models. These mechanisms discourage true multi-institutional integration, penalize complex interdisciplinary designs, and offer no structural financial incentives for senior PIs to co-lead grants with junior researchers.

B. Measurable Indicators & Recommendation
1) Cross-Disease & Cross-IC Synergy Score: Reward proposals that demonstrate cross-cutting mechanisms (e.g., targeting cellular senescence or metabolic dysfunction common to cancer, neurodegeneration, and cardiovascular disease simultaneously).

2) IDeA State Satellite & Pilot Project Requirements for Center Grants: Mandate or heavily weight collaborative satellite/pilot project funding within major center and program awards (e.g., P01s, U54s,

ADRCs). Requiring these large infrastructure awards to formalize sub-award or pilot partnerships with institutions in Institutional Development Award (IDeA) states will drive geographic funding distribution away from coastal concentration and build sustainable regional capacity.

3) MPI Protection & ESI-Co-MPI Expansion: Ensure that any proposed PI grant limits explicitly exclude or weight co-MPI awards that pair an established senior PI with an Early Stage Investigator (ESI). To incentivize genuine co-leadership without penalizing overall PI grant capacity, provide an expanded direct-cost ceiling (e.g., an additional $50,000–$100,000/year) for applications where the junior PI manages an independent sub-budget (minimum 30% of direct costs).

5. Entrepreneurship and Translation: A. Key Bottleneck: The SBIR/STTR application process remains excessively slow and structurally misaligned with private capital deployment cycles. While NIH has introduced Entrepreneur-in-Residence (EIR) programs and mentorship networks (e.g., SEED), these figures serve in purely advisory capacities without budget authority, direct grant oversight, or selection power. As a result, commercialization awards are still evaluated and managed by traditional academic study sections and career program officers who lack direct venture, industry, or regulatory execution experience—leading high-potential biotech spinouts to view NIH non-dilutive funding as inefficient compared to private capital.

1) SBIR/STTR Centralization & Venture-Experienced Program Directors: Shift EIRs and venture experts from peripheral advisory roles into formal Program Director/Manager positions with explicit budget authority and milestone-based award power (modeled after DARPA/ARPA-H PMs). Centralize SBIR/STTR program administration into a unified office staffed by leaders with proven private-sector, venture, or biotech drug development experience.

2) FDA-NIH Joint Taskforce on Preventive Therapeutics: Mandate direct structural coordination between NIH translational divisions and the FDA to formalize approval pathways, surrogate biomarkers, and composite clinical trial endpoints for therapies targeting common age-related disease drivers and multi-morbidity mechanisms.

3) Expedited Review for Trained Commercializers: Provide streamlined grant review considerations and expedited turnaround times for academic investigators who complete NIH-recognized entrepreneurship accelerator modules (e.g., I-Corps or institute-backed commercialization bootcamps) before applying for commercialization funding (SBIR/STTR).

6. Foundational Scientific Exploration: A. Key Bottleneck: Study sections systematically penalize high-risk, paradigm-shifting proposals in favor of incremental extensions of established findings. This risk aversion is compounded by the NIH's organ- and disease-specific IC structure, which lacks dedicated mechanisms to fund foundational biology that spans multiple chronic disease pathways simultaneously.

B. Measurable Indicators & Recommendations
1) Dual-Stage "Anonymized Concept" Review for High-Risk Junior Awards: Establish a mandatory two-stage review process for high-risk seed mechanisms targeting Early Stage Investigators (ESIs). In Stage 1, study sections evaluate and score a 3-page conceptual grant proposal anonymously—strictly stripped of PI name, institutional affiliation, and publishing history—focusing solely on the transformative potential

and logic of the hypothesis. Only applications scoring in the top percentile advance to Stage 2, where feasibility and environment are assessed, effectively removing the "trust factor" penalty from initial concept evaluation.

2) Expansion of "Preliminary-Data-Free" Junior Mechanisms: Expand preliminary-data-exempt mechanisms (modeled on the Director's New Innovator Award - DP2) specifically tailored for early-career researchers testing paradigm-shifting hypotheses. Reviewers for these tracks must be formally instructed to evaluate logic, feasibility of design, and potential impact rather than demanding extensive preliminary datasets that junior labs lack the capital to generate.

3) Cross-Institute Geroscience & Foundational Consortia: Establish formal, co-funded Cross-Institute Consortia (jointly funded by ICs such as NIA, NHLBI, NCI, and NINDS) equipped with dedicated, ring-fenced grant budgets and specialized review panels. These consortia would explicitly evaluate and fund foundational research targeting common biological mechanisms of aging and tissue dysfunction across multiple disease silos, insulating cross-cutting, high-risk hypotheses from standard organ-specific study section bias.

4) Structural Realignment via NIHLAR: Establish a dedicated National Institute for Healthy Longevity and Aging Research (NIHLAR) to concentrate geroscience, healthspan extension, and foundational aging biology into a unified institute. Establishing NIHLAR decouples foundational preventive biology from organ-specific disease silos, ensuring bold, transformative hypotheses receive focused peer review, targeted appropriations, and dedicated leadership.

7. Public Impact: A. Key Bottleneck: Grants are rarely re-evaluated dynamically during their funding lifecycle, resulting in sustained funding for stagnated or redundant programs.
B. Measurable Indicators & Recommendations

1) Standardized Grant Evaluation Criteria (Allocation Scoring): Evaluate incoming proposals using a strict 1–9 scoring matrix across 5 actionable dimensions:
a. Publication Saturation vs. Translational Gap: Penalizes over-explored, low-yield pathways; prioritizes underexplored targets.
b. Novelty in Mechanism or Concept: Evaluates cross-disease relevance and non-canonical pathways.
c. Technology & Translational Innovation: Assesses tech integration (AI, digital phenotyping, novel delivery).
d. Collaboration & Reproducibility: Requires multi-institutional rigor and open science commitments.
e. Clinical Trial / Adoption Path: Requires realistic regulatory and public health implementation milestones.

8. Other Areas: N/A

Description: Submitting on behalf of the Alliance for Longevity Initiatives in response to NIH RFI NOT-OD-26-087. Our comments offer concrete policy recommendations to modernize NIH funding incentives, eliminate structural biases and siloed research for understanding the complexity of human health and disease. Our goal is to align NIH’s mission with more novel funding mechanisms to support next generation scientists, policymakers, and entrepreneurs so they can scale real-world outcomes.

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: • Replication findings must be discoverable to deliver value.
The value of replication research depends on its discoverability. Replication evidence that cannot be found, by researchers, systematic reviewers, knowledge curators, or increasingly by AI systems, cannot correct the record or inform future work. Our work shows there's a gap in surfacing replication information across multiple knowledge channels. At the same time, AI shows promise as a new route for bringing replication evidence to users even without being explicitly prompted to look for it.

We propose following metrics to measure the discoverability and practical impact of replication studies:

• Retrievability rate for replication studies
The "retrievability rate" simply asks: if you go looking for the replication evidence, can you actually find it? Concretely, it would be measured by taking a sample of original findings subject to NIH-funded replication attempts, searching for each one the way an ordinary user would (search the claim or the study in Google, Google scholar, and AI assistants), and checking whether the replication evidence surfaces in the results. The retrievability rate is the percentage of cases where it does. If NIH funds 100 replications and only 30 can be found this way a year later, the rate is 30%, and NIH knows 70% of its investment is effectively invisible.

• Knowledge correction rate for *failed* replications:
For failed replications, it is especially important to track whether new replication evidence is incorporated into both academic and public knowledge.
Does citation to the original finding decline, in academic, policy, and media publications?
Are replication findings always co-cited with the original finding, in academic, policy, and media publications?
For live public knowledge channels (wikipedia, textbooks and AI etc.) that mention the original finding, what % updates in response to new replication information?
Detailed methods are provided in the attached paper of ours.
Additional information:
• Simple mechanisms for make replication discoverable: broad internet presence
We found that replication records presented as simple text on a single webpage (e.g., FORRT Reversals & Replications) are much more likely to be surfaced than those available only through complex databases

or journal articles. Such webpages are easier for search engines and AI systems to index, increasing the chances that replication evidence will eventually reach relevant researchers, practitioners, and educators. By extension, even researchers simply posting their replication findings on a personal webpage may make them more visible than leaving them buried in databases or journal publications. In addition, large-scale replication projects (e.g., the Reproducibility Project: Psychology) that test multiple phenomena are especially vulnerable to discoverability failure. Individual replication outcomes are subsumed within aggregate statistics and a single publication, making them invisible to anyone searching for evidence on a specific original finding.

• Action: funders should require dissemination beyond journal publication
NIH should mandate and fund dissemination for replication studies it supports. Grantees conducting replications should be required to disseminate findings beyond journal publications. Preferred methods include publishing accessible summaries on project websites and depositing results in curated replication databases like FORRT. NIH should also require that multi-study replication projects report each constituent replication as individual records (e.g., one entry per original claim), so that evidence about any given finding can be located directly.

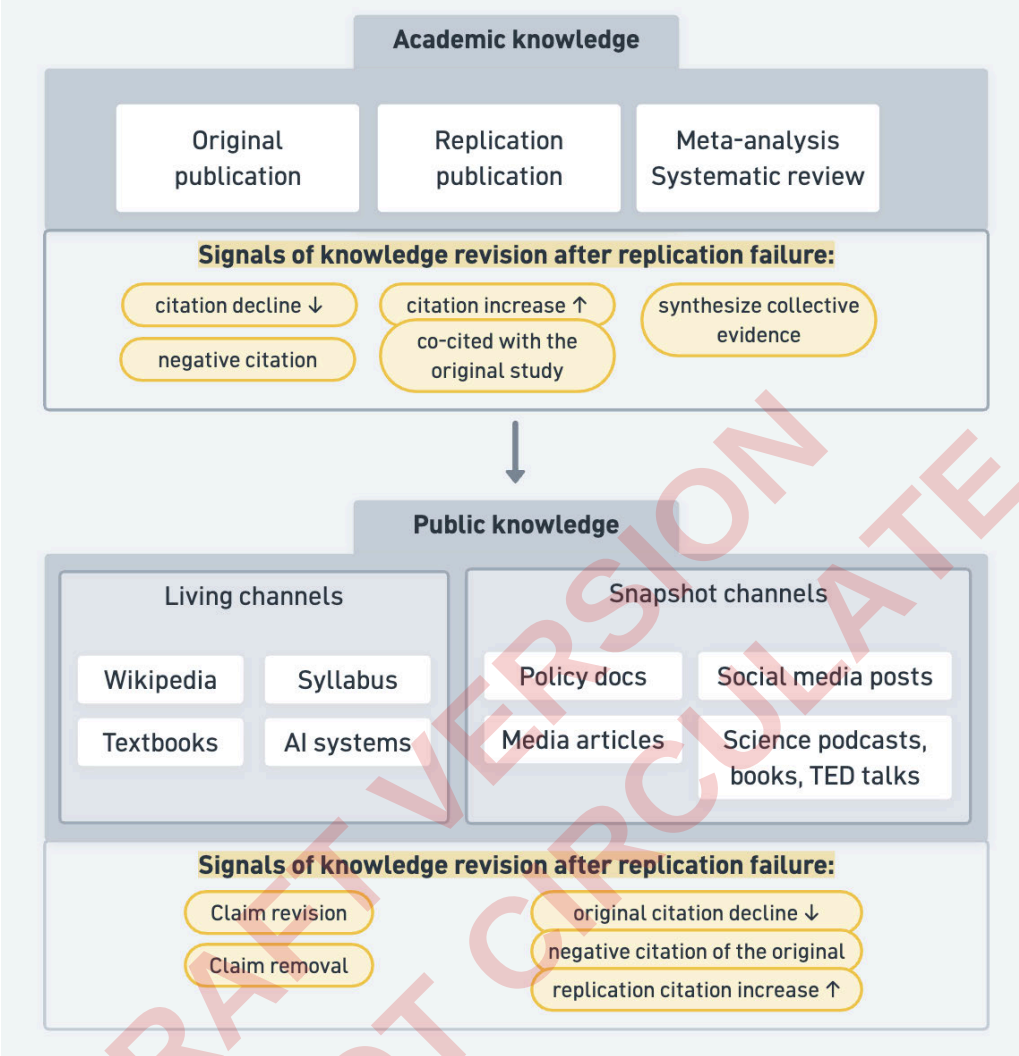
Description: associated research paper

Title: Are replication failures reflected in public knowledge?
Authors: Wu Youyou, Yang Yang, Brian Uzzi
Keywords*:* replicability, science communication, AI for science

Abstract:
Behavioural science now routinely replicates and verifies published findings. Replication is a powerful mechanism for science to self-correct, but it is only the first step. New evidence must also reach researchers, students, and the public and update their understanding. Within academic scholarship, there is some evidence that failed replications have led to reduced citations of the original studies. Far less is known about how many non-replicable findings continue to circulate through mainstream channels through which students and the public access knowledge. This study tracked research findings with well-established replication failures and assessed whether three public knowledge channels revised their content in response. We also queried two AI platforms about the original findings to assess whether their responses reflected new replication evidence. Traditional channels including Wikipedia, textbooks, and university course syllabi, acknowledged replication failures roughly one-third of the time, which was higher than researchers' predictions in a preregistered survey. AI systems performed substantially better: ChatGPT acknowledged replication failures for up to 80% of findings, rising to 95% among findings with high online visibility. We also discovered that such knowledge revision was more likely to occur when replication records appeared on a simple, openly accessible webpage, and less likely when buried within large-scale replication projects. These findings suggest that scientific self correction depends not only on producing replication evidence, but also on making that evidence easy to find. We recommend that researchers and funders invest in dissemination to help replication evidence reach the public.



DRAFT VERSION
DO NOT CIRCULATE

Introduction

More than a decade ago, *Science* published a landmark study showing that fewer than half of 100 psychology findings replicated (OSC, 2015). The result sparked widespread attention to the replicability of science and inspired replication efforts across disciplines. Most recently, *Nature* published a series of papers examining the replicability and robustness of 3,900 studies across the social and behavioural sciences. They again found that roughly half of findings failed to replicate (Tyner et al., 2026).

Yet conducting replications is only a starting point of science's self-correction process. Replication findings must then ripple downstream, updating academic discourse and ultimately shaping public understanding. Figure 1 illustrates how knowledge revision should theoretically occur following a replication failure, and how the outcome can be empirically observed.

Figure 1. The knowledge revision pipeline: how replication failures can propagate through academic and public knowledge channels

DRAFT VERSION DO NOT CIRCULATE

Within academic d scourse, knowledge revision may be signalled by declining citations of the original paper, increased cita ons f the replication paper, or co-citation of both. Several studies have directly examined the citation impact of replication failures (e.g., Clark et al., 2023). The effects vary by analyt cal approach, ranging from modest citation declines following a replication failure to no detectable change.

Beyond academia, new replication evidence should also update what the public and students learn. We distinguish between two types of public knowledge channels: snapshot channels (e.g., media reports, policy documents, and social media posts) capture information at a single point in time and are rarely revised; living channels (e.g., Wikipedia, textbooks, and AI systems) can be revised as new evidence emerges.

To our knowledge, no study has examined whether replication failures propagate across public knowledge channels. We aim to address that gap. In our view, a robust replication failure does not automatically invalidate the original study, but it should be acknowledged and incorporated into accounts of the topic.

The current paper will focus on living channels like Wikipedia because they provide a clear, binary signal of knowledge revision. For each mention of the original study, we measure whether the replication failure has been acknowledged or not. We did not focus on snapshot channels such as media reports because of data and methodological limitations. Since individual records are rarely revised, knowledge revision must instead be inferred from citation patterns over time (e.g., Clark et al., 2023). This approach relies on sustained attention to the original paper, which is typical in academic literature but rare in public knowledge channels. Supplementary Text 1 provides a more detailed explanation.

Methods

Our sample of replication records came from the Framework for Open and Reproducible Research Training (FORRT, Hartmann et al., 2025). The FORRT Replication Databa e (FReD) is among the most comprehensive repositories of original papers and their replication outcomes in the social, cognitive, and behavioural sciences. Vo unteers continuously recorded references, phenomenon descriptions, and effect sizes for both original and replication papers. We drew additional replication records from a predecessor project “FORRT Replications and Reversals”.

We restricted our sample to 153 original papers with documented replication failures based on four criteria: (1) replications must have been published in a peer-reviewed journal; (2) the original study had not been retracted, ruling out retraction as an alternative explanation for knowledge revision; (3) replication studies had sample sizes at least 2.5 times that of the original study, a commonly accepted threshold for adequate statistical power (Simonsohn, 2015); (4) all available replication attempts were unsuccessful, as determined by the replication authors. These criteria were designed to isolate robust, unambiguous replication failures that clearly warrant revision of the original scientific record. Further methodological details can be found in Supplementary Text 2.

For each original paper, we tracked its presence and assessed knowledge revision across three traditional channels: Wikipedia, textbooks, and university course syllabi. We further queried AI systems as a fourth, emerging knowledge channel. Complete methodological details can be found in Supplementary Text 3.

Wikipedia has long been a primary gateway to science for non-experts. Altmetric Explorer was used to identify Wikipedia pages that mention any of the original papers in our sample. We then manually examined 124 Wikipedia mentions for evidence of knowledge revision (yes / no). Knowledge revision was defined as the removal of claims based on the original finding, or any mention of replication failure or controversy. We adopted this generous knowledge revision criterion because partial updates, such as a brief note of controversy, still represent meaningful engagement with the replication results. We excluded cases where original papers were not referenced in relation to the replicated finding, or appeared merely as bibliographic records such as on the author’s profile page.

DRAFT VERSION
DO NOT CIRCULATE

Textbooks translate scientific knowledge into educational canon. We examined 16 introductory social psychology textbooks for knowledge revision, drawn from a list recommended by the Social Psychology Network (2025) for teaching purposes. We focused on social psychology given its prominence in the replication crisis (Lakens, 2025) and our domain expertise in evaluating knowledge revision. For each textbook, the most current edition was compared with a previous edition to determine knowledge revision. Knowledge revision was again defined as the removal of claims based on the original paper, or any mention of replication failure or controversy. We evaluated 73 textbook mentions and excluded cases where original papers were not referenced in relation to the replicated finding (e.g., cited only for its methods or definitions).

Course syllabi shape the scientific diet of the next generation. S llabi data were retrieved from Open Syllabus. We identified 116 syllabi that assigned original papers that later f iled replication. For each syllabus, we tracked whether the assigned paper was subsequently removed following the replication failures. Because Open Syllabus data do not c ntain full syllabus content, we cannot assess the context of each paper assignment. A paper may be removed for reasons unrelated to replication failu e, or retained but taught critically. These two possibilities likely offset each other, resulting in a middle estimate

AI systems now mediate information consumption for billions. We therefore included AI as a fourth knowledge channel to assess knowledge revision, focusing on two popular platforms. ChatGPT is the most widely used conversational AI platform, with 1 billion active users in June 2026. Google AI Overview have 2 billion monthly users globally. We investigated Google AI Overview also because of its passive delivery model: AI-generated summaries appear automatically atop search results. Sixty percent of U.S. adults say they read AI search engine summaries (Gottfried et al., 2026).

We queried both AI systems about the 153 original papers and coded their responses. We used two types of prompts for AI. The first was a “lay prompt”: “Tell me about the research on [summary of the finding].” Summaries of the findings were provided by FORRT volunteers, typically written as a phenomenon name followed by a brief description (e.g., “Elderly priming; hearing about old age makes people walk slower.”). Where summaries were absent, we constructed them in the same format. The second was an “expert prompt”: “Tell me about this research: [the APA reference of the paper].” Knowledge revision was defined as any mention of replication failure or related controversy in the AI-generated response.

Our deliberately minimal prompting strategy was intended to approximate real-world use rather than optimise for detection of replication information. Critically, we did not explicitly prompt the AI to discuss replication, and each query was conducted in a fresh session without prior context.

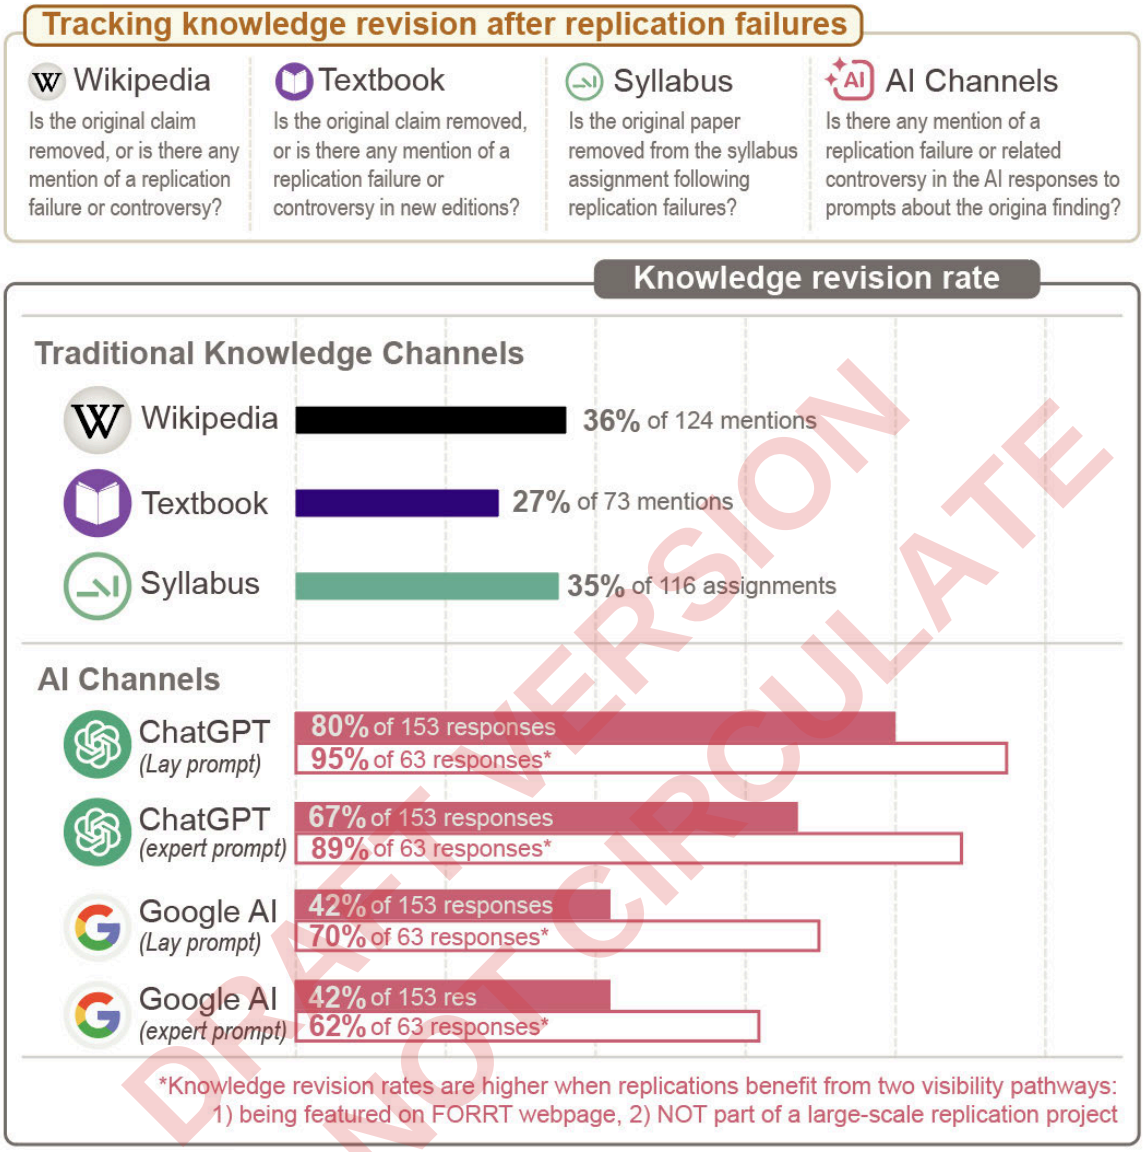
Results

Knowledge revision rate following replication failures

Figure 2 summarises the knowledge revision rates for the four knowledge channels. Among the traditional channels, Wikipedia displayed the highest knowledge revision rate (36%), followed by course syllabi (35%) and textbooks (27%). Supplementary Texts 3.1 to 3.3 provide further descriptive analyses, including whether revisions are concentrated among a few papers and whether revision occurred through claim removal or modification.



We found that these observed rates exceeded researchers' expecta ions. In a pre-registered survey, 24 attendees at the International Conference on the Science o Science and Innovation 2026 estimated knowledge revision rates for traditional channels before seeing our indings. Participants were pessimistic about knowledge revision following eplication failure (*M* = 21.0%, *Mdn* = 15.0%, *SD* = 18.2%). Supplementary Text 3.4 includes more details.

AI systems generally showed higher knowledge revision rates than traditional channels. ChatGPT outperformed Google AI Overview across both prompt ypes (lay prompt: 80% vs. 42%; expert prompt: 67% vs. 42%). We also found that ChatGPT responses are longer and more detailed than Google AI Overview. Supplementary Text 3.5 provides examples of AI responses and additional analyses including revision rate across phenomenon groups (e.g., priming effects).

The strong performance is unsurprising given AI's access to broad internet sources, including the scientific literature. When we repeated the ChatGPT queries with web search disabled, revision rates fell from 80% to 42% for lay prompts and from 67% to 39% for expert prompts. This suggests that access to external sources contributes substantially to knowledge revision.

Figure 2. How often knowledge channels revise information about original findings after replication failures.

Potential pathways for improving knowledge revision

We further exami ed wo pathways that may explain why some findings were more likely to attract knowledge revision than others. The first pathway is visibility via the FORRT Replications and Reversals webpage (https://forrt.org/reversals/). The website consolidates replication records on a single, openly accessible page, making them easy to find for both human readers and AI systems. According to FORRT organisers, this webpage attracts much more traffic than complex, database-format resources such as FReD. Findings featured on the webpage showed significantly higher revision rates across all AI systems (14–39 percentage points higher, see Table S2). A similar pattern appeared in Wikipedia. No significant effects emerged for textbooks or syllabi, possibly because too few of their findings (n = 11 and 12) were featured on the webpage to detect an effect. Supplementary Text 4.3 shows that the effect is unlikely to be

driven by the overrepresentation of particular phenomenon groups (e.g., priming effects) on FORRT.

A second pathway is reduced visibility when replications are embedded within large-scale replication projects (e.g., ManyLabs). These initiatives typically aim to estimate overall replication rates, with individual findings receiving little standalone attention. Consistent with this, findings from large-scale projects had significantly lower revision rates across all AI systems (34–47 percentage points lower, see Table S2). Similar patterns were observed for Wikipedia and syllabi. No significant effect emerged for textbooks, possibly because too few of the findings (n = 9) were from large-scale projects.

Combining both visibility pathways — salient web presence and individual replication attention — the 63 findings meeting both criteria achieved knowledge revision rates of 95% on ChatGPT (Figure 2). These results suggest that targeted dissemination strategies, combined with AI's ability to surface information, can potentially greatly expand the reach of replication evidence to the general public.

DRAFT VERSION
DO NOT CIRCULATE

Conclusions and policy implications

Do replication findings reach the general public? We found that knowledge revision following replication failure occurs roughly one third of the time across traditional knowledge channels: Wikipedia, textbooks, and university course syllabi. This is higher than what researchers predicted, and should encourage continued replication efforts. Yet there is still a long way to go. Our sample comprised the most robust, unambiguous replication failures available, and all of them deserve to be mentioned alongside the original finding in any knowledge channel.

AI systems represent a promising new pathway for replication evidence to reach the public. Replication records that are more visible and accessible online were associated with higher AI revision rates, indicating that targeted dissemination strategies may further close the gap.

Disseminating and consuming replication evidence

Our findings point to several concrete recommendations across different actors.

Meta-researchers should continue building infrastructure to systematically collect and curate replication records, as exemplified by FORRT. Accessibility of these resources for both human access and AI indexing is key to effective dissemination. We discovered that simple, openly accessible webpages listing individual replication records outperform complex database-format resources.

Researchers conducting replications should actively disseminate findings beyond journal publication — by contributing to replication databases, publishing accessible summaries on project websites, or sharing findings on social media. Broader web presence increases the likelihood of both knowledge curators and AI systems surfacing replication evidence.

Researchers from large-scale replication projects should ensure individual findings receive standalone attention rather than being subsumed within aggregate statistics.

Research funders should invest in dissemination as much as in replication itself, supporting both meta-scientific infrastructure such as FORRT and CurateScience (https://curatescience.org/), and individual researchers seeking to publicise their findings.

Knowledge curators, such as book authors, science journalists, Wikipedia editors, and educators, should make use of the available tools to periodically review and update their materials in light of replication evidence. One example is the FORRT Library of Reproduction and Replication Attempts (FLoRA) Annotator (https://forrt.org/annotator/), which allows users to upload manuscripts, reference lists, or reading materials to identi wh h cited studies have been replicated and what the outcomes were.

Knowledge consumers, such as readers, students, practi ioners, and policymakers, can use AI as a first point of access to replication information, w ile v rifying claims through dedicated resources such as those developed by FORRT. In our analysis, ChatGPT demonstrated better knowledge revision than Google AI Overview and is a more reliable starting point.

Finally, knowledge revision is not only a matter of noticing and adding replication information. Incorporating the new evidence into a coherent narrative is a challenge in itself. Knowledge curators such as textbook authors and Wikipedia editors must contextualise replication results alongside original findings. There is often a strong incentive to retain original narratives even when the underlying evidence is uncertain. Training and guidance for knowledge curators are needed to navigate this science communication challenge.

242. Future of Cancer Care Today

I am responding: On behalf of an organization

Name: Bayli DiVita Dean

Name of Organization: Future of Cancer Care Today

Type of Organization: Research Participant/Patient Advocacy Organization/Patient Advocate/Caregiver

Role: Organizational Official

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: Future of Cancer Care Today (FCCT) is a non-profit that helps cancer families navigate the path beyond standard of care. Our work gives us a recurring view of a specific failure in the biomedical system: important science often exists, but patients cannot readily use it. Data and tissue may be difficult to obtain or move; relevant trials may be difficult to identify; promising technologies may encounter regulatory or manufacturing barriers; and knowledge that has been generated may never become accessible in clinical practice.

We therefore encourage NIH to measure scientific impact not only by what investigators produce, but by what their work makes possible: whether knowledge and scientific capabilities can be accessed, reused, validated, adopted, and ultimately translated into meaningful benefit for patients.

Families we work with consistently identify a recurring barrier: their records, imaging, genomic data, and tissue are difficult to move on urgent timelines, particularly when tissue preservation decisions may need to be made within days. The recurring failure is not missing science; it is that data and tissue which already exist are hard to obtain, move, combine, or reuse.

NIH should reward infrastructure and research practices that make underlying clinical, genomic, imaging, and tissue-derived data available to the individual and portable across the research and care ecosystem. Drawing on the barriers we watch families hit, this means rewarding: patient control of tumor tissue and comprehensive sequencing of it, preserved in forms that enable downstream testing rather than foreclosing it; access to the underlying data itself, including raw DNA/RNA sequencing files and exploratory diagnostics, not only a summary report; modernized privacy rules and a strong patient right of access under HIPAA; interoperability that frees data from EMRs, including action to ensure systems exchange data rather than trapping it; and patient-directed release that lets a person send data and samples to any recipient they choose, for care or for research.

The researchers, repositories, platforms, and institutions that make patient-directed sharing possible, and that honor it promptly, should be credited for it, and NIH public repositories, such as NCI's Childhood Cancer Data Initiative, should accept clinical, longitudinal data that patients can both submit and access.

Measurable indicators: whether patients can obtain usable copies of their clinical, imaging, and genomic data, including raw files; time to complete a release and completeness of the record; portability, meaning whether a patient can transmit data and tissue to another party without rebuilding the record from scratch; the share of specimens preserved in formats enabling downstream research; and documented downstream reuse in research, trial identification, or care.

Feasibility. NIH should fund shared infrastructure and standards rather than requiring each institution to build its own patient-facing system. Absent that, this indicator would reward well-resourced institutions and penalize the sites serving families least able to move their own data.

Safeguards. Patient-submitted data must be matched by rigorous consent, privacy protection, and data-quality safeguards, and incentives should reward returning value to contributors.

3. Training and Mentorship: N/A

4. Collaboration: Team-based and community-engaged science depends on labor that is invisible to author-order and citation metrics, such as sustaining patient partnerships, convening advisory boards, coordinating multi-site teams, and co-developing questions with the people affected, yet this is often what makes findings valid, adoptable, and trusted. NIH should extend a contributor taxonomy (e.g., CRediT) to name patient-advisory, recruitment, co-design, and dissemination roles; reward sustained engagement over one-time consultation; and make coordinating and integrating roles assessable so credit is not concentrated on first and last authors. Our substantive recommendations sit under Data Sharing and Translation.

5. Entrepreneurship and Translation: For patients with rare or advanced disease, the binding constraint is usually not invention but the path from a scientific rationale to responsible access. A definition of translational impact that stops at patents, licenses, and company formation misses the work that most determines whether a discovery reaches a person. We ask NIH to credit barrier-removal in the areas our families repeatedly encounter.

Faster, responsible paths to investigational therapies. NIH should credit work that improves early-phase pathways and access: allowing investigators to choose any federally compliant IRB; a notification pathway for Phase 1 safety studies where IRB approval is sufficient; Right to Try and conditional approval after Phase 1, so promising therapies are not lost; and appropriate weighting of the resulting evidence, so that data from expanded-access and Right to Try use must clear a high bar before being held against an experimental drug. Making real-time, adaptive trial infrastructure permanent, including the kind of real-time response monitoring that defines a first-principles approach, would shorten the path from question to enrollment.

Fit-for-purpose production for personalized medicine. Personalized therapeutics are frequently low-volume by nature. NIH should treat as translational impact the development of "GMP-light" manufacturing for low drug volumes, verifying the output rather than only the production process, and regulatory pathways that approve algorithms and processes, not only individual molecules, so a validated personalized method can reach the next patient without restarting approval from zero.

Reimbursement matched to rare disease. NIH should credit the development of context-driven evidence

and reimbursement models appropriate to populations too small for conventional development economics.

Policy translation as creditable work. Much of this is policy translation, generating the evidence for a change, drafting it, and building the endorsement to enact it, progressing through four stages: an evidence base; a concrete change such as regulatory or legislative language; support from affected professional, industry, and patient communities; and adoption or implementation. Investigators should receive credit for substantive contributions at any stage, weighted toward implementation and patient benefit.

Defining a "patient-first industry." NIH-supported commercialization should be judged not by whether a company formed, but by whether the resulting organization makes science materially more useful to individuals: returning usable data to patients, preserving patient control of tissue, enabling access beyond a single institution, reducing the time and cost of personalized manufacturing, supporting responsible early-access pathways, and designing evidence generation around small populations.

Applying NIH's three verbs. Incentivize documented contributions to translation-enabling change, not only commercialization. Assess them through verifiable artifacts, including published analyses, regulatory submissions, adopted language, formal endorsements, and implementation records, rather than self-report. Integrate them into the biosketch and progress report, with reviewers authorized to weigh them.

Safeguard. Company formation, patents, endorsements, and capital raised are not impact by themselves. The measure is what became possible for people, and these measures must reward responsible access, never premature access or weaker safety standards.

6. Foundational Scientific Exploration: N/A

7. Public Impact: Publication and citation counts measure influence within the research community; they do not measure whether knowledge reached, was trusted by, or benefited the people it was meant to serve. A discovery has limited public impact if patients cannot learn it exists, access the relevant trial or diagnostic, or reach the clinicians able to use it. We recommend NIH complement bibliometric measures with verifiable indicators of downstream impact: documented uptake into clinical guidelines (e.g., NCCN), care pathways, and validated patient-education resources; accessible, plain-language dissemination usable by patients and clinicians; and equity of reach into the populations most affected. NIH should capture these through a brief, structured "Public and Community Impact" statement in the biosketch and progress report, modeled on the Data Management and Sharing Plan, with explicit language authorizing reviewers to weigh it.

8. Other Areas: Organizing principle. The ultimate purpose of biomedical research is not to maximize publications, approvals, or institutional compliance; it is to improve the health and lives of individuals. In clinical settings, that means orienting the system to maximize patient survival and benefit rather than to minimize institutional or practitioner liability. NIH's impact framework should give greater weight to work as it moves closer to meaningful health benefit, while preserving appropriate measures for foundational research whose effects emerge over longer horizons.

Feasibility across career stage and institution. Any new indicator should be easy to report, independently verifiable, and interpreted in light of an investigator's resources and career stage, so that community-engaged and less-resourced investigators are not disadvantaged.

Structured evidence over automated scoring. Reward the substance of impact — knowledge that improves health and is trusted by those it serves — through structured evidence and brief narrative assessed by informed reviewers, not a new automated score.

Guard against gaming: count outcomes, not artifacts. NIH should not reward the number of datasets deposited, advisory boards convened, companies formed, whitepapers written, or endorsement letters collected. These matter only when they demonstrably contribute to reuse, adoption, implementation, improved access, or patient benefit.

We would welcome the opportunity to provide further detail, including anonymized patterns from our case portfolio.

243. Massachusetts Biotechnology Council

I am responding: On behalf of an organization

Name: Patrick Brown

Name of Organization: Massachusetts Biotechnology Council

Type of Organization: Professional Organization/Association

Role: Organizational Official

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: An investigator whose work yields an issued patent, an executed license, a company, an IND, and a first-in-human trial has produced precisely the public value this RFI describes. Under current metrics, almost none of it registers. NIH already collects much of the data needed to change that. What is missing is the decision to treat these as measures of scientific impact rather than as compliance filings.
Recommendations
• Establish a defined set of translational indicators. We recommend: license and option agreements executed; companies formed; follow-on private capital raised by those companies; SBIR and STTR awards received; INDs and investigational device exemptions filed; clinical trials initiated; FDA designations granted, including Orphan Drug, Fast Track, Breakthrough Therapy, and Regenerative Medicine Advanced Therapy; and approved products traceable to the award. Making these indicators publicly available would itself change institutional behavior, at minimal marginal cost.
• Reduce the structural frictions facing investigator-founders. Certain current rules, such as founder equity and SBIR primary employment requirements, routinely necessitate management plans that distance the founder from the research. NIH should examine whether these rules match how academic discoveries actually reach companies.
• Strengthen SBIR and STTR as the translational bridge and measure the bridge. The most consequential failure point is between Phase II completion and the first institutional private financing.
• Recognize translational effort that does not succeed commercially. A program that fails for reasons of biology after a genuine translational attempt should not be scored below a program that never attempted translation at all.

6. Foundational Scientific Exploration: Private capital cannot fund foundational research. Venture funds operate on defined horizons and cannot underwrite ten to fifteen years of basic research work with an unknown endpoint. The reason our members can build companies at all is that NIH does the work that no investor will fund. Applying near-term translational indicators to that portfolio would be self-

defeating. It would shift NIH toward the incremental, fundable work the private sector is already positioned to do.
Recommendations
• Protect a defined share of the portfolio from any translational metric. NIH should identify basic and high-risk mechanisms as explicitly exempt, so that investigators and study sections can rely on it.
• Evaluate high-risk programs on the distribution of outcomes, not the average. A portfolio of transformative awards in which most projects fail and a few change a field is a successful portfolio.

7. Public Impact: Public impact is the hardest of these areas to measure and the most important to measure well, because it is the basis on which sustained federal investment in biomedical research is justified.
Recommendations
• Report health outcomes traceable to NIH funding: approved therapeutics, diagnostics, and devices with a documented line back to NIH-supported research; changes to clinical practice guidelines citing NIH-funded evidence; and, where data permit, patient populations reached.
• Report economic impact at the state and regional level. NIH funding supports employment, institutional research capacity, and regional cluster formation. Massachusetts is the clearest available case study of the full sequence, from NIH-funded academic discovery through spinout formation, private financing, clinical development, manufacturing, and employment. Estimates commonly place significant returns on economic activity per every dollar of NIH funding. NIH should adopt a consistent methodology, publish results by state, and update them annually.

8. Other Areas: N/A

Re: Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

To Whom It May Concern:

The Massachusetts Biotechnology Council (MassBio) appreciates the opportunity to respond to the National Institutes of Health (NIH) Request for Information on Measuring and Rewarding Scientific Impact. MassBio represents more than 1,700 member organizations, including biotechnology and pharmaceutical companies, academic medical centers, research universities, disease foundations, and the service providers that support them. Our members include many institutions and companies that perform NIH-funded research, with Massachusetts a national leader, receiving approximately $3.5 billion in NIH funding annually, more per capita than any other state. The funding translates into new treatments for patients, high wage jobs and a growing workforce, and significant economic development across the State and the country.

We support the premise of this RFI. Publication counts and citation metrics capture only one dimension of the value NIH creates. They also render invisible much of the activity that actually moves a discovery toward a patient. Realigning NIH measures of success is a worthwhile undertaking that if implemented successfully will unlock new transformative innovations for patients across the country. We focus our comments on three of the areas identified in the notice: entrepreneurship and translation, foundational scientific exploration, and public impact.

Entrepreneurship and Translation

An investigator whose work yields an issued patent, an executed license, a company, an IND, and a first-in-human trial has produced precisely the public value this RFI describes. Under current metrics, almost none of it registers. NIH already collects much of the data needed to change that. What is missing is the decision to treat these as measures of scientific impact rather than as compliance filings.

Recommendations

- Establish a defined set of translational indicators. We recommend: license and option agreements executed; companies formed; follow-on private capital raised by those companies; SBIR and STTR awards received; INDs and investigational device exemptions filed; clinical trials initiated; FDA designations granted, including Orphan Drug, Fast Track, Breakthrough Therapy, and Regenerative Medicine Advanced Therapy; and

approved products traceable to the award. Making these indicators publicly available would itself change institutional behavior, at minimal marginal cost.

- Reduce the structural frictions facing investigator-founders. Certain current rules, such as founder equity and SBIR primary employment requirements, routinely necessitate management plans that distance the founder from the research. NIH should examine whether these rules match how academic discoveries actually reach companies.
- Strengthen SBIR and STTR as the translational bridge and measure the bridge. The most consequential failure point is between Phase II completion and the first institutional private financing.
- Recognize translational effort that does not succeed commercially. A program that fails for reasons of biology after a genuine translational attempt should not be scored below a program that never attempted translation at all.

Foundational Scientific Exploration

Private capital cannot fund foundational research. Venture funds operate on defined horizons and cannot underwrite ten to fifteen years of basic research work with an unknown endpoint. The reason our members can build companies at all is that NIH does the work that no investor will fund. Applying near-term translational indicators to that portfolio would be self-defeating. It would shift NIH toward the incremental, fundable work the private sector is already positioned to do.

Recommendations

- Protect a defined share of the portfolio from any translational metric. NIH should identify basic and high-risk mechanisms as explicitly exempt, so that investigators and study sections can rely on it.
- Evaluate high-risk programs on the distribution of outcomes, not the average. A portfolio of transformative awards in which most projects fail and a few change a field is a successful portfolio.

Public Impact

Public impact is the hardest of these areas to measure and the most important to measure well, because it is the basis on which sustained federal investment in biomedical research is justified.

Recommendations

- Report health outcomes traceable to NIH funding: approved therapeutics, diagnostics, and devices with a documented line back to NIH-supported research; changes to clinical practice guidelines citing NIH-funded evidence; and, where data permit, patient populations reached.
- Report economic impact at the state and regional level. NIH funding supports employment, institutional research capacity, and regional cluster formation. Massachusetts is the clearest available case study of the full sequence, from NIH-funded academic discovery through

spinout formation, private financing, clinical development, manufacturing, and employment. Estimates commonly place significant returns on economic activity per every dollar of NIH funding. NIH should adopt a consistent methodology, publish results by state, and update them annually.

Conclusion

MassBio appreciates NIH taking on this important effort. We would welcome the opportunity to discuss these recommendations further, and we are prepared to convene NIH staff with our member companies, academic medical centers, and investors to work through implementation and feasibility questions in more detail.

Thank you for your consideration.

Sincerely,

Kendalle Burlin O'Connell
Ceo & President
Massachusetts Biotechnology Council (MassBio)

244. Case Western Reserve University School of Medicine

I am responding: On behalf of an organization

Name: CTSC of Northern Ohio

Name of Organization: Case Western Reserve University School of Medicine

Type of Organization: Not Applicable

Role: Organizational Official

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: In the framework defined by NCATS, rigor and reproducibility determine whether research findings are dependable, transferable, and reusable. This alignment with the NIH gold-standard science document emphasizes that transparency is directly tied to the credibility and utility of biomedical research. To improve this, NIH should pivot from box-checking compliance to rewarding verifiable practices and transparent learning.
NIH should distinguish clearly between related concepts. Computational reproducibility refers to obtaining consistent results using the same data, code, and analytical procedures. Replicability refers to obtaining sufficiently consistent findings through new data collection or an independently conducted study. Generalizability concerns whether findings apply across populations, settings, models, or conditions beyond those originally examined. These distinctions should inform study-type-specific expectations rather than be collapsed into one generic rigor score. NIH should shift from documentation of intent toward evidence of practice.
We recommend that NIH adopt the Transparency and Openness Promotion (TOP) framework to distinguish between study registration, protocol availability, data and code transparency, and verification.
Key indicators of scientific rigor should include:
Time-stamped protocols, analysis plans, or preregistrations when appropriate to the research design.
Clear distinctions of confirmatory, exploratory, and post hoc analyses.
Transparent justification and reporting of sample size, randomization, blinding, inclusion and exclusion criteria, missing-data handling, and analytical decisions.
Authentication and provenance documentation for critical data, specimens, models, reagents, and software.
Availability of data, code, workflows, and computational environments sufficient to reproduce reported analyses, subject to ethical and legal constraints.
Timely reporting of null and negative results.
Independent computational reproduction, robustness testing, sensitivity analysis, or replication where scientifically warranted.
Evidence that replication findings or methodological audits led to improved protocols, standards, or subsequent research.
Concise definitions are essential for consistent review: reproducibility should refer to obtaining consistent computational results with the same data and code, while replicability refers to obtaining consistent results in new studies. NIH can operationalize this shift through study-type-specific review guidance and pilot rigor-and-transparency modules in progress reports, ensuring that the goal remains

improved practice rather than administrative burden. In addition, replication studies should be evaluated according to their methodological quality and informational value, not whether they reproduce the original finding.

2. Data, Software, and Model Sharing: NIH's 2023 Data Management and Sharing (DMS) Policy was a significant step toward universal sharing, but mandating behaviors is distinct from rewarding value. Compliance focuses on infrastructure; true incentive requires a framework that captures the downstream utility of shared resources—impact that is frequently delayed, distributed, and invisible to traditional metrics.

Data, software, and models generate scientific value only when they are interoperable, reusable, and accompanied by rich provenance. The decisive work occurs at the inception of a study, where standardized definitions, documented workflows, and validated capture procedures determine the future utility of research assets. To incentivize this, NIH must reward the quality of sharing rather than the mere presence of a repository link.

We recommend that NIH:

Incentivize Infrastructure: Officially recognize data stewardship, software engineering, and documentation as essential direct project costs.

Acknowledge Professionals: Ensure research librarians and data specialists receive named contributor credit for their roles in managing these resources.

Shift Measurement Criteria: Evaluate sharing success through indicators like persistent identifiers, versioned code, executable workflows, and clear metadata, rather than raw download counts.

Prioritize Responsible Usability: Assess sharing quality based on "responsible usability"—whether data is as open as ethically permissible with predictable access routes for qualified users—rather than penalizing necessary, clearly justified restrictions. Usability indicators may include installation and execution success, machine-readable metadata, interoperable formats, executable workflows, accessible documentation, user support, and reasonable time between a qualified request and access.

Evidence Value via Reuse: Value indicators may include independent reuse, adaptation in other settings, inclusion in external pipelines or platforms, use in replication studies, citation in research or guidance, incorporation into standards, and evidence that the resource reduced duplication, cost, or time.

Mandates alone are insufficient. NIH must cultivate an ecosystem where specialized labor, standardized infrastructure, and aligned rewards turn shared outputs into sustainable, collaborative scientific assets.

3. Training and Mentorship: The CTSA Program builds the workforce required for modern translational science. By prioritizing cross-disciplinary team science and boundary-crossing partnerships, the network aligns directly with the Translational Science Principles defined by the National Center for Advancing Translational Sciences (NCATS). These principles call for "translational scientists" who function as domain experts, process innovators, and team players—an identity that contrasts sharply with the traditional, individual-focused R01 research paradigm.

The CTSA network’s training mechanisms, such as the KL2 Mentored Career Development Award and the TL1 Linked Training Award, are specifically designed to cultivate this multi-disciplinary expertise. However, recent evidence suggests current efforts must evolve. Freedman et al. (2026) found that researchers affiliated with CTSA hubs report only slight-to-moderate confidence in translational science (TS) principles, particularly in areas like efficiency, productive failure, and risk-taking. Most participants lacked formal training in TS. Crucially, the authors conclude that training alone is insufficient without

systemic reward structures (e.g., tenure, honors) that recognize hours worked and risks taken, rather than solely counting research outputs.
To better evaluate these efforts, NIH should move beyond publication metrics and instead measure the development of core translational capabilities. The 14-item confidence scale developed by Freedman et al. (2026) offers a resource for assessing workforce development, but it must be paired with behavioral indicators of competence.
NIH should distinguish among mentoring inputs, mentoring processes, developmental outcomes, career outcomes, and ecosystem outcomes. Potential indicators include:
Individualized development plans, documented mentoring agreements, and regular review of progress.
Evidence of mentor preparation, including training in feedback, research integrity, sponsorship, and conflict management.
Demonstrated mastery of rigorous methods, team science, and data management.
Successful interdisciplinary and cross-sector collaboration.
Progress toward trainee-specific goals and career advancement.
Timely advancement, career stability, role alignment, and persistence in the biomedical or health-related workforce.
Quality of the mentoring relationship, psychological safety, clarity of expectations, and access to professional networks.
NIH should recognize instructional contributions from research professionals—including librarians, statisticians, and regulatory specialists—as valuable investments. Strong mentors and team-mentoring structures should receive grant-review credit and institutional protection. Finally, evaluation of these outcomes should be aggregated over time and interpreted contextually, ensuring that effective mentorship and workforce growth remain the priority over traditional prestige markers.

4. Collaboration: As a Clinical and Translational Science Collaborative (CTSC), we advocate for rewarding translational science principles that transcend disciplinary boundaries. While holistic health strategies—addressing the physical, mental, social, and environmental dimensions of well-being—are increasingly central to clinical care, research assessment remains largely disease-specific. The NCATS focus on cross-cutting translational barriers offers a vital alternative to the traditional NIH Institute and Center (IC) structure, yet researchers operating within this framework frequently struggle with existing grant mechanisms, particularly the R01. Study sections often favor disciplinary silos, frequently penalizing the novelty and innovation inherent in team-based, cross-disciplinary proposals.
Collaboration is the operational foundation of CTSA hubs. To better recognize this work, NIH must move beyond assessment models that obscure the contributions of essential team members. We recommend requiring structured contributor statements—utilizing the CRediT taxonomy—to acknowledge diverse roles including software engineering, data curation, statistical analysis, and project management, rather than focusing solely on PI status.

Furthermore, NIH should pilot cross-IC referral and review pathways for proposals that address shared translational barriers. Review panels for such proposals should integrate diverse scientific, operational, and community expertise. Finally, NIH should provide explicit support for research software engineers, statisticians, and project managers, while ensuring new assessment criteria do not impose undue administrative burdens on early-career investigators.
Potential collaboration indicators include:
Clarity and completeness of contributor attribution.

Evidence that the team's composition matches the scientific and translational problem.
Integration across disciplines, institutions, professions, sectors, or communities.
Shared decision-making and governance.
Inclusion of relevant methodological, operational, clinical, and lived-experience expertise at appropriate stages.
Interoperable processes, shared protocols, and effective data or resource exchange.
Resolution of scientific, operational, or regulatory barriers through collaboration.
Durability of productive partnerships when continuity is scientifically valuable.
Development of new shared infrastructure, methods, standards, or networks.
Evidence that contributions were distributed fairly and that junior or less institutionally powerful members were not rendered invisible.
Social network analysis may offer useful program-level evidence concerning the development of multidisciplinary and cross-institutional ecosystems. Measures such as connectivity, brokerage, disciplinary diversity, cross-sector reach, and participation over time can help characterize collaborative structures. However, network measures should be interpreted with caution under the guidance of network scientists.

5. Entrepreneurship and Translation: The National Center for Advancing Translational Sciences (NCATS) provides a highly comprehensive and systematically organized commercialization infrastructure within the federal biomedical research enterprise. By integrating national-scale training initiatives, such as I-Corps at NCATS, funding mechanisms including SBIR/STTR, physical bio-incubators, and the expert networks of Clinical and Translational Science Awards (CTSA) hubs, NCATS has established a powerful engine for translating discoveries into real-world health solutions. This structural strength is derived not from isolated programs, but from a coordinated national ecosystem governed by the 2025–2030 Strategic Plan.
The CTSA network offers a distinct value proposition that differentiates it from elite university Technology Transfer Offices (TTOs). Rather than replicating the high-scale venture capital integration characteristic of individual institutions like Stanford or MIT, the CTSA network provides a standardized and nationally coordinated commercialization infrastructure. These systems demonstrate maximum effectiveness when operating collaboratively, as evidenced by successful models at Northwestern, Minnesota, Virginia, and Washington.
While translation and entrepreneurship represent vital pathways to enhanced health outcomes, patents, licenses, and company formation constitute intermediate milestones rather than definitive evidence of public benefit. CTSA hubs assist investigators in defining unmet needs, testing feasibility, navigating regulatory pathways, and engaging end-users to determine whether an innovation should advance. The NIH should reward this responsible progress through evidence-based indicators, such as the validation of unmet needs; meaningful patient and stakeholder involvement; reproducible prototypes; independent technical validation; pre-specified go/no-go milestones; regulatory and clinical benchmarks; manufacturing readiness; and demonstrable improvements in accessibility, affordability, or quality. Assessment measures must align precisely with the specific stage of innovation, avoiding the assumption that every discovery warrants commercialization. Furthermore, the NIH should recognize the specialized expertise of translational professionals in regulatory science, implementation, manufacturing, and partnership development. We recommend that the NIH enhance the visibility of this work through milestone-based supplements, proof-of-concept awards, and increased credit in biosketches and grant renewals. Finally, transparency in 'negative' de-risking results—which prevent investment in unsafe or

ineffective products—should be celebrated as valuable scientific learning. Assessment frameworks must prioritize evidence of validity, utility, and responsible deployment over mere revenue or valuation, while ensuring rigorous conflict-of-interest management and the protection of research participants.

6. Foundational Scientific Exploration: The CTSA network provides vital cross-cutting infrastructure through entities such as the Trial Innovation Network and the SMART IRB platform to coordinate multi-institutional challenges and support research transcending individual Institute and Center missions. Formalizing this framework at the NIH level would provide the resources necessary to institutionalize these critical translational activities.
NIH should evaluate foundational research through expert narrative review emphasizing:
The importance of the scientific question.
The quality and transparency of the underlying reasoning.
Methodological rigor and the appropriateness of the experimental or theoretical approach.
The degree to which the work opens a new research direction or challenges a consequential assumption.
Creation of new methods, models, resources, or conceptual frameworks.
Informative negative or contradictory findings.
Evidence that the work changed subsequent scientific questions, methods, or investment.
Long-term influence on fields, training, or scientific infrastructure.

Productive failure should be recognized when a well-designed study tests a consequential proposition, generates credible evidence, and changes future decisions. NIH should avoid retrospectively labeling every unsuccessful project as productive; the value must be demonstrated through the quality of the work and the learning produced.
Longer assessment horizons are essential. Some foundational contributions will not demonstrate influence within a typical three- to five-year grant cycle. NIH could permit delayed impact updates, retrospective portfolio analyses, and renewal narratives describing how previous findings altered research trajectories. Such evidence should inform organizational learning but should not create indefinite reporting requirements for individual investigators.

7. Public Impact: Public impact represents a core component of translational science, yet it is seldom attributable to an individual investigator or a single publication. Consequently, the NIH should evaluate impact through a transparent contribution pathway that links research activities to ultimate public benefit, while appropriately accounting for temporal lags, external influences, community contexts, and shared attribution. In accordance with the CTSC's emphasis on community participation, broad applicability, implementation, and enhanced health outcomes within Northern Ohio and beyond, this approach should incorporate proximal indicators. These indicators include sustained patient and community involvement in priority-setting and research design, accessible return of results, adoption of validated tools, incorporation of findings into clinical guidelines, standards, public policy, education, or research infrastructure, and prompt rectification of inaccurate claims.
Intermediate indicators may include reach, adoption, implementation fidelity, sustainability, cost, accessibility, acceptability, appropriateness, feasibility, service quality, changes in professional or organizational behavior, and equitable implementation across settings. Long-term indicators may include changes in clinical outcomes, population health, quality of life, productivity, economic activity, system performance, or public trust. Such outcomes should be attributed to a specific body of research only when the contribution claim is supported by credible evidence and competing influences are

acknowledged. Similarly, public trust should be evaluated based on transparency regarding uncertainty and conflicts, public comprehension, responsiveness to affected communities, accessibility of results, and the quality and durability of partnerships, rather than popularity, favorable media coverage, or social media activity. Furthermore, the NIH should recognize community-engagement expertise, partnership maintenance, implementation support, public communication, and accessibility efforts as budgeted and credited contributions. Community organizations and patient partners should receive appropriate compensation and formal acknowledgment in contributor statements, and reviewers must evaluate whether their engagement substantively influenced the research rather than merely verifying the existence of an advisory group.

• Other Areas.

It is recommended that the National Institutes of Health implement a structured contribution portfolio framework rather than substituting one simplistic metric for another. NIH should implement a structured contribution portfolio rather than replace one simplistic metric with another. Ethical conduct, scientific rigor, complete reporting, and applicable data sharing should serve as baseline expectations, after which broader impact could be assessed through expert review of a limited number of selected contributions, consistent with responsible research-assessment principles (Declaration on Research Assessment, 2013; Moher et al., 2020). Applicants could identify no more than five significant contributions, explain their specific roles and those of other contributors, provide persistent identifiers or other verifiable evidence where available, and present concise evidence of rigor, reuse, influence, mentorship, collaboration, translation, foundational learning, implementation, or public benefit. Eligible contributions could include peer-reviewed publications, datasets, software, methods, standards, replication studies, training programs, team leadership, research infrastructure, community partnerships, and responsible translational milestones; however, grant funding itself should not be treated as evidence of impact. Evaluation criteria should be published in advance, tailored to the type of research, and interpreted in the context of career stage, discipline, institutional mission, available resources, and the time required for impact to emerge. To reduce administrative burden, NIH should draw evidence from repositories, ORCID records, and existing progress reports wherever feasible, while providing reviewers with appropriate training, evaluation anchors, and calibration examples. No applicant should be expected to demonstrate excellence in every category. Before widespread adoption, NIH should pilot the framework across multiple Institutes and Centers, funding mechanisms, career stages, and institution types. The CTSA network could provide a useful pilot environment because it integrates disciplines, institutions, infrastructure, workforce development, community engagement, and translation. Evaluation of the pilot should examine reviewer agreement, administrative burden, differential effects across groups and institutions, and whether the framework improves research practices and funding decisions. NIH should maintain transparency by publishing its rubrics, pilot protocols, aggregate findings, audits, and revisions while monitoring for unintended consequences, including inflated contributor claims, disadvantages to fields with fewer repositories or longer impact horizons, uncompensated documentation work, and the conversion of qualitative judgment into a hidden numerical score. Indicators that do not improve decisions or scientific behavior should be revised or retired. Ultimately, NIH should reward the practices, people, and infrastructure that make scientific findings trustworthy and useful without creating another prestige hierarchy or burdensome compliance exercise.

8. Other Areas: On behalf of the Clinical and Translational Science Collaborative (CTSC) of Northern Ohio at Case Western Reserve University (CWRU), we respectfully submit this formal response to the National Institutes of Health (NIH) Request for Information regarding Measuring and Rewarding Scientific Impact (NOT-OD-26-087). As a designated Clinical and Translational Science Award (CTSA) hub with nearly 19 years of experience fostering clinical and translational research across a seven-institution consortium, we appreciate this essential dialogue and provide our perspective as an organization deeply dedicated to the core values the NIH intends to enhance and incentivize.

The recent inauguration of the agency-wide Replication and Reproducibility Initiative by the NIH marks a significant and necessary paradigm shift in the definition and measurement of success within the biomedical research enterprise. The mission and objectives of CTSA hubs correspond directly with the thematic interests outlined in this Request for Information. For CTSA institutions, this reflects the fundamental, daily operations of translational science: establishing robust systems and cross-sector partnerships that enhance research rigor, improve operational efficiency, expand scientific inclusivity, and maximize public health outcomes.

The CTSA Program was strategically implemented to mitigate the structural and operational impediments that decelerate the progression of scientific discoveries along the translational continuum—from initial basic observations to clinical implementation and subsequent population-level health improvements. Utilizing our extensive background as a translational science hub, our institutional dedication to advancing health outcomes, and our perspective that prospective NIH metrics must accurately evaluate both individual and collective achievements, scholarly and operational contributions, and institutional and public-facing initiatives that collectively define meaningful scientific advancement. We incorporate insights from peer-reviewed literature across the translational science spectrum and align with established standards to facilitate the institutionalization and promotion of replication and reproducibility practices throughout the biomedical research enterprise.
The proposed approach should rest on five principles.
First, scientific impact is multidimensional. No single indicator can adequately represent scientific quality, usefulness, influence, workforce development, translation, or public benefit.
Second, indicators must be aligned with the purpose, stage, and modality of the work. Appropriate evidence for a basic-science discovery differs from evidence for a dataset, clinical intervention, implementation strategy, training program, community partnership, or regulatory tool.
Third, quantitative indicators should inform rather than replace expert judgment. Responsible research-assessment frameworks consistently emphasize that metrics must be transparent, field-sensitive, contextualized, and subordinate to qualitative assessment.
Fourth, NIH should reward contributions and behaviors that improve the research ecosystem, including rigorous methods, transparent reporting, stewardship, replication, mentorship, collaboration, infrastructure development, and responsible decisions not to advance ineffective or unsafe innovations.
Fifth, NIH must evaluate its own assessment system. Any new framework should be piloted, audited for differential effects and gaming, and revised or retired when indicators create burden without improving decisions or scientific behavior.

245. American Association of Physicists in Medicine (AAPM)

I am responding: On behalf of an organization

Name: Emily Townley

Name of Organization: American Association of Physicists in Medicine (AAPM)

Type of Organization: Professional Organization/Association

Role: Organizational Official

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: Framing

Medical physics is the discipline of applying physics to medicine including but not limited to applying physical principles to medical imaging and cancer treatment. As such, medical physicists are engaged in clinical practice, research and education in these fields. They are trained to support all aspects of patient safety and efficacy in the usage of highly sophisticated technologies (MRIs, CT scanners, Radiation Therapy treatment modalities) in advancing the detection, diagnosis, assessment and treatment of disease.

As part of their training, clinical practice and research practice, medical physicists perform the actions that make biomedical measurement trustworthy, shareable, and translatable. Making measurements reproducible - through standardized test objects, standardized methods, and shared reference data and tools - is among the field's highest-value contributions, and it is precisely the kind of work that conventional impact metrics systematically undercount.

Areas ripe for replication and reproducibility efforts

Some specific relevant examples are that medical physicists commonly perform measurements on equipment using standardized test objects, frequently referred to as phantoms, using a standardized set of test procedures. These tests are used to assess equipment performance that ranges from meeting a manufacturer's specification during acceptance testing, to performing tests to characterize the performance under a wide range of clinical conditions (for example, for pediatric vs. adult patients).

Thus, medical physicists are well versed in developing and using standardized test objects and standardized testing methods, both of which are strong prerequisites for replication and reproducibility efforts. In addition, many medical physicists have been instrumental in other efforts which are key to replication and reproducibility efforts including, but not limited to: (a) developing innovative test objects (physical phantoms), (b) digital reference objects which serve as test objects that can be used to evaluate algorithm performance in specific ways; (c) customized analysis tools (e.g. software tools) that they have released as open source tools to colleagues and to the public; (d) publicly available datasets including, but not limited to: (i) the Lung Imaging Database Consortium (LIDC) dataset hosted on NCI's TCIA database; (ii) more recently the Medical Imaging and Data Resource Center (MIDRC)

(https://data.midrc.org) and many others hosted on TCIA or public websites and repositories such as Zenodo; and (e) references and/or open source analysis tools to facilitate the replication and reproducibility evaluations (an example of this is the MIDRC MetricTree https://www.midrc.org/performance-metrics-decision-tree, which the FDA has adopted as one of its regulatory science tools https://cdrh-rst.fda.gov/mic-met-tree-decision-tree-medical-imaging-aiml-classification-metrics).

New strategies for the AI era

AI and machine-learning models used in biomedical science raise a distinct reproducibility challenge. Many now operate in settings where a clinician must act on a model's output quickly, such as AI-assisted treatment planning or contouring, leaving little room for after-the-fact validation. New strategies are therefore needed to establish reproducibility before and during deployment, not only at publication. These could include routine pre-deployment testing against standardized reference cases, periodic re-testing on a defined schedule, such as at initial implementation and then again at set intervals or per patient before treatment, and layered quality checks that continue to monitor a live model's performance rather than validating it only once. Sustaining this kind of ongoing verification will require dedicated infrastructure and reporting standards, including appropriate documentation of model performance, transparency, limitations, and, where applicable, explainability. NIH should also consider what dissemination and reporting incentives would make this practical for investigators to sustain, recognizing that clinical reimbursement mechanisms such as CPT codes fall outside NIH's own purview.

Incentives and infrastructure

Medical physicists have been able to find ways to carry out reproduction and replication activities in spite of a lack of incentives, but they face serious headwinds such as lack of funding, perception of a lack of innovation (typically required for publication and certainly for grant funding) and difficulty in sharing patient data (sharing phantom data and digital reference objects are much easier, but there are still some obstacles). There are examples of studies in our field where reproducibility efforts were carried out, but many of these were funded by grant mechanisms such as U01 (NCI's Quantitative Imaging Network or QIN and the aforementioned LIDC). Our journals, Medical Physics and the Journal of Applied Clinical Medical Physics (JACMP) both support a Medical Physics Dataset Article (MPDA), but these have been lightly used.

Furthermore, the recent effort of research practices to enhance reproducibility and replicability has brought an emphasis on transparency and explainability, which has fostered new attention to these issues. Practices that have been used elsewhere in medicine may be useful to consider here as well, including pre-registration of a study, transparency of data sharing, AI-models, and a persistent researcher identifier (such as ORCID), which could facilitate the use of advanced computational techniques as well as the globalization of research capabilities and collaboration.

To sustain incentives and infrastructure that would support the replication and reproduction of existing findings, it would be helpful to be able to: (a) fund research projects that would be specifically intended to support multicenter collaboration to replicate and reproduce results in a specific context and in such a

way as to support teams at various institutions to carry out the reproducibility exercise (funding both the data collection and analysis); (b) provide support for efforts to publish open source tools that would enhance these replication and reproducibility efforts, including supporting the additional expenses in making open source tools available (many journals add costs to make publications Gold OA).

Defining Causal Research

NIH's request for comment on defining causal research is also relevant to medical physics, particularly as AI and computational tools become embedded in clinical decision-making. Medical physicists routinely use physical phantoms, digital reference objects, and other known reference conditions to evaluate technologies under controlled experimental conditions. These approaches can isolate the effect of a specific technical intervention, such as a reconstruction algorithm, calibration method, or AI model, while controlling sources of variability that may confound evaluation in clinical data. Such controlled experiments can provide important evidence about cause and effects relationships for technical and computational interventions and can complement, rather than replace, causal inference from clinical and population-level data.

2. Data, Software, and Model Sharing: Framing

Medical physics is the discipline that makes biomedical measurement trustworthy, shareable, and translatable. Much of that work - validating that a result reproduces, building the tools that let others reuse a dataset, maintaining the infrastructure a whole subfield depends on - is exactly the kind of contribution that conventional impact metrics (citations, first/last authorship, grant dollars) systematically undercount. Software and data infrastructure should be recognized and funded as first-class scientific output, not treated as a byproduct of research grants aimed primarily at publications (see Whelan BM, Brock KK, Li Z, "Software from publicly funded research should be free and open source for research," Med Phys 2024; https://doi.org/10.1002/mp.17107).

Measurable Indicators NIH Could Use

• Software/tool releases as a distinct, credited output, tracked separately from publications - e.g., a persistent identifier (RRID, or DOI via Zenodo/Software Heritage) logged in RPPR/progress reports, not just mentioned in a methods section. Also, linking of DOI of peer-reviewed publication with DOI of the dataset, as on MIDRC.
• Reuse and dependency metrics, not just downloads: the number of independent labs or downstream products building on a tool. Widely adopted community platforms in imaging and radiotherapy physics (e.g., ITK, VTK, 3D Slicer, SciPy, matRad, CERR) demonstrate that reuse, not citation count, is the real signal of scientific value.
• Reproduction/replication attempts enabled: whether another lab can independently verify a published result using the released code and data. This is measurable - e.g., linked reproduction reports, containerized pipelines with recorded successful re-runs - in a way citation counts are not.
• Maintenance activity, not just initial release: issue response time, commit frequency, or a documented succession plan when a PI moves on. Release without upkeep tends to produce unusable, poorly documented, task-specific code, so any indicator scheme should reward sustained stewardship over a one-time drop.

• Documented dissemination plans and their fulfillment, since NIH grant review already asks applicants to state a dissemination plan; NIH could track completion rates against those stated plans as an accountability metric.

Implementation Approaches

• Tiered expectations rather than a uniform mandate. A strong presumption of open release fits standard research grants well, but a single rule applied uniformly across standard research grants, SBIR/STTR small-business awards, and Academic-Industry Partnership grants risks working against NIH's own commercialization goals. A "free for research use, protected for commercial use" model — similar to research-only licensing already common in biomedical technology transfer — is a better fit for SBIR/STTR and industry-partnered awards.

• Budget for it explicitly. Dissemination-quality software (documentation, packaging, a stable repository, periodic updates) is a real cost that standard research grant budgets do not currently anticipate. NIH could add an allowable, reviewable budget line for software maintenance/dissemination (complementing the open-source-tool support recommended in our Rigor and Reproducibility response section), analogous to data-management-plan costs under the 2023 Data Management and Sharing Policy, with continuation funding tied to a minimal maintenance track record, not just initial release.

• Credit infrastructure builders directly. Long-lived, well-maintained platforms require continuous, dedicated funding, not incidental grant output. A supplement or dedicated mechanism for maintaining widely reused community tools - distinct from the award that originally produced them - would recognize infrastructure maintenance as its own category of scientific labor rather than a byproduct of an unrelated project grant.

• Use existing reporting infrastructure. Since NIH already asks applicants to state a dissemination plan and factors it into review, NIH could formalize follow-through reporting (e.g., in RPPRs) rather than creating a new compliance layer.

Two Clear Examples

Example 1: the Operational Ontology for Oncology (O3)

Radiation oncology offers a working model of what professional society-led, multistakeholder data infrastructure can look like in practice. The Operational Ontology for Oncology (O3), developed under the American Association of Physicists in Medicine's Big Data Subcommittee (https://aapmbdsc.azurewebsites.net/) beginning in 2019, standardizes the clinical elements, attributes, value sets, and relationships needed to make electronic health record and treatment-planning data usable for aggregation, quality improvement, and AI-ready research (Mayo CS et al., "Operational Ontology for Oncology (O3)," Int J Radiat Oncol Biol Phys 2023; https://doi.org/10.1016/j.ijrobp.2023.05.033; PMCID PMC10741247). The current version defines 42 key elements, 359 attributes, 144 value sets, and 155 relationships, prioritized by clinical significance, likelihood of being captured in existing systems, and feasibility of workflow change.

Several features of how O3 was built and disseminated map directly onto the recommendations above:

• Multi-professional-society governance rather than a single-lab effort. O3 was developed jointly with the American Society of Radiation Oncology, Canadian Association of Radiation Oncology, Canadian Organization of Medical Physicists, European Society of Therapeutic Radiation Oncology, and NRG Oncology, with additional input from government agencies (NIH, NCI, VA) and electronic-record vendors.

This distributes both the domain expertise and the long-term stewardship burden across institutions rather than concentrating it in one grant-funded team.
• A public, iterative comment process. An open-access website was used for two public comment cycles (2021 and 2022), alongside targeted review by specialty groups, vendors, and standards bodies — a low-cost, replicable model for incorporating broad stakeholder input into a data standard without requiring every contributor to be a co-investigator.
• Interoperability with existing infrastructure, not a parallel standard. O3 was deliberately mapped to SNOMED CT, NCI Thesaurus, and HL7 FHIR, and several of its concept definitions were incorporated directly into HL7 FHIR and IHE-RO interoperability testing. This is a concrete example of the "extend and interoperate" principle that keeps a domain-specific standard from becoming an isolated silo.
• Machine-usable, freely available outputs. Beyond the ontology itself, the project released a JSON file and SQL database-creation scripts into the public domain, directly enabling other institutions to implement the standard rather than merely read about it.
• Staged rollout tied to feasibility, not an all-at-once mandate. Recommendations to clinics explicitly phase implementation — full capture of first-priority elements within one to two years for most clinics and three years for the majority — which reflects the kind of tiered, capacity-aware timeline recommended above rather than a uniform compliance deadline.
O3 also illustrates a limitation NIH should weigh: this multi-year, 30-plus-member effort was sustained largely through volunteer committee time within a professional society rather than a dedicated funding line. That model produced a high-quality standard, but it is not obviously scalable to every subfield of biomedicine, and it underscores why dedicated funding for infrastructure-building consortia — not just for the investigators who happen to originate a standard — is worth NIH's direct support.

Example 2: the Medical Imaging and Data Resource Center (MIDRC)
A complementary model comes from medical imaging data infrastructure and software tools to help understand ones' data, rather than terminology standards. The Medical Imaging and Data Resource Center (https://www.midrc.org/), initiated in 2020 and funded by the National Institute of Biomedical Imaging and Bioengineering, is co-led by the American College of Radiology, the Radiological Society of North America, and the American Association of Physicists in Medicine, and hosted at the University of Chicago on the Gen3 platform. It was created to accelerate machine-learning research by making large volumes of imaging data — originally COVID-19 chest imaging, now expanding to cancer, diabetes, chronic liver disease, coronary artery disease, and COPD — available through a common access point rather than scattered across individual institutional repositories.

Several structural choices here are directly relevant to how NIH could support data and model sharing at scale:
• A dedicated funding vehicle for infrastructure, not a research grant repurposed for it. The center is funded through an NIH contract mechanism rather than an investigator-initiated grant, with data intake, curation, de-identification, and quality assessment treated as a funded/established core function rather than an unfunded expectation placed on individual labs. This is a working example of the "distinct infrastructure funding category" recommended above, rather than a hypothetical.
• Centralized open data commons with intake with distributed, harmonized access. Imaging and meta data flow in through dedicated intake portals, is anonymized at the contributing site, is standardized centrally, and is then made available through an open data commons with a public access point for

building cohorts, sparing individual research teams from having to solve data harmonization independently for every new dataset.
• A reserved, non-public sequestered data commons. A portion of incoming data is deliberately held out from the public commons specifically to support independent validation, benchmarking, and data-science challenges. This is a concrete, exportable version of the "measurable indicator" recommended above — a held-out test set enabling objective benchmarking of models, which were trained on the shared data, rather than relying on self-reported performance; expediting translation through regulatory and to clinical care.
• A distributed biomedical imaging hub (BIH) for indexing other existing repositories to enable more comprehensive searches and discoveries for cohort building, especially useful for rare diseases where only a few cases exist at multiple institutions.
• A suite of user-friendly web-based and downloadable tools to assist AI researchers in tasks such as cohort building through stratified sampling, choosing appropriate metrics and statistical analyses for robust evaluations, determining and comparing data representativeness across datasets, evaluating both performance and presence of bias when comparing AI algorithms, deidentification tools for imaging data and radiology reports, and harmonization tools – all tools that investigators can use to expedite their research.
• A stated bridge to commercialization and regulatory translation. The held-out validation resource is explicitly framed as supporting industry translation and regulatory approval, showing that a centrally funded public data commons and a commercialization pathway are not mutually exclusive — a direct answer to the concern that data/software sharing mandates might undercut translation incentives – and can serve as a mechanism of sustainability.
• Governance that scales the scope over time. What began as a narrowly scoped, urgent-need resource (COVID-19 imaging) has since broadened its disease coverage and, through a recent philanthropic grant, its international reach, rather than being built to a fixed, one-time specification. Multiple professional-society-run subcommittees and working groups govern this expansion, echoing the multistakeholder governance structure described above.
Together, the two examples cover different but complementary layers of the same problem: one standardizes what the data means, and the other standardizes how the data is collected, held, and accessed. NIH's ability to point to concrete infrastructure funded this way is a strong signal that dedicated infrastructure investment, held out from standard research-grant budgets, is a proven vehicle rather than a speculative one.

Benefits

• Reduced duplicated effort across labs solving the same measurement, registration, or reconstruction problems.
• Stronger reproducibility posture, directly responsive to well-documented replication concerns in biomedical research more broadly.
• Increased translational reach for tools that would otherwise sit unused in a single lab, particularly benefiting smaller institutions and low-resource settings that cannot license commercial equivalents.

Unintended Consequences to Guard Against

Penalizing small businesses and industry partnerships. A uniform open-source mandate applied to SBIR/STTR or Academic-Industry Partnership grants could undercut NIH's own directive to promote commercialization, a pathway that is at least as impactful as open release for translating research into usable clinical tools.
• Repositories full of low-value code. Mandating release without funding the work needed to make code usable by others risks producing repositories filled with undocumented, task-specific scripts that add compliance burden without adding scientific value. Any incentive structure should reward usable release, not mere release.
• Slower research pace. If investigators must build to open-source, deployable standards throughout a project rather than at its end, exploratory and early-stage work may slow down. Decoupling "release standard" from "in-progress code" — e.g., requiring open availability at publication/award-closeout rather than continuously — would mitigate this.

Feasibility across Career Stages, Disciplines, and Institution Types

Early-career investigators and small/under-resourced labs face the steepest relative cost of packaging and maintaining software; funding mechanisms and review credit should explicitly account for this rather than assuming uniform capacity to comply. Standard research grants do not currently fund this work, and not every investigator has a software-engineering skill set — though this is an increasingly expected and learnable skill, not a permanent excuse for opacity.
• Small businesses and startups operating under SBIR/STTR need protection for competitively sensitive code even while participating in a "research-use" sharing norm. Enforcement of "research use only" licensing is an unresolved operational question NIH guidance should address directly, since the practical burden of proving misuse would otherwise fall on small companies least equipped to pursue it.
• Large platform-maintaining groups need a fundamentally different, continuous funding model than a typical project grant. Policy should recognize infrastructure maintenance as a distinct award category rather

3. Training and Mentorship: Framing

The mission of the AAPM is to “advance medicine through excellence in the science, education and professional practice of medical physics.” Accordingly, AAPM is committed to the education, training, and mentorship of aspiring and early-career medical physics professionals and researchers. While a number of NIH funding opportunities exist specifically to promote the growth and stability of the biomedical research workforce through training and mentorship (such as the Institutional National Research Service Award (T32) and the Ruth L. Kirschstein National Research Service Award (NRSA) Individual Predoctoral Fellowship (F31)), training and mentorship should be expected to pervade all scientific research endeavors. NIH-funded research should include an expectation of training and mentorship activities as a component of impact and success measures to signify the value of the next generation of biomedical scientists being trained alongside those researchers who are making cutting-edge advances in research today.

The typical training trajectory for medical physicists begins with a strong undergraduate physics background, followed by an accredited graduate program in medical physics. After graduate training, medical physicists contribute in several ways to biomedical science and healthcare. Some pursue

research-focused roles in academia or participate in industry innovation; some go on to a clinical physics residency, after which they will focus on clinical work (possibly combined with research activities) in a hospital setting. Consequently, medical physicists, whether employed in academia, industry, or the clinic, have been trained by their advisors and mentors in rigorous research practices, which are integral for both the advancement of science and for state-of-the-art clinical care. Imparting rigorous research skills to future generations of medical physicists is a hallmark of AAPM's mission that has resulted in a tradition of excellence in scientific research training and mentorship and, importantly, measures of success that can be translated to the biomedical research workforce at large.

Measurable indicators NIH could use

AAPM places a high value on intentional programming to foster rigor in research training for medical physicists. It has two aspects of measurable indicators that the NIH could translate for the assessment of scientific impact broadly, both for biomedical fields of study and for individual investigators providing mentorship and training.

• Undergraduate mentorship. AAPM currently sponsors two undergraduate research fellowship programs: the Summer Undergraduate Fellowship Program (SUFP) and the Driving Recruitment through Education and Mentoring Program (DREAM). AAPM conducts an annual evaluation of immediate program outcomes. It also recently began surveying past participants to measure a range of long-term outcomes, including research deliverables from the fellowship and continuation to graduate school and other training programs. Specific measures of training and mentorship success that could be translated broadly to biomedical research include the number of summer undergraduate research fellows the research team mentors through an NIH-funded research project, research deliverables within such fellowships, the number of mentored undergraduates who later enter graduate programs, and impact on pursuing research.
• Graduate and residency mentorship. The accreditation of medical physics graduate and residency programs by the Commission on Accreditation of Medical Physics Education Programs (CAMPEP) provides a structure that tracks trainees across clinical, research, and industry career destinations. This framework could be translated to biomedical science at large. For example, annual CAMPEP reporting includes number of applicants, number of trainees admitted, numbers of graduates, and subsequent positions. There are additional research training features in the CAMPEP standards: required graduate research, research-integrated residencies, responsible conduct of research training, and research ethics instruction. These metrics could all be used to quantify the impact of graduate and resident involvement in NIH-funded research.

Implementation approaches

Several implementation paths could turn the measures already collected by the field of medical physics into indicators usable across biomedical science. AAPM could publish a white paper documenting the indicators it collects, how it collects them, and the reasoning behind each, then jointly author companion pieces with stakeholders in other biomedical fields to identify which indicators transfer directly and which require adaptation. This would give the broader biomedical community a proven starting point rather than requiring each discipline to design workforce indicators from scratch.

Undergraduate research programs could collectively implement moderately frequent survey cycles (e.g., every five years) and adopt use of a persistent researcher identifier (such as Open Researcher and Contributor ID (ORCID) now commonly used to track scientific publications of individual researchers) captured at the time of the fellowship so participants can be followed across institutions and career stages without requiring formal reporting by them.

Graduate and other advanced training programs could initiate or extend existing annual reporting with a small set of standardized measures of research outcomes, such as entry into research training, research outputs produced during training, and sustained engagement in research. Other areas of biomedical science could adopt the same measures, giving NIH indicators that are consistent, standardized, and comparable across disciplines.

Finally, individual trainers and mentors in medical physics could adopt these simple measures on their own, accessing and aggregating them (such as ORCID-tracked outputs) or collecting them, providing brief reports of research training impact in research proposal applications and reports.

Benefits

Medical physics has trained researchers for scientific impact for decades and already has solid indicators that are being collected, enhancing the potential for translation to other fields. Aggregation at both the field level (in the case of undergraduate research programs and graduate/advanced training programs) and the investigator level can help inform the public about the impact that training and mentorship has in science.

Unintended consequences to guard against

It is important to note that reporting could be burdensome for groups and individuals without sufficient staffing and resources. Thus, the chosen measures should be both simple and informative to maximize the collection and reporting of the information.

Counting research deliverables could penalize programs whose main purpose is exposure to the field. For example, in short undergraduate experiences, research output is not the central goal and the time window (often 10 weeks or less) limits what a trainee can potentially produce. Therefore, measures of the impact of training and mentorship should be considered holistically. Further, trainees who move out of a given field should not be counted as attrition. Their research activities can impact other areas of biomedical science. It is also beneficial for individuals trained in rigorous research to go on to impact other sectors, such as finance, education, and non-profit organizations.

4. Collaboration: Framing

Team-based science is an area in which medical physicists make substantial contributions that are often inadequately recognized by conventional measures of scientific impact. As biomedical research becomes more convergent, the medical physicist's role is increasingly a connective one - designing the measurements, harmonizing data across sites and scanners, building and validating the shared

resources, and defining the metrics that let a large, multi-institutional effort function as a single scientific enterprise. This work is essential to whether a collaboration's results can be trusted, yet it rarely produces first- or last-author publications and is therefore largely invisible to evaluation built around authorship position, citation counts, and individual grant dollars.

Medical physics also offers concrete, working models of large-scale team science. Illustrating the value of team science, the Operational Ontology for Oncology (O3) and the Medical Imaging and Data Resource Center (MIDRC), both described in our responses to other sections of this RFI, are each sustained not by a single laboratory but by multi-society, multi-institution collaboration.

How Team Science is Actually Organized: MIDRC

MIDRC (https://www.midrc.org/) is a multi-institutional initiative co-led by three professional societies — the American College of Radiology, the Radiological Society of North America, and the American Association of Physicists in Medicine — funded by NIBIB and hosted at the University of Chicago. It coordinates imaging data from academic medical centers, community hospitals, and other contributors into a single harmonized resource, and it is governed through a structure of subcommittees, working groups, Technology Development Projects, and Collaborative Research Projects, recently expanding internationally through MIDRC-Global.
What makes MIDRC work is not principally any one discovery; it is sustained coordination across disciplines. Radiologists, medical physicists, data scientists, informaticists, statisticians, and clinicians must be aligned on how data are curated, de-identified, annotated, harmonized, and evaluated. Within that structure, medical physicists occupy a characteristically connective role, establishing harmonization and quality-assessment methods, designing the validation resources and community benchmarking (e.g., Grand Challenges) that let algorithms be compared objectively, and defining the performance and bias metrics the whole community relies on. This is high-value scientific labor that determines whether the shared resource is trustworthy, yet it maps poorly onto first/last-author metrics.

Measurable Indicators NIH could Use

• Role-based contribution taxonomies. NIH could incorporate structured contribution taxonomies, such as CRediT, into its evaluation framework to identify and credit the specific roles that convergent science depends on – including data curation and harmonization, annotation, validation-set design, standards and ontology development, quality assurance, and consortium governance - rather than relying primarily on authorship position.
• Recognition of consortium and working-group leadership as a creditable scientific contribution in biosketches and progress reports, so that stewardship of a shared standard or resource (e.g., leading a MIDRC working group or an O3 development effort) is visible and valued.
• Outputs enabled by collaboration. NIH could recognize measurable scientific products that depend on coordinated contributions across disciplines or institutions, such as harmonized multicenter datasets, shared validation resources, consensus measurement protocols, interoperable standards, or independent multisite validation. These outputs provide stronger evidence of meaningful team science than simply counting the number of participating investigators, institutions, or organizations.
• Contribution distinct from sole attribution. Indicators should let evaluators credit an essential link in a

longer collaborative chain without requiring that the contributor be able to claim the whole result - the connective, enabling contribution should be assessable on its own terms.

Implementation Approaches

• Use existing reporting infrastructure. A structured contribution taxonomy could be captured in RPPRs and biosketches rather than through a new compliance layer, letting team roles be recorded where NIH already collects investigator information.
• Credit and fund the coordinating core. Sustaining team science at scale requires supporting the coordination functions themselves — intake, harmonization, annotation, validation, and governance — as dedicated infrastructure, complementing the infrastructure-funding recommendations in our Data, Software, and Model Sharing response rather than assuming these functions emerge from participating investigators' individual project grants.
• Recognize professional societies as collaboration infrastructure. O3 and MIDRC both show professional societies serving as durable, neutral conveners that distribute domain expertise and long-term stewardship across institutions; NIH could formally recognize this convening role when assessing the feasibility and sustainability of team-based efforts.

Benefits

Recognizing team-based and connective contributions would encourage researchers, including medical physicists, to take on the essential coordinating work that convergent science depends on, rather than being disincentivized by metrics that ignore it. Such recognition would also give NIH a more accurate picture of how modern biomedical results are actually produced — in which measurement, harmonization, and validation contributions are often the difference between trustworthy and untrustworthy findings. And it would make credit more equitable for contributors whose work does not surface as first/last authorship, including early-career researchers and staff scientists who frequently perform this connective labor.

Unintended Consequences to Guard Against

• Box-checking and gaming. A contribution taxonomy could devolve into rote role-tagging; indicators should reward substantive, verifiable contribution rather than mere listing.
• Over-granular credit that dilutes meaning. Assigning credit to many small roles risks making all contributions look equivalent; the aim is to make essential connective work visible, not to flatten distinctions between central and peripheral contributions.
• Penalizing the invisible contributor twice. If team-science credit is added but evaluation still defaults to authorship position and citation counts, the contributors this reform is meant to recognize will remain disadvantaged; the indicators must carry real weight in review, not sit alongside unchanged traditional metrics.
• Equating team size with scientific value. Metrics intended to recognize collaboration should not inadvertently disadvantage rigorous research conducted by individual investigators or small teams. Collaboration should be recognized when it adds scientific value or enables work that could not otherwise be accomplished, rather than rewarded based on the number of investigators, disciplines, or institutions involved.

5. Entrepreneurship and Translation: Framing

AAPM recommends that NIH define translation broadly and evaluate it according to the pathway by which a discovery produces practical benefit. Patents, licenses, company formation, and investment can be relevant indicators, but they are neither necessary nor sufficient evidence of scientific or public impact. In medical physics, translation is not limited to starting a company, licensing intellectual property, or obtaining a patent; consequential translation often occurs through independent technical validation, clinical commissioning, regulatory science, integration into clinical workflows, incorporation into professional standards, open-source dissemination, and adoption across healthcare institutions. Translation may consist of moving a physical principle, algorithm, device, imaging method, dosimetric technique, or decision-support tool through technical validation, independent replication, regulatory evaluation, clinical commissioning, workflow integration, professional guidance or standardization, multisite adoption, and demonstrated improvement in safety, quality, efficiency, access, or outcomes.

A concrete example of translational impact that would be largely missed by conventional commercialization metrics is AAPM's TG-51 protocol for clinical reference dosimetry. Published in 1999 and maintained through subsequent addenda (2014 for photon beams, 2024 for electron beams) by a standing AAPM working group, it moved a measurement-science advance into standardized clinical practice with no patent or commercial product - and, according to IROC Houston, has been implemented by 99.8% of North American institutions with compliant machines. It exemplifies high-impact translation achieved through professional standardization and multisite adoption rather than commercialization.

Measurable Indicators NIH Could Use

Evaluation should be appropriate to the innovation's maturity. Early-stage work should not be judged by sales or clinical outcomes, while mature work should not be judged solely by publications. Stage-appropriate indicators could include:

Early-stage indicators:
- Reproducible technical performance.
- Benchmarking against accepted reference methods.
- Documentation of uncertainty and failure modes.
- Assessment of clinical or user needs.
- Engagement of patients, clinicians, and intended users.

Translational-development indicators:
- Independent or multisite validation.
- Human-factors and workflow testing.
- Regulatory milestones.
- Interoperability with clinical systems.
- Performance across populations, equipment, and institutional settings.
- Consideration of safety, cybersecurity, maintainability, and lifecycle costs.

Adoption and deployment indicators:

• Clinical commissioning or adoption.
• Inclusion in clinical trials, standards, or professional guidance.
• Improvements in quality, safety, access, cost, or efficiency.
• Uptake outside the originating institution.
• Availability of training resources and post-deployment monitoring.
• Sustainable maintenance and technical support.

This framework should recognize multiple dissemination models. An openly available algorithm, reference dataset, quality-assurance method, or consensus standard may, in some circumstances, create greater public value than a patented technology that achieves limited adoption. Some high-impact innovations are intentionally disseminated through open-source software, public datasets, standards, or nonexclusive licensing, and these should not be treated as less valuable than proprietary commercialization.

Implementation Approaches

Implementation mechanisms could include a structured translational-impact narrative in progress reports and biosketches, milestone plans appropriate to the technology's maturity, supplements supporting independent validation and clinical implementation, and access to regulatory and commercialization expertise for institutions without extensive technology-transfer infrastructure. NIH should also support protected time, entrepreneurial education, regulatory expertise, implementation science, and partnerships among academia, healthcare organizations, government, and industry. NIH should support transparent management of financial conflicts while recognizing that responsible collaboration among academia, healthcare institutions, government, and industry is often necessary for successful translation.
NIH should recognize the contributions of the full translational team, including investigators responsible for measurement science, software, validation, quality assurance, regulatory strategy, clinical workflow integration, training, and long-term technical stewardship. Metrics should recognize each individual's contribution rather than attributing all success to the patent holder, founder, or laboratory director (consistent with our Collaboration response).

Benefits

Defining translation broadly, and recognizing open dissemination alongside commercialization, increases the reach of innovations that would otherwise sit unused, particularly for smaller institutions and low-resource settings. Failed or discontinued translation attempts can also produce valuable information about safety, generalizability, usability, cost, or clinical feasibility: a rigorously conducted translational effort that identifies a safety limitation, lack of generalizability, or poor clinical fit can prevent ineffective or harmful implementation and should be regarded as a meaningful contribution. NIH should reward rigorous learning, not only successful products.

Unintended Consequences to Guard Against

NIH should avoid reliance on raw counts of patents, licenses, start-ups, or investment. These indicators

can be readily inflated and do not establish clinical usefulness, accessibility, safety, or benefit to the public; NIH should avoid rewarding patent accumulation, as patents vary substantially in quality and public value and may never lead to a usable intervention. Translational impact should instead be evaluated through converging evidence that an innovation is valid, usable, responsibly disseminated, and capable of improving health or healthcare delivery. Conflict-of-interest transparency is essential, but industry collaboration should not itself be regarded as evidence of bias or diminished scientific value.

Feasibility Across Career Stages, Disciplines, and Institution Types

Smaller institutions and investigators without extensive technology-transfer offices need equitable access to translational assistance. Stage-appropriate evaluation is itself a feasibility safeguard: judging early-stage or foundational work by sales or clinical outcomes would disadvantage exactly the investigators and institutions least able to carry a technology to market alone.

6. Foundational Scientific Exploration: Framing

Traditional metrics of scientific evaluation — citation rates, high-impact journal counts, and short-term deliverables — systematically undervalue the capital-intensive infrastructure, methodological validation, and multi-center tool generation required for high-risk, foundational biomedical innovations. Using FLASH radiotherapy (ultra-high-dose-rate irradiation) and advanced radiation dosimetry (for FLASH-RT and radiopharmaceutical therapies) as core exemplars, this response details specific non-citation indicators, implementation mechanisms, risk mitigations, and career-stage safeguards to realign NIH funding and evaluation with modern foundational scientific research. These recommendations are intended to apply to high-risk foundational research generally.

FLASH Radiotherapy as a Paradigm for Foundational Scientific Exploration

FLASH radiotherapy (FLASH-RT) delivers radiation at ultra-high dose rates, greater than 40 Gy/s, and is under active investigation for its potential to widen the therapeutic window by sparing healthy tissue while preserving tumor control. The underlying biological mechanisms, including oxygen depletion, free-radical kinetics, and mitochondrial effects, and the physical requirements for delivering and monitoring ultra-fast beams, remain incompletely understood and are the subject of ongoing preclinical and early clinical study. Progress depends on sustained investment in beamline engineering, physics infrastructure, and standardized assay protocols. This work is necessary to determine whether and how FLASH-RT can be safely translated to patients, yet it does not register on short-term citation counts. FLASH-RT illustrates why conventional metrics undervalue foundational work: its scientific value lies as much in rigorously mapping mechanism and uncertainty as in confirming a positive result.

Measurable indicators.

Specific, measurable indicators of foundational impact include
• Community technology adoption - the number of independent research and clinical centers adopting an open-source beam-delivery architecture, target chamber, or pulse-control framework.
• Standardized protocol adherence - community-wide implementation of standardized radiobiological protocols, oxygen-control standards, and beam-calibration procedures.

• Shared open-data repositories - public deposition of raw, multi-center biological and physics datasets, such as the NCI Cancer Data Service, to support independent mechanistic modeling.
• Interdisciplinary team capabilities - validated institutional infrastructure bringing together accelerator physicists, radiobiologists, computational scientists, and clinical oncologists.

Incentives and funding mechanisms

Proposed NIH incentives and funding mechanisms include milestone-driven infrastructure grants (i.e., U01 and U24 cooperative agreements and RM1 Research Opportunity Awards to support long-term physical beam-line construction, standardization, and inter-institutional calibration networks) and rewarding rigorous non-replications, establishing funding lines explicitly devoted to independent replication of the FLASH effect across variable dose rates, tissue types, and oxygenation levels, rewarding biological boundary-mapping over positive-outcome bias.

Unintended consequences

One unintended consequence should be managed directly: over-incentivizing 'high-risk' novel modalities without sufficient mechanistic rigor could lead to premature clinical translation or unvalidated biological claims. This can be mitigated by tying translational funding milestones to mandatory, independent multi-center validation of physical beam characteristics and biological endpoints prior to Phase I/II clinical-trial initiation.

Career-stage and institutional considerations

Early-career investigators who lead team-science infrastructure work, such as accelerator design or dosimetry modeling, face a particular risk under current evaluation norms, since this work is essential to a project's success but rarely generates first- or last-author publications. Structured contribution credit along the lines recommended in our Collaboration response, such as recognizing methodological leadership in biosketches and progress reports through a taxonomy like CRediT, would let these investigators document their role without relying on authorship position alone to demonstrate their contribution.

Advanced Radiation Dosimetry as an Enabling Foundational Science

Advanced radiation dosimetry provides the essential quantitative foundation for safe, effective, and reproducible research in novel modalities, including FLASH radiotherapy, MR-guided adaptive therapy, and targeted radiopharmaceutical therapeutics (RPTs) such as Lutetium-177 (177Lu) and Actinium-225 (225Ac). Because dosimetry outputs take the form of open-source software packages, Monte Carlo codes, physical phantoms, and metrology standards, rather than high-volume primary-outcome papers, traditional metrics dismiss dosimetry as a routine support service rather than a primary scientific driver.

Measurable indicators

Specific, measurable indicators of foundational impact include

• Regulatory and guideline integration - formal adoption of novel dosimetric frameworks into FDA regulatory filings, SNMMI/AAPM consensus protocols, or NCI National Clinical Trials Network (NCTN) trial designs
• Computational reach and software adoption - unique downloads, active code forks, and platform integrations of open-access dosimetry software such as MIRDcalc and voxel-level Monte Carlo tools
• Standardized calibration distribution - deployment of validated physical or digital reference phantoms across academic and community clinical-trial sites.
Proposed NIH incentives and funding mechanisms

Two mechanisms are proposed. First, dedicated methodology-infrastructure awards — funding mechanisms such as R24 or U24 — focused on open-source dosimetry-tool creation, computational-phantom expansion, and multi-center metrological traceability. Second, mandatory dosimetric rigor standards that require patient-specific or voxel-level dosimetry across all NIH-funded clinical trials investigating novel radiopharmaceuticals or ultra-high-dose-rate modalities.

Unintended consequences

The principal unintended consequence to manage is incentivizing pure software or hardware development detached from biological or clinical utility; this can be mitigated by requiring all funded dosimetry projects to demonstrate explicit integration with biological-response models, toxicity-reduction endpoints, or clinical-trial harmonization.

Career-stage and institutional considerations

Finally, with respect to institutional equity and access, open-source dosimetry suites and shared reference datasets reduce financial barriers for non-R01-intensive institutions and community medical centers, broadening diverse patient participation in advanced radiopharmaceutical clinical trials.

Conclusion

NIH should explicitly recognize technology creation, open infrastructure, consensus standards, and multi-institutional collaboration as primary indicators of scientific impact within the Foundational Scientific Exploration category. By expanding evaluation metrics beyond traditional citation counts, NIH can better sustain long-term support for high-risk foundational research of this kind.

7. Public Impact: Framing

AAPM supports NIH's effort to recognize the broader public impact of biomedical research. Public impact should encompass not only new drugs and devices, but also improvements in the safety, quality, accessibility, reliability, and efficiency of healthcare. Medical physics illustrates the importance of this broader approach, and provides an example of public impact that is important but often largely invisible to patients. Much of the field's public benefit arises from the measurement, validation, dosimetry, quality-assurance, and technical infrastructure that enables imaging and radiation therapy to be delivered safely and accurately, including safer imaging, more accurate radiation therapy, reduced unnecessary exposure, consistent quantitative measurements, earlier detection, fewer errors, better

workflows, and wider access to high-quality care. The Image Gently and Image Wisely campaigns — multidisciplinary national radiation-safety initiatives in pediatric and adult imaging - provide visible examples of how evidence generated through imaging science, radiation protection, protocol optimization, and quality improvement can ultimately be translated through professional initiatives into broad public benefit. Their impact is distributed across patients and institutions and is realized through changes in practice rather than through a single product or discovery.

In safety-focused disciplines, public impact may also consist of adverse events that do not occur: an unnecessary imaging examination avoided or optimized, a treatment error prevented, or an unsafe or ineffective technology identified before widespread clinical implementation. Such preventive impact is inherently difficult to capture through conventional outcome metrics, but it can represent substantial value to patients and the healthcare system.

Measurable Indicators NIH Could Use

Public impact could be evaluated at several levels, spanning patient, clinical, health-system, population, and societal outcomes:
• Patient - safety, outcomes, experience, and treatment burden.
• Clinical - guideline adoption, diagnostic quality, treatment accuracy, and workflow reliability.
• Health system - reduced errors, avoided procedures, efficiency, interoperability, and cost.
• Population - access, geographic reach, disparities, and scalability.
• Societal - public trust, scientific literacy, workforce development, informed public policy, and economic activity.

Concrete examples across these levels include improvements in diagnostic performance or treatment accuracy; reductions in unnecessary radiation exposure, errors, repeat procedures, or treatment burden; adoption of validated practices or standards; improved interoperability and workflow reliability; dissemination to community, rural, or other resource-constrained settings; reductions in disparities in access or performance; and evidence that research findings have informed clinical guidance, regulation, or public policy.

Outcomes should be interpreted in relation to the investigator's contribution. Process and intermediate outcomes are legitimate indicators when they are credibly connected to public benefit, and metrics should account for the potentially long interval between foundational research and widespread clinical impact.

Implementation Approaches

Assessment should combine appropriately selected indicators with a concise narrative describing the investigator's contribution, the affected population, the strength of the evidence, and the expected time horizon. NIH should permit intermediate and preventive outcomes when investigators can describe a credible pathway to public benefit. For example, a validated quality-assurance method may reduce the probability of future errors even when the errors prevented cannot be directly counted.

Several practical measures would support fair and reliable evaluation of public impact:
• Use a short menu of indicators rather than one universal score, and allow investigators to select the indicators relevant to their work.
• Require evidence or links supporting major impact claims.
• Give reviewers guidance on contribution versus attribution and on differing translational timelines.
• Keep reporting concise and reuse information already collected in biosketches and progress reports.
• Recognize maintenance, replication, negative findings, and prevention of harm.
• Avoid composite rankings or formulas that imply false precision, and periodically assess whether particular indicators are encouraging gaming or distorting research priorities.

Evaluators should distinguish contribution from sole attribution: individual researchers often provide an essential link in a longer chain of discovery, validation, implementation, and clinical care, but cannot independently determine final health outcomes. (This principle recurs across our responses – see our Collaboration and Entrepreneurship and Translation responses - and applies with equal force to public-impact assessment.)

Public trust should be supported through transparent communication of benefits, limitations, uncertainty, conflicts of interest, and the performance of emerging technologies such as artificial intelligence. Accessibility should mean more than publishing a paper; it can include usable documentation, interoperability, affordability, training, disability access, language access where relevant, and feasibility in community and rural settings. Patient and community engagement should be recognized when it substantively influences research questions, study design, communication, dissemination, implementation, or access — not simply by counting the number of meetings held.

Benefits

A broad, multi-level view of public impact captures how biomedical science actually delivers durable value: not only through new products, but through safer, more accurate, more accessible, and more reliable care. Population-level safety initiatives (such as Image Gently and Image Wisely) exemplify this durable value, the benefit accrues broadly across many patients and institutions rather than through a single marketable product. Recognizing preventive and negative findings - for example, research demonstrating that a technology is unsafe, biased, non-generalizable, or unsuitable for clinical use - protects patients and conserves public resources, and represents genuine public value even when it does not lead to product adoption. A framework that credits enabling and infrastructure contributions ensures that the largely invisible work behind safe, effective imaging and radiation therapy is neither overlooked nor undervalued.

Unintended Consequences to Guard Against

NIH should avoid requiring investigators to claim direct changes in mortality, economic return, or other distal outcomes that cannot be reliably attributed to one project. Over-reliance on simplistic "lives saved" or economic-return calculations invites over-claiming and disadvantages foundational, enabling, safety-focused, and infrastructure-oriented research. A portfolio of contextualized evidence would better capture how biomedical science delivers durable value to the public. Because a new framework could

itself introduce distortions, NIH could pilot it in selected programs before applying it broadly, and evaluate it for bias by discipline, career stage, institution type, and access to commercialization infrastructure.

8. Other Areas: The American Association of Physicists in Medicine (AAPM) is the professional society of medical physicists — scientists who apply physics to medicine to advance the safe, accurate, and effective use of imaging and radiation therapy in patient care and research. On behalf of our members, we thank NIH for its leadership in examining how scientific impact is measured and rewarded, and we welcome the opportunity to respond to NOT-OD-26-087. Medical physics sits at the intersection of measurement science, technology development, and clinical translation, and our members contribute to biomedical research in ways - reproducibility infrastructure, data and software sharing, standardization, training, and team-based enabling work - that are essential to rigorous science yet often undervalued by conventional impact metrics. We offer the following comments in that spirit and stand ready to serve as a continuing resource to NIH as this important effort moves forward.

246. Inter-university Consortium for Political and Social Research (ICPSR)

I am responding: On behalf of an organization

Name: Elizabeth Moss, with Maggie Levenstein, and Trent Alexander

Name of Organization: Inter-university Consortium for Political and Social Research (ICPSR)

Type of Organization: Other

Type of Organization - Other: Research Data Repository

Role: Other

Role - Other: Librarian (Moss); Investigator/Researcher (Levenstein and Alexander)

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: The Inter-university Consortium for Political and Social Research (ICPSR) appreciates the opportunity to respond to NIH's Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087). ICPSR is one of the world's largest digital repositories of social and behavioral science research data. As a replication-ready repository, ICPSR preserves data, documentation, and provenance metadata, with the technical and legal infrastructure to support sharing, including for data that are large, complex, or sensitive. Certified by CoreTrustSeal (ICPSR, 2024), ICPSR is an archive dedicated to providing good data stewardship that maximizes the value of federal investments, ensures that scientists are credited for creating data products, supports replication of original research, and creates new opportunities for research. ICPSR currently preserves and disseminates approximately 27,000 data studies containing hundreds of thousands of individual data files, with over 850,000 downloads each year. As a strong supporter of replication in biomedical, behavioral, and social science research, ICPSR hosts more than 7,000 research replication packages in journal repositories on its self-publishing platforms. Additionally, for 63 years, successive generations of early-career scholars have received training in quantitative research methodology through courses in the ICPSR Summer Program, where they are exposed to best practices in research. Further, ICPSR promotes transparency and replicability by publishing extensive guidelines for data depositors on how to prepare data files and documentation to ensure their reuse (ICPSR, 2020). ICPSR strongly supports NIH's interest in identifying the "critical research and infrastructure needs necessary to advance rigorous and reliable scientific findings" (NIH, 2026). ICPSR further supports NIH's efforts to expand measures of scientific success through acknowledging, elevating, and rewarding scientists who share data. In tandem with NIH, ICPSR also recognizes the value in rewarding scholars who reuse shared data and then make adequate information and tools available to replicate their results.

In addition to serving as data stewards and supporting study replication, ICPSR has a long history of linking publication-associated replication materials to the curated data it distributes. Data distributed by ICPSR form the foundation for tens of thousands of research articles, reports, dissertations, books, and other works that advance science, and are collected in the ICPSR Bibliography of Data-related Literature (ICPSR, 2026), a one-of-a-kind searchable database that captures, organizes, and makes discoverable research findings stemming from ICPSR datasets. Each citation record in the database is enhanced with

metadata linking the publication to the underlying data used by its author. The Bibliography plays a crucial role in demonstrating the long-term impact of NIH-funded datasets. However, a further step could be taken to recognize authors who reuse data and make it easier to test their methods and reproduce their findings.

Data repositories are well positioned to play a larger role in recognizing investigators who reuse data and provide replication packages when they publish their findings, since the platforms on which shared data are made available form a natural home for source data, published findings based on those data, and the tools essential to replicating study findings. Linking such resources together makes each meaningful in context, multiplies the usefulness and impact of NIH investments, and helps recognize investigators' rigorous efforts to make results from publicly funded research reproducible.

Measurable indicators of science that should be recognized and incentivized:
--Researchers publish in journals or on platforms that assign scholarly works with persistent identifiers, e.g., DOIs, to ensure long-term accessibility.
--Researchers reuse archived data and include links to their replication packages that contain their analytic code, software, and other tools essential for replication.
--Data repositories flag or highlight publications in which authors include links to their replication packages.
--Data repositories encourage authors to deposit their replication packages, which are linked to the original dataset they reused.
--Data repositories that house replication packages requiring restricted access offer a streamlined process for granting access for testing replicability.
--Data repositories systematically collect and link their distributed data to the citing literature, and they also link findings, replication packages, and original archived data to disseminate them together, thereby simplifying and promoting the reproduction of results.

Implementation approaches:
--Trusted repositories should provide a data citation and an accompanying persistent data identifier for all deposited datasets, and require data reusers to cite the data in publications in which the data were analyzed.
--Publishers should require the explicit citation of source data and replication packages in scholarly works. Without explicit citation and persistent identifiers, automatic linking among data, literature, and replication packages is more difficult.
--NIH should support archival system infrastructure that links research data to the primary and secondary findings generated from those data.
--NIH should support efforts by archives and repositories to single out publications that provide access to replication packages and use their platforms to promote best practices.
--Investigators who have received recognition from trusted data repositories can include such accomplishments in their NIH grant applications and progress reports.
--NIH should encourage archives not only to collect links to data-related publications but also to find and link to, or even archive, the replication packages associated with those publications.
--NIH should encourage archives and repositories to reach out to authors whose replication materials are not available online but are available by request, and encourage authors to preserve them.

--NIH should support efforts by archives and repositories to disseminate data with the citing papers and the replication packages associated with them.

Potential benefits or unintended consequences:
--Authors may more frequently make use of provided citations and unique identifiers to formally cite data.
--It becomes easier to identify which shared datasets support which publications, analyses, and downstream discoveries.
--It becomes easier for researchers to build upon existing research, since the citing literature is identified and available for replication or extension.
--Transparency and replicability are prioritized by making replication materials available alongside the data.
--More authors will provide links to replication packages when publishing results.
--By collecting publications that reuse data and including replication packages, archives and repositories will be able to identify investigators who enable replication.
--Greater public trust in, and a stronger evidence base for, biomedical and behavioral science will result.
--A potential unintended consequence is that creating viable replication packages when restricted data were used can be difficult due to privacy concerns, indirectly penalizing researchers who reuse those data. Archives could mitigate this by providing secure options for replication testing. Also, by highlighting publications whose authors provided replication packages, repositories risk endorsing the content of their analysis rather than the practice of sharing the necessary tools to replicate the experiment or study using the same methods and conditions to achieve the same result.

2. Data, Software, and Model Sharing: Over the past 64 years, ICPSR has built infrastructure for researchers to share data with the academic research community, receiving significant funding from NIH and other federal agencies (e.g., the Office of Justice Programs), as well as private foundations and member institutions. Data sharing has become a core expectation for researchers conducting federally funded scientific research. Today, nearly every federal agency providing research funding requires a data management and sharing plan as a condition of receiving an award (e.g., DOE, 2023; NASA, 2022; NEH,

2025; NIH, 2023; NSF, 2024). Both funding agencies and scholarly journals recognize the value of publishing corroborating data, and they require authors to make their data publicly available in trusted repositories to ensure robust metadata adequately describe and give context to the data, provide systems that protect confidential and sensitive information, register data with persistent, machine-readable identifiers, make data available in formats that will be useable over time, and provide online catalogs and discovery tools to ensure the data can be found and reused. ICPSR supports NIH's efforts to realign its measures of success, in order to recognize scholarly contributions beyond traditional measures of productivity. Research data as a scholarly information object has measurable impact that informs scholarship in ways publication metrics, alone, cannot. ICPSR supports NIH in its efforts to give credit to investigators who do the hard work of preparing, documenting, and sharing data to extend its value for the future.

Tracking the use and reuse of these shared data collections is a practical way for data repositories to help data creators demonstrate the scientific value they have generated. Like many repositories and archives, ICPSR measures the number of accounts created, dataset page views, downloads, data-use agreements, and access requests. However, these metrics do not necessarily indicate that data were cited, analyzed in publications, or used to replicate or extend prior findings. A researcher may download a dataset but never use it, or multiple members of a research team may access data that results in one publication. Conversely, a dataset may be used extensively over time in ways that are not fully captured by download counts alone. To address this limitation, ICPSR supports creating linkages between shared datasets and publications based on those datasets. By linking datasets to downstream publications, ICPSR provides an infrastructure that gives investigators the credit they deserve for preparing, documenting, and sharing data. This architecture is the database known as the ICPSR Bibliography of Data-related Literature (Moss et al., 2015; ICPSR, 2026). A publicly available tool for discovering data via the citing literature, it serves as an example of how repositories can demonstrate the scientific value generated by shared data resources.

Continually expanding, the Bibliography's database currently contains nearly 130,000 citations to publications that meaningfully use data distributed at ICPSR. The collection represents over 60 years of scholarship, including in public health, behavioral health, and biomedical research funded by NIH. Often, output based on these data is published decades after the data were originally collected and shared, proving their continued usefulness. The Bibliography was built with support from the National Science Foundation (SES 9977984) under a continuing grant from 1999 to 2003. Thereafter, it has been funded by ICPSR's 800 member institutions, as well as by foundations and federal agencies. In the past decade, thanks in part to increased support from several NIH-funded data repositories at ICPSR, the Bibliography has grown at an accelerated pace, adding 5,000 to 7,000 citations per year. To populate the Bibliography, a small team of librarians and information professionals set up manual or API queries within bibliographic databases to find evidence of data use in the scholarly literature. They collect citations to publications that use the data and enhance each citation record with links to the data in ICPSR's collection. All publications associated with a given dataset then appear displayed with the data on ICPSR's public websites, like any other important metadata element. Careful human curation is required in order to make the collection meaningful, and not diluted with publications that merely mention datasets but do not actually conduct analysis using them.

The Bibliography can be searched, returning relevant results that point to publications linked to data. In this way, the Bibliography serves as both a data discovery tool and a compilation of scholarly works based on each dataset. Funders, data creators, researchers, and students can see not only the available data in the Bibliography but also how those data were used by others. Each publication's citation links a site user to the full text if they have access to it, and to the underlying data held at ICPSR. Thus, site users can discover analyses of data to replicate, avoid duplicating analyses that have already been done, identify cross-disciplinary implications and uses of the data, study how data resources are used, conduct citation analyses, better understand the data life cycle, and learn of methodological issues associated with the data, some of which are covered solely in the published literature. Crucially, the Bibliography acts as a de facto reward mechanism for data creators. A list of citing works, permanently linked to their shared data, helps demonstrate its value and justify future support from funders.

As the Bibliography has grown, bibliometricians and other scholars have found the full collection of citations, with its highly curated linkages between data and the citing literature, to be a unique dataset (ICPSR, 2026) for conducting research. They take advantage of its rich citation metadata, often combining the Bibliography with other sources to better understand the range of scholarship enabled by shared data. Some researchers have used co-citation analysis to measure the diversity and novelty of research data reuse (Lafia et al., 2022b). Others take advantage of the fact that, by definition, the authors in the Bibliography have analyzed data. By accessing corresponding author information, researchers can contact authors who reuse data and survey them about their experiences working with secondary data (e.g., Million et al., 2025). Hence, having convenient access to a sample of this group of published authors can inform researchers about successful data reuse. Still other researchers have used the data-literature links in the Bibliography to study the downstream impacts of poorly reused or problematic data noted in Retraction Watch, drawing links between retracted papers and archived datasets (Narayan et al., 2026). With the increasing number of retractions in the biomedical literature (Hwang et al., 2023), it is more important than ever to have tools like the Bibliography to use in conjunction with other resources to help make flaws in data more visible to potential reusers.

Due to several factors, it can be difficult and costly to find the universe of published and unpublished works resulting from analyses of data held at ICPSR. For instance, librarians and information professionals who populate the Bibliography must make do with tools not designed for data discovery and use. Most platforms that host bibliographic databases focus on scientific article retrieval and do not support field searching that can isolate search matches where they appear in the methods and data sections of publications. Ironically, due to the inconsistency in how data are described in works and tagged or linked where those works are hosted, the best source for accessing metrics of data use is considered to be the data repository (Apartis, et al., 2024). Poor citing practices also can be a barrier for repositories trying to track data reuse (Vannan, 2020). In ICPSR's case, each citation is evaluated to ensure it is linked accurately to a specific dataset(s), since authors can be imprecise, opaque, or negligent in how they cite research data (Moss & Lyle, 2018). Inevitably, some reuse goes undetected; therefore, the data creator never receives credit for it. More computational efforts are being developed to determine how often shared data are cited. To help in this endeavor, ICPSR supplies data-literature linkage metadata from the Bibliography to the Data Citation Corpus (DataCite & Make Data Count, 2024), which in turn enables linkages to be made by entities like OpenAlex (Priem et al.), a free, open-source catalog and database of the global research ecosystem. With data citation information supplied by

repositories and publishers, their services enable tracking publications and data that are registered with Digital Object Identifiers (DOIs). But these services still depend heavily on repositories to provide vetted data citations. For these reasons and more, the cost of collecting and linking shared data to the literature using it can be too high. As a result, ICPSR is one of only a few large-scale domain repositories tracking data use with human review to ensure the accuracy and relevance of the linkages.

In the future, researchers might leverage machine learning and generative AI (GenAI) to reduce the costs and frustrations associated with manually curating a collection like the Bibliography. In one experiment using the Bibliography, machine learning models were trained to recognize data use in publications (Lafia et al., 2022a), in an effort to reduce the amount of human judgement required to identify actual data use, and to do so at scale. It may be possible to use GenAI to build a domain-agnostic prototype of a tool that other repositories could use. A dynamic bibliographic metadata service could identify candidate related publications from external open source corpora, evaluate likely dataset-publication relationships, and route recommendations for staff review. Other tools may be created using GenAI to mine collections like the Bibliography to reveal and highlight existing interdisciplinary collaborations and other unforeseen benefits of sharing and reusing data. GenAI may also help reveal unexpected aspects of the secondary research being conducted across the social and biomedical sciences, surfacing more ways in which those who share data or share replication packages deserve recognition for the scholarship they enable.

Measurable indicators of science that should be recognized and incentivized:
--Data creators prepare, document, and share data for reuse in trusted data repositories.
--Data repositories link shared data to works that reused the shared data, to the extent possible.
--Repositories and archives help demonstrate the scientific value generated by shared data.
--Funders and data creators can verify that their data are reused, by which researchers, and in what disciplines.
--Data repositories, data creators/agencies, data funders, and information scientists can determine whether reuse extends beyond the original research team, whether the data support new research questions, whether the data contribute to interdisciplinary science, whether the data are used in training, replication, or policy-relevant work, and whether investments in curation and metadata increase downstream reuse.

Implementation approaches:
--Trusted repositories should provide a data citation and an accompanying persistent data identifier for all deposited datasets, requiring data reusers to cite the data in publications in which the data were analyzed.
--NIH should support trusted repositories in their efforts to discover and make linkages between shared data and the literature that uses it.
--NIH should invest in the infrastructure of data repositories and build on existing tools to create additional metrics of downstream reuse, connecting datasets to researchers, institutions, grants, and publications.
--NIH should support repository efforts to enhance publication citations beyond standard citation elements by leveraging robust metadata and persistent identifiers available in open sources.
--NIH should support data repositories seeking to develop GenAI mechanisms to increase efficiency in

finding data for reuse.
--NIH should invest in research to uncover networks of interdisciplinary data reuse hidden in the citing literature.

Potential benefits or unintended consequences:
--Data seekers may gain an understanding of the data by reading works that use it.
--Funders, investigators, and others have access to a metric of shared data reuse.
--High-value data may be recognized by reuse in publications, not simply by download metrics.
--Data reusers may gain a better understanding of the uses and limitations of datasets, avoid duplicating effort, ask new questions, apply new analytical methods, and extend findings from the original dataset, thereby increasing its long-term value.
--Data repositories may be able to measure the impact of NIH-funded data after grants are completed.
--Potential unintended consequences could include placing additional burdens on small data repositories. By providing links between data studies and the citing literature, data repositories risk prioritizing data reuse quantity over the quality of scholarship.

247. Engineering Biology Research Consortium

I am responding: On behalf of an organization

Name:

Name of Organization: Engineering Biology Research Consortium

Type of Organization: Professional Organization/Association

Role: Organizational Official

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: 1. Rigor and Reproducibility Engineering biology contributes to biomedical discovery through the development and validation of new biological systems, technologies, and methods. Rigor and reproducibility are therefore important not only for individual hypothesis-driven findings but also for the tools and capabilities that enable subsequent research. Development of an engineered cell system, organoid model, synthetic gene circuit, genome-editing component, or other biological technology may require extensive characterization and benchmarking across biological systems, laboratories, protocols, and measurement environments before reliably supporting other research. NIH should therefore consider evidence such as: -Independent replication, validation, or benchmarking of methods, platforms, biological systems, or findings, documented through publications, reports, datasets, or other appropriate research outputs -Characterization and documentation of limitations, failure modes, and appropriate uses through methods publications, technical reports, protocols, or other research outputs -Development and validation of standardized protocols, reference materials, or measurement approaches, including evidence of independent testing or adoption -Reproducibility of computational models, software, and experimental workflows, supported by accessible code, data, documentation, or replication studies -Evidence that methods, platforms, or biological systems perform consistently across laboratories, biological systems, protocols, measurement environments, or novel application contexts Where possible, NIH should recognize these contributions through existing or emerging research outputs, such as validated protocols, benchmarking datasets, technical reports, methods publications, repository records, or independent validation studies, rather than requiring entirely new reporting mechanisms. These indicators should support expert assessment rather than function as automatic scores or thresholds. NIH should also recognize well-documented negative results, limitations, unsuccessful approaches, and replication failures when they generate information that prevents duplication of ineffective approaches, clarifies the conditions under which findings hold, or improves subsequent research.

2. Data, Software, and Model Sharing: 2. Data, Software, and Model Sharing Engineering biology can contribute to biomedical discovery through shared datasets, computational tools, biological resources, experimental models, and research infrastructure that enable research beyond the projects that created them. A validated genetic-component library, engineered cell line, organoid system, biological dataset, or computational design tool may enable other researchers to pursue new questions, validate findings, or develop new applications. These contributions can advance biomedical discovery even when they are not fully reflected in publication or citation metrics. NIH should not only assess whether resources are

shared, but also their quality, usability, interoperability, and downstream scientific value. Relevant evidence could include: -Quality and completeness of documentation and metadata -Interoperability and adherence to relevant standards -Independent validation or benchmarking -Repository reuse metrics and attribution tracking (e.g., software downloads, dataset citations, biological repository requests) alongside narrative descriptions of downstream adoption -Integration into other research workflows, models, platforms, or novel application contexts -Contributions to reproducibility or new research questions The absence of immediate reuse should not automatically indicate a lack of value, particularly for new resources whose applications may emerge over longer time horizons. NIH should also recognize the development of standards, reference materials, protocols, and other community infrastructure that enables research across institutions

3. Training and Mentorship: 3. Training and Mentorship NIH should recognize training and mentorship that build scientific capabilities across the biomedical research enterprise rather than simply counting trainees supervised or graduated. Engineering biology often requires expertise spanning molecular biology, engineering, computation, automation, and quantitative methods; developing this interdisciplinary capacity can enable new research approaches across an entire field. NIH could consider evidence such as: -Development of interdisciplinary training programs and curricula -Creation of shared training resources and educational materials -Development of new technical competencies -Contributions to interdisciplinary research communities -Evidence of trainees subsequently contributing to research, technology development, public-sector activities, industry, education, or other parts of the biomedical ecosystem Measures should account for differences across career stages and research environments. NIH should recognize both direct mentorship and contributions to broader training infrastructure, including shared curricula, workshops, and community resources.

4. Collaboration: 4. Collaboration As biomedical research becomes increasingly interdisciplinary and convergent, NIH should develop approaches for assessing and recognizing substantive contributions to team-based science without equating contribution with authorship position or individual publication output. Engineering biology is inherently collaborative, often bringing together biologists, engineers, computational scientists, clinicians, and technology developers. Contributions such as enabling technologies, biological platforms, verified datasets, computational methods, and experimental workflows may be essential to a team's scientific output without being fully reflected in authorship position or publication counts. NIH should therefore consider: -Structured contribution statements detailing specific technical, methodological, or platform contributions to team science beyond authorship position -Development of enabling technologies and shared experimental capabilities -Creation of computational methods, biological platforms, or experimental workflows -Contributions to team-based infrastructure -Leadership or coordination of interdisciplinary research efforts -Evidence that a contribution enabled new research, novel applications, or capabilities Evaluation should recognize meaningful scientific contribution within collaborative research rather than simply rewarding the number of collaborations or co-authorships. Structured contribution statements, building on existing NIH approaches to describing contributions to science, could provide useful evidence for reviewers.

5. Entrepreneurship and Translation: 5. Entrepreneurship and Translation Engineering biology spans

6. Foundational Scientific Exploration: 6. Foundational Scientific Exploration Engineering biology also illustrates the importance of recognizing contributions whose significance may emerge only over time. The development of a new biological capability and the generation of large-scale datasets can precede

recognition of the questions, phenomena, or applications they ultimately make possible, creating opportunities for discovery and innovation that are difficult to anticipate in advance. NIH should therefore: -Avoid systematically favoring short-term outcomes over exploratory or foundational research -Recognize enabling technologies and platforms whose applications may be difficult to predict -Account for well-documented negative results, limitations, and iterative development -Allow impact to emerge over longer time horizons -Ensure support for a broad portfolio of biomedical discovery pathways, including hypothesis-driven science as well as the creation of datasets, methodologies, technologies, platforms, and other enabling resources The technologies underlying modern genome editing, such as CRISPR-based techniques, emerged from decades of foundational research whose eventual applications could not necessarily have been predicted. Similarly, large-scale datasets such as those generated through the Human Genome Project have continued to enable discoveries and applications decades after their initial development. More broadly, developing a biological platform or computational capability may itself be a significant scientific contribution because it allows researchers to investigate questions that were previously inaccessible.

7. Public Impact: 7. Public Impact Engineering biology can contribute to public impact through multiple pathways, including advances in health, scientific infrastructure, workforce development, biotechnology and biomanufacturing innovation, and public-sector capabilities. These contributions may be direct or may occur through technologies and platforms that enable subsequent research and applications. NIH should therefore consider evidence such as: -Advances in health and biomedical research -Improvements in clinical practice or patient outcomes -Scientific and technological infrastructure -Standards and reference systems -Workforce development -Public-sector research and technological capabilities -Biotechnology and biomanufacturing innovation Public impact should not be defined solely by immediate clinical outcomes, commercialization, or economic activity. Doing so could systematically disadvantage foundational and enabling research whose ultimate public benefits emerge through subsequent scientific and technological advances or use of technologies in novel settings or application areas. The appropriate pathway and timeframe for demonstrating public impact will vary across research areas, career stages, institution types, and stages of technology development.

8. Other Areas: Other Comments: Implementation, Administrative Burden, and Unintended Consequences NIH should implement any new approach without creating substantial reporting burdens or replacing one rigid metrics system with another. Wherever possible, NIH should use information already available through grant applications, publications, repositories, and other existing systems. Proposed indicators should also be evaluated for unintended consequences, including metric gaming, pressure toward short-term clinical or commercial outcomes, and disadvantages for early-career researchers, interdisciplinary fields, or less-resourced institutions. NIH should consider piloting approaches that give reviewers structured evidence of contribution and impact without creating fixed quantitative thresholds. For example, NIH could allow researchers to identify a limited number of significant contributions and provide evidence such as: -Documented use of a dataset, software tool, biological resource, platform, protocol, or technology by researchers or organizations outside the originating group -Independent replication, external benchmarking, or validation of a method, model, platform, or biological system -Technology transfer, licensing, industry or public-sector adoption, standards development, or incorporation into clinical, research, or manufacturing workflows, where appropriate to the maturity of the work -Structured contribution statements describing substantive scientific or technical contributions that may not be reflected by authorship position -Letters or

statements documenting contributions from relevant stakeholders beyond academic collaborators, including industry, clinical, public-sector, or other research partners, where those stakeholders can provide direct evidence of the contribution's significance, utility, or application Evaluation frameworks should also remain adaptable as scientific practices, technologies, and forms of research output evolve.

File Upload: https://osp.od.nih.gov/wp-content/uploads/ninja-forms/77/EBRC-Response-to-Request-for-Information-on-Measuring-and-Rewarding-Scientific-Impact_NOT-OD-26-087.pdf

Description: introduction and conclusion to our response.

EBRC Engineering Biology Research Consortium

Response to NIH's Request for Information on Measuring and Rewarding Scientific Impact

The Engineering Biology Research Consortium (EBRC) is a nonprofit, public-private partnership that brings together scientists, engineers, and industry leaders to advance the field of engineering biology to address national and global needs. EBRC's members include experts from over 100 universities and research institutes, alongside leaders from more than 30 companies, philanthropies, and other organizations. Working closely with partners across the engineering biology ecosystem, EBRC focuses on four key areas: Research Roadmapping, Policy & International Engagement, Education, and Security.

EBRC appreciates the opportunity to respond to the National Institutes of Health (NIH) Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087). EBRC supports NIH's efforts to broaden how scientific contribution and impact are recognized across the biomedical and biological research enterprise. Engineering biology exemplifies the interdisciplinary, collaborative, iterative, and translational approaches NIH seeks to better recognize. Traditional publication- and citation-based measures may underrepresent important engineering biology contributions to biomedical research, including shared biological platforms, computational tools, standards, datasets, enabling technologies, research infrastructure, and intellectual property that enable subsequent research, discoveries, and breakthroughs across fields. As NIH considers updating its evaluation criteria, capturing these contributions requires a system designed for flexible, multifaceted research models. EBRC therefore encourages NIH to develop a flexible, multidimensional, principles-based approach that recognizes diverse forms of scientific contribution without replacing one rigid metrics-based system with another.

Cross-Cutting Principles for Measuring and Rewarding Scientific Impact

Across the seven areas identified in the RFI, EBRC recommends that NIH use indicators as complementary evidence for expert assessment, rather than as proxies for scientific value or as automatic scores or thresholds. Evaluation should account for differences in research context, career stage, discipline, institution type, and the time horizon over which impact may emerge. NIH should also avoid indicators that encourage metric gaming, prioritize short-term outcomes, or reward quantity over meaningful contribution.

1. Rigor and Reproducibility

Engineering biology contributes to biomedical discovery through the development and validation of new biological systems, technologies, and methods. Rigor and reproducibility are therefore important not only for individual hypothesis-driven findings but also for the tools and capabilities that enable subsequent research. Development of an engineered cell system,

organoid model, synthetic gene circuit, genome-editing component, or other biological technology may require extensive characterization and benchmarking across biological systems, laboratories, protocols, and measurement environments before reliably supporting other research.

NIH should therefore consider evidence such as:

- Independent replication, validation, or benchmarking of methods, platforms, biological systems, or findings, documented through publications, reports, datasets, or other appropriate research outputs
- Characterization and documentation of limitations, failure modes, and appropriate uses through methods publications, technical reports, protocols, or other research outputs
- Development and validation of standardized protocols, reference materials, or measurement approaches, including evidence of independent testing or adoption
- Reproducibility of computational models, software, and experimental workflows, supported by accessible code, data, documentation, or replication studies
- Evidence that methods, platforms, or biological systems perform consistently across laboratories, biological systems, protocols, measurement environments, or novel application contexts

Where possible, NIH should recognize these contributions through existing or emerging research outputs, such as validated protocols, benchmarking datasets, technical reports, methods publications, repository records, or independent validation studies, rather than requiring entirely new reporting mechanisms.

These indicators should support expert assessment rather than function as automatic scores or thresholds. NIH should also recognize well-documented negative results, limitations, unsuccessful approaches, and replication failures when they generate information that prevents duplication of ineffective approaches, clarifies the conditions under which findings hold, or improves subsequent research.

2. Data, Software, and Model Sharing

Engineering biology can contribute to biomedical discovery through shared datasets, computational tools, biological resources, experimental models, and research infrastructure that enable research beyond the projects that created them. A validated genetic-component library, engineered cell line, organoid system, biological dataset, or computational design tool may enable other researchers to pursue new questions, validate findings, or develop new applications. These contributions can advance biomedical discovery even when they are not fully reflected in publication or citation metrics.

NIH should not only assess whether resources are shared, but also their quality, usability, interoperability, and downstream scientific value. Relevant evidence could include:

- Quality and completeness of documentation and metadata
- Interoperability and adherence to relevant standards
- Independent validation or benchmarking
- Repository reuse metrics and attribution tracking (e.g., software downloads, dataset citations, biological repository requests) alongside narrative descriptions of downstream adoption
- Integration into other research workflows, models, platforms, or novel application contexts
- Contributions to reproducibility or new research questions

The absence of immediate reuse should not automatically indicate a lack of value, particularly for new resources whose applications may emerge over longer time horizons. NIH should also recognize the development of standards, reference materials, protocols, and other community infrastructure that enables research across institutions.

3. Training and Mentorship

NIH should recognize training and mentorship that build scientific capabilities across the biomedical research enterprise rather than simply counting trainees supervised or graduated. Engineering biology often requires expertise spanning molecular biology, engineering, computation, automation, and quantitative methods; developing this interdisciplinary capacity can enable new research approaches across an entire field.

NIH could consider evidence such as:

- Development of interdisciplinary training programs and curricula
- Creation of shared training resources and educational materials
- Development of new technical competencies
- Contributions to interdisciplinary research communities
- Evidence of trainees subsequently contributing to research, technology development, public-sector activities, industry, education, or other parts of the biomedical ecosystem

Measures should account for differences across career stages and research environments. NIH should recognize both direct mentorship and contributions to broader training infrastructure, including shared curricula, workshops, and community resources.

4. Collaboration

As biomedical research becomes increasingly interdisciplinary and convergent, NIH should develop approaches for assessing and recognizing substantive contributions to team-based science without equating contribution with authorship position or individual publication output.

Engineering biology is inherently collaborative, often bringing together biologists, engineers, computational scientists, clinicians, and technology developers. Contributions such as enabling technologies, biological platforms, verified datasets, computational methods, and experimental workflows may be essential to a team's scientific output without being fully reflected in authorship position or publication counts.

NIH should therefore consider:

- Structured contribution statements detailing specific technical, methodological, or platform contributions to team science beyond authorship position
- Development of enabling technologies and shared experimental capabilities
- Creation of computational methods, biological platforms, or experimental workflows
- Contributions to team-based infrastructure
- Leadership or coordination of interdisciplinary research efforts
- Evidence that a contribution enabled new research, novel applications, or capabilities

Evaluation should recognize meaningful scientific contribution within collaborative research rather than simply rewarding the number of collaborations or co-authorships. Structured contribution statements, building on existing NIH approaches to describing contributions to science, could provide useful evidence for reviewers.

5. Entrepreneurship and Translation

Engineering biology spans fundamental discovery, engineering, technology development, validation, scale-up, and application, with meaningful contributions occurring throughout this continuum. A novel genetic circuit, genome-editing technology, computational design tool, engineered cell system, or organoid model may demonstrate translational value through technical validation, characterization, standardization, and de-risking well before commercialization.

NIH should consider technology maturity, including where appropriate frameworks such as Technology Readiness Levels (TRLs). To assess translational progress without creating rigid commercialization targets, reviewers should consider contextual evidence such as:

- Documented progress from proof-of-concept toward testing in relevant application environments
- External characterization, multi-laboratory validation, or testing by industry, clinical, or public-sector partners
- Executed MTAs, licensing agreements, or other technology-transfer activities
- Contributions to consensus standards or regulatory readiness activities
- Adoption of design tools, genetic parts, or protocols into third-party research or DBTL workflows

- Application or implementation of emerging technologies in new domains or translational contexts

These indicators should serve as qualitative evidence for expert assessment rather than requirements for successful research. NIH should avoid creating pressure to commercialize research that is better suited to foundational or enabling work. Approaches to data and resource sharing should similarly balance openness with legitimate considerations related to intellectual property, privacy, biosecurity, and responsible access.

6. Foundational Scientific Exploration

Engineering biology also illustrates the importance of recognizing contributions whose significance may emerge only over time. The development of a new biological capability and the generation of large-scale datasets can precede recognition of the questions, phenomena, or applications they ultimately make possible, creating opportunities for discovery and innovation that are difficult to anticipate in advance.

NIH should therefore:

- Avoid systematically favoring short-term outcomes over exploratory or foundational research
- Recognize enabling technologies and platforms whose applications may be difficult to predict
- Account for well-documented negative results, limitations, and iterative development
- Allow impact to emerge over longer time horizons
- Ensure support for a broad portfolio of biomedical discovery pathways, including hypothesis-driven science as well as the creation of datasets, methodologies, technologies, platforms, and other enabling resources

The technologies underlying modern genome editing, such as CRISPR-based techniques, emerged from decades of foundational research whose eventual applications could not necessarily have been predicted. Similarly, large-scale datasets such as those generated through the Human Genome Project have continued to enable discoveries and applications decades after their initial development. More broadly, developing a biological platform or computational capability may itself be a significant scientific contribution because it allows researchers to investigate questions that were previously inaccessible.

7. Public Impact

Engineering biology can contribute to public impact through multiple pathways, including advances in health, scientific infrastructure, workforce development, biotechnology and biomanufacturing innovation, and public-sector capabilities. These contributions may be direct

or may occur through technologies and platforms that enable subsequent research and applications.

NIH should therefore consider evidence such as:

- Advances in health and biomedical research
- Improvements in clinical practice or patient outcomes
- Scientific and technological infrastructure
- Standards and reference systems
- Workforce development
- Public-sector research and technological capabilities
- Biotechnology and biomanufacturing innovation

Public impact should not be defined solely by immediate clinical outcomes, commercialization, or economic activity. Doing so could systematically disadvantage foundational and enabling research whose ultimate public benefits emerge through subsequent scientific and technological advances or use of technologies in novel settings or application areas. The appropriate pathway and timeframe for demonstrating public impact will vary across research areas, career stages, institution types, and stages of technology development.

Other Comments: Implementation, Administrative Burden, and Unintended Consequences

NIH should implement any new approach without creating substantial reporting burdens or replacing one rigid metrics system with another. Wherever possible, NIH should use information already available through grant applications, publications, repositories, and other existing systems. Proposed indicators should also be evaluated for unintended consequences, including metric gaming, pressure toward short-term clinical or commercial outcomes, and disadvantages for early-career researchers, interdisciplinary fields, or less-resourced institutions.

NIH should consider piloting approaches that give reviewers structured evidence of contribution and impact without creating fixed quantitative thresholds. For example, NIH could allow researchers to identify a limited number of significant contributions and provide evidence such as:

- Documented use of a dataset, software tool, biological resource, platform, protocol, or technology by researchers or organizations outside the originating group
- Independent replication, external benchmarking, or validation of a method, model, platform, or biological system
- Technology transfer, licensing, industry or public-sector adoption, standards development, or incorporation into clinical, research, or manufacturing workflows, where appropriate to the maturity of the work

- Structured contribution statements describing substantive scientific or technical contributions that may not be reflected by authorship position
- Letters or statements documenting contributions from relevant stakeholders beyond academic collaborators, including industry, clinical, public-sector, or other research partners, where those stakeholders can provide direct evidence of the contribution's significance, utility, or application

Evaluation frameworks should also remain adaptable as scientific practices, technologies, and forms of research output evolve.

Conclusion

EBRC supports NIH's effort both to broaden and to more accurately define how scientific contribution and impact are recognized and rewarded across the biomedical research enterprise. Engineering biology demonstrates both the need for this evolution and the challenges of developing measures that can fairly capture modern, interdisciplinary, technology-driven research.

A flexible, multidimensional, principles-based approach can better recognize diverse contributions by:

- Recognizing indicators of scientific impact and contributions beyond traditional publications, citations, journal impact factor, and authorship position
- Maintaining expert judgment in evaluation
- Accounting for differences across disciplines, career stages, and research models
- Recognizing foundational and long-term contributions
- Recognizing enabling technologies, platforms, data, software, standards, and infrastructure as critical to biomedical discovery
- Minimizing administrative burden and unintended incentives
- Allowing evaluation frameworks to evolve alongside science and technology

Such an approach can strengthen incentives for rigorous, collaborative, innovative, and translational research while preserving support for foundational science and the diverse pathways through which biomedical impact emerges.

Date: August 19th, 2026
Re: Response to RFI on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Introduction

We appreciate the opportunity to provide feedback supporting the NIH's efforts to refine how scientific impact is measured and rewarded. It is widely recognized that traditional metrics of scientific output, such as publication counts, citation impact, and funded grants, cannot fully characterize how scientific work impacts clinical care and population health. As such, there are clear opportunities to refine measurement of scientific impacts and rewards which recognize the complex and non-linear nature of bench to bedside translational science.

A Dual Framework for Impact: Discovery vs. Community

We propose a framework that recognizes two distinct, but complementary, forms of scientific impact. First, *discovery impact* is the direct impact of the scientific work. It may encompass success in achieving a grant's specific aims, the advancement of knowledge, or the validation of a new theory. Discovery impact, which is foundational to advances in translational science, should itself be recognized and rewarded. Second, *community impact* reflects the downstream impact of scientific work on the communities it is meant to serve. Community impact is increasingly valued as an ultimate goal of translational research, as it indicates successful translation of scientific work to improved clinical and public health outcomes. While both types of impact are important, there has generally been a stronger emphasis on discovery impact. Academic reward structures have favored innovative or theoretically significant findings, often with a lack of emphasis on how these findings are leveraged to improve clinical care and population health.

Because there is nearly always a significant delay between a scientific discovery and its translation into practice, academic reward structures should be broadened to further incentivize downstream community impact – for example, changes in clinical practice

or healthcare policy – without discounting the importance of the basic discoveries that made these improvements possible.

Limitations of Current Frameworks

While tools such as the Translational Science Benefits Model (TSBM) and other approaches like logic models are valuable in understanding and communicating impact, there is a tendency to employ them linearly – for example, by identifying clear and direct connections between research findings and subsequent downstream impacts. However, the journey from bench to bedside is not always linear; it can be an indirect, long-term journey involving multiple pathways.

There are several important challenges in substantiating community impact. For one, improvements in clinical and public health practice often arise from cumulative knowledge and systemic changes, as noted above, rather than from a single discovery. Additionally, the data and information required to demonstrate clinical impact is often stored in healthcare delivery systems or community health records rather than in academic databases.

Bridging the Gap: Implementation Science and Community Engagement

There is increasing recognition among CTSA awardees of the importance of applying the principles of dissemination and implementation (D&I) science to translational science. Despite a substantial and well-researched D&I literature base, many academic health systems lack robust mechanisms to ensure that research is not just translated, but implemented and sustained.

To address this, we propose several strategic shifts in how impact is measured and rewarded. First, we must invest in training CTSC-supported researchers – especially basic scientists – in D&I science. It is essential to develop effective methods for teaching D&I that are relevant to researchers, especially those who may not traditionally view their work through an implementation lens. Second, community-partnered metrics should be incorporated into the research and implementation process. Rather than simply obtaining community validation of a pre-determined result, communities should have meaningful influence over research priorities, outcomes, and implementation. When this is accomplished, it is more straightforward to demonstrate that research projects were tailored to be responsive to community needs.

Given the complexity of team science, we believe that social network modeling approaches can reveal how knowledge diffuses through professional networks into

clinical practice, capturing the often less visible work of mentorship and knowledge transfer.

Recommendations for Rewarding Impact

To support collaborative research that leads to community impact, we recommend the NIH consider:

- Establish incentives that reward both high-value discovery impact (e.g., basic discovery or advancement of knowledge) as well as community impact (e.g., the creation of guidelines, changes to policy, or the successful adaptation of a treatment across diverse clinical settings).
- To account for longer-term implementation in clinical medicine and public health, expand the timeframe for measuring impact beyond the standard grant cycle.
- Given the essential role of implementation partners and community stakeholders in achieving downstream impact, ensure that their contributions are recognized.

A Note on Unintended Consequences

Finally, it bears mentioning that once measures are tied to funding and professional rewards, researchers may optimize their work to perform well on specific metrics. It may therefore be important to monitor unintended consequences, such as efforts to optimize performance on the measures, overstating causal contributions, or neglecting valuable work whose impact is difficult to quantify according to the measures used. We recommend that any new reward systems include mechanisms to monitor these unintended consequences. This will help ensure that the pursuit of measurable impact does not interfere with the pursuit of rigorous, responsible science.

1. Rigor and Reproducibility: The Inter-university Consortium for Political and Social Research (ICPSR) appreciates the opportunity to respond to NIH's Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087). ICPSR is one of the world's largest digital repositories of social and behavioral science research data. As a replication-ready repository, ICPSR preserves data, documentation, and provenance metadata, with the technical and legal infrastructure to support sharing, including for data that are large, complex, or sensitive. Certified by CoreTrustSeal (ICPSR, 2024), ICPSR is an archive dedicated to providing good data stewardship that maximizes the value of federal investments, ensures that scientists are credited for creating data products, supports replication of original research, and creates new opportunities for research. ICPSR currently preserves and disseminates approximately 27,000 data studies containing hundreds of thousands of individual data files, with over 850,000 downloads each year. As a strong supporter of replication in biomedical, behavioral, and social science research, ICPSR hosts more than 7,000 research replication packages in journal repositories on its self-publishing platforms. Additionally, for 63 years, successive generations of early-career scholars have received training in quantitative research methodology through courses in the ICPSR Summer Program, where they are exposed to best practices in research. Further, ICPSR promotes transparency and replicability by publishing extensive guidelines for data depositors on how to prepare data files and documentation to ensure their reuse (ICPSR, 2020). ICPSR strongly supports NIH's interest in identifying the "critical research and infrastructure needs necessary to advance rigorous and reliable scientific findings" (NIH, 2026). ICPSR further supports NIH's efforts to expand measures of scientific success through acknowledging, elevating, and rewarding scientists who share data. In tandem with NIH, ICPSR also recognizes the value in rewarding scholars who reuse shared data and then make adequate information and tools available to replicate their results.

In addition to serving as data stewards and supporting study replication, ICPSR has a long history of linking publication-associated replication materials to the curated data it distributes. Data distributed by ICPSR form the foundation for tens of thousands of research articles, reports, dissertations, books, and other works that advance science, and are collected in the ICPSR Bibliography of Data-related Literature (ICPSR, 2026), a one-of-a-kind searchable database that captures, organizes, and makes discoverable research findings stemming from ICPSR datasets. Each citation record in the database is enhanced with

metadata linking the publication to the underlying data used by its author. The Bibliography plays a crucial role in demonstrating the long-term impact of NIH-funded datasets. However, a further step could be taken to recognize authors who reuse data and make it easier to test their methods and reproduce their findings.

Data repositories are well positioned to play a larger role in recognizing investigators who reuse data and provide replication packages when they publish their findings, since the platforms on which shared data are made available form a natural home for source data, published findings based on those data, and the tools essential to replicating study findings. Linking such resources together makes each meaningful in context, multiplies the usefulness and impact of NIH investments, and helps recognize investigators' rigorous efforts to make results from publicly funded research reproducible.

Measurable indicators of science that should be recognized and incentivized:
--Researchers publish in journals or on platforms that assign scholarly works with persistent identifiers, e.g., DOIs, to ensure long-term accessibility.
--Researchers reuse archived data and include links to their replication packages that contain their analytic code, software, and other tools essential for replication.
--Data repositories flag or highlight publications in which authors include links to their replication packages.
--Data repositories encourage authors to deposit their replication packages, which are linked to the original dataset they reused.
--Data repositories that house replication packages requiring restricted access offer a streamlined process for granting access for testing replicability.
--Data repositories systematically collect and link their distributed data to the citing literature, and they also link findings, replication packages, and original archived data to disseminate them together, thereby simplifying and promoting the reproduction of results.

Implementation approaches:
--Trusted repositories should provide a data citation and an accompanying persistent data identifier for all deposited datasets, and require data reusers to cite the data in publications in which the data were analyzed.
--Publishers should require the explicit citation of source data and replication packages in scholarly works. Without explicit citation and persistent identifiers, automatic linking among data, literature, and replication packages is more difficult.
--NIH should support archival system infrastructure that links research data to the primary and secondary findings generated from those data.
--NIH should support efforts by archives and repositories to single out publications that provide access to replication packages and use their platforms to promote best practices.
--Investigators who have received recognition from trusted data repositories can include such accomplishments in their NIH grant applications and progress reports.
NIH should encourage archives not only to collect links to data-related publications but also to find and link to, or even archive, the replication packages associated with those publications.
--NIH should encourage archives and repositories to reach out to authors whose replication materials are not available online but are available by request, and encourage authors to preserve them.

--NIH should support efforts by archives and repositories to disseminate data with the citing papers and the replication packages associated with them.

Potential benefits or unintended consequences:
--Authors may more frequently make use of provided citations and unique identifiers to formally cite data.
--It becomes easier to identify which shared datasets support which publications, analyses, and downstream discoveries.
--It becomes easier for researchers to build upon existing research, since the citing literature is identified and available for replication or extension.
--Transparency and replicability are prioritized by making replication materials available alongside the data.
--More authors will provide links to replication packages when publishing results.
--By collecting publications that reuse data and including replication packages, archives and repositories will be able to identify investigators who enable replication.
--Greater public trust in, and a stronger evidence base for, biomedical and behavioral science will result.
--A potential unintended consequence is that creating viable replication packages when restricted data were used can be difficult due to privacy concerns, indirectly penalizing researchers who reuse those data. Archives could mitigate this by providing secure options for replication testing. Also, by highlighting publications whose authors provided replication packages, repositories risk endorsing the content of their analysis rather than the practice of sharing the necessary tools to replicate the experiment or study using the same methods and conditions to achieve the same result.

2. Data, Software, and Model Sharing: Over the past 64 years, ICPSR has built infrastructure for researchers to share data with the academic research community, receiving significant funding from NIH and other federal agencies (e.g., the Office of Justice Programs), as well as private foundations and member institutions. Data sharing has become a core expectation for researchers conducting federally funded scientific research. Today, nearly every federal agency providing research funding requires a data management and sharing plan as a condition of receiving an award (e.g., DOE, 2023; NASA, 2022; NEH,

2025; NIH, 2023; NSF, 2024). Both funding agencies and scholarly journals recognize the value of publishing corroborating data, and they require authors to make their data publicly available in trusted repositories to ensure robust metadata adequately describe and give context to the data, provide systems that protect confidential and sensitive information, register data with persistent, machine-readable identifiers, make data available in formats that will be useable over time, and provide online catalogs and discovery tools to ensure the data can be found and reused. ICPSR supports NIH's efforts to realign its measures of success, in order to recognize scholarly contributions beyond traditional measures of productivity. Research data as a scholarly information object has measurable impact that informs scholarship in ways publication metrics, alone, cannot. ICPSR supports NIH in its efforts to give credit to investigators who do the hard work of preparing, documenting, and sharing data to extend its value for the future.

Tracking the use and reuse of these shared data collections is a practical way for data repositories to help data creators demonstrate the scientific value they have generated. Like many repositories and archives, ICPSR measures the number of accounts created, dataset page views, downloads, data-use agreements, and access requests. However, these metrics do not necessarily indicate that data were cited, analyzed in publications, or used to replicate or extend prior findings. A researcher may download a dataset but never use it, or multiple members of a research team may access data that results in one publication. Conversely, a dataset may be used extensively over time in ways that are not fully captured by download counts alone. To address this limitation, ICPSR supports creating linkages between shared datasets and publications based on those datasets. By linking datasets to downstream publications, ICPSR provides an infrastructure that gives investigators the credit they deserve for preparing, documenting, and sharing data. This architecture is the database known as the ICPSR Bibliography of Data-related Literature (Moss et al., 2015; ICPSR, 2026). A publicly available tool for discovering data via the citing literature, it serves as an example of how repositories can demonstrate the scientific value generated by shared data resources.

Continually expanding, the Bibliography's database currently contains nearly 130,000 citations to publications that meaningfully use data distributed at ICPSR. The collection represents over 60 years of scholarship, including in public health, behavioral health, and biomedical research funded by NIH. Often, output based on these data is published decades after the data were originally collected and shared, proving their continued usefulness. The Bibliography was built with support from the National Science Foundation (SES 9977984) under a continuing grant from 1999 to 2003. Thereafter, it has been funded by ICPSR's 800 member institutions, as well as by foundations and federal agencies. In the past decade, thanks in part to increased support from several NIH-funded data repositories at ICPSR, the Bibliography has grown at an accelerated pace, adding 5,000 to 7,000 citations per year. To populate the Bibliography, a small team of librarians and information professionals set up manual or API queries within bibliographic databases to find evidence of data use in the scholarly literature. They collect citations to publications that use the data and enhance each citation record with links to the data in ICPSR's collection. All publications associated with a given dataset then appear displayed with the data on ICPSR's public websites, like any other important metadata element. Careful human curation is required in order to make the collection meaningful, and not diluted with publications that merely mention datasets but do not actually conduct analysis using them.

The Bibliography can be searched, returning relevant results that point to publications linked to data. In this way, the Bibliography serves as both a data discovery tool and a compilation of scholarly works based on each dataset. Funders, data creators, researchers, and students can see not only the available data in the Bibliography but also how those data were used by others. Each publication's citation links a site user to the full text if they have access to it, and to the underlying data held at ICPSR. Thus, site users can discover analyses of data to replicate, avoid duplicating analyses that have already been done, identify cross-disciplinary implications and uses of the data, study how data resources are used, conduct citation analyses, better understand the data life cycle, and learn of methodological issues associated with the data, some of which are covered solely in the published literature. Crucially, the Bibliography acts as a de facto reward mechanism for data creators. A list of citing works, permanently linked to their shared data, helps demonstrate its value and justify future support from funders.

As the Bibliography has grown, bibliometricians and other scholars have found the full collection of citations, with its highly curated linkages between data and the citing literature, to be a unique dataset (ICPSR, 2026) for conducting research. They take advantage of its rich citation metadata, often combining the Bibliography with other sources to better understand the range of scholarship enabled by shared data. Some researchers have used co-citation analysis to measure the diversity and novelty of research data reuse (Lafia et al., 2022b). Others take advantage of the fact that, by definition, the authors in the Bibliography have analyzed data. By accessing corresponding author information, researchers can contact authors who reuse data and survey them about their experiences working with secondary data (e.g., Million et al., 2025). Hence, having convenient access to a sample of this group of published authors can inform researchers about successful data reuse. Still other researchers have used the data-literature links in the Bibliography to study the downstream impacts of poorly reused or problematic data noted in Retraction Watch, drawing links between retracted papers and archived datasets (Narayan et al., 2026). With the increasing number of retractions in the biomedical literature (Hwang et al., 2023), it is more important than ever to have tools like the Bibliography to use in conjunction with other resources to help make flaws in data more visible to potential reusers.

Due to several factors, it can be difficult and costly to find the universe of published and unpublished works resulting from analyses of data held at ICPSR. For instance, librarians and information professionals who populate the Bibliography must make do with tools not designed for data discovery and use. Most platforms that host bibliographic databases focus on scientific article retrieval and do not support field searching that can isolate search matches where they appear in the methods and data sections of publications. Ironically, due to the inconsistency in how data are described in works and tagged or linked where those works are hosted, the best source for accessing metrics of data use is considered to be the data repository (Apartis, et al., 2024). Poor citing practices also can be a barrier for repositories trying to track data reuse (Vannan, 2020). In ICPSR's case, each citation is evaluated to ensure it is linked accurately to a specific dataset(s), since authors can be imprecise, opaque, or negligent in how they cite research data (Moss & Lyle, 2018). Inevitably, some reuse goes undetected; therefore, the data creator never receives credit for it. More computational efforts are being developed to determine how often shared data are cited. To help in this endeavor, ICPSR supplies data-literature linkage metadata from the Bibliography to the Data Citation Corpus (DataCite & Make Data Count, 2024), which in turn enables linkages to be made by entities like OpenAlex (Priem et al.), a free, open-source catalog and database of the global research ecosystem. With data citation information supplied by

repositories and publishers, their services enable tracking publications and data that are registered with Digital Object Identifiers (DOIs). But these services still depend heavily on repositories to provide vetted data citations. For these reasons and more, the cost of collecting and linking shared data to the literature using it can be too high. As a result, ICPSR is one of only a few large-scale domain repositories tracking data use with human review to ensure the accuracy and relevance of the linkages.

In the future, researchers might leverage machine learning and generative AI (GenAI) to reduce the costs and frustrations associated with manually curating a collection like the Bibliography. In one experiment using the Bibliography, machine learning models were trained to recognize data use in publications (Lafia et al., 2022a), in an effort to reduce the amount of human judgement required to identify actual data use, and to do so at scale. It may be possible to use GenAI to build a domain-agnostic prototype of a tool that other repositories could use. A dynamic bibliographic metadata service could identify candidate related publications from external open source corpora, evaluate likely dataset-publication relationships, and route recommendations for staff review. Other tools may be created using GenAI to mine collections like the Bibliography to reveal and highlight existing interdisciplinary collaborations and other unforeseen benefits of sharing and reusing data. GenAI may also help reveal unexpected aspects of the secondary research being conducted across the social and biomedical sciences, surfacing more ways in which those who share data or share replication packages deserve recognition for the scholarship they enable.

Measurable indicators of science that should be recognized and incentivized:
--Data creators prepare, document, and share data for reuse in trusted data repositories.
--Data repositories link shared data to works that reused the shared data, to the extent possible.
--Repositories and archives help demonstrate the scientific value generated by shared data.
--Funders and data creators can verify that their data are reused, by which researchers, and in what disciplines.
--Data repositories, data creators/agencies, data funders, and information scientists can determine whether reuse extends beyond the original research team, whether the data support new research questions, whether the data contribute to interdisciplinary science, whether the data are used in training, replication, or policy-relevant work, and whether investments in curation and metadata increase downstream reuse.

Implementation approaches:
--Trusted repositories should provide a data citation and an accompanying persistent data identifier for all deposited datasets, requiring data reusers to cite the data in publications in which the data were analyzed.
--NIH should support trusted repositories in their efforts to discover and make linkages between shared data and the literature that uses it.
--NIH should invest in the infrastructure of data repositories and build on existing tools to create additional metrics of downstream reuse, connecting datasets to researchers, institutions, grants, and publications.
--NIH should support repository efforts to enhance publication citations beyond standard citation elements by leveraging robust metadata and persistent identifiers available in open sources.
--NIH should support data repositories seeking to develop GenAI mechanisms to increase efficiency in

finding data for reuse.
--NIH should invest in research to uncover networks of interdisciplinary data reuse hidden in the citing literature.

Potential benefits or unintended consequences:
--Data seekers may gain an understanding of the data by reading works that use it.
--Funders, investigators, and others have access to a metric of shared data reuse.
--High-value data may be recognized by reuse in publications, not simply by download metrics.
--Data reusers may gain a better understanding of the uses and limitations of datasets, avoid duplicating effort, ask new questions, apply new analytical methods, and extend findings from the original dataset, thereby increasing its long-term value.
--Data repositories may be able to measure the impact of NIH-funded data after grants are completed.
--Potential unintended consequences could include placing additional burdens on small data repositories. By providing links between data studies and the citing literature, data repositories risk prioritizing data reuse quantity over the quality of scholarship.

Description: Note this submission is a duplicate of one sent already today, but the copy of that submission emailed to us did not retain all of the text in some places. This is a second attempt to submit our response using the form. In case a similar issue occurs, we have uploaded a PDF file containing the same information being sent via the form. Thank you.

Rigor and Reproducibility

The Inter-university Consortium for Political and Social Research (ICPSR) appreciates the opportunity to respond to NIH's Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087). ICPSR is one of the world's largest digital repositories of social and behavioral science research data. As a replication-ready repository, ICPSR preserves data, documentation, and provenance metadata, with the technical and legal infrastructure to support sharing, including for data that are large, complex, or sensitive. Certified by CoreTrustSeal (ICPSR, 2024), ICPSR is an archive dedicated to providing good data stewardship that maximizes the value of federal investments, ensures that scientists are credited for creating data products, supports replication of original research, and creates new opportunities for research. ICPSR currently preserves and disseminates approximately 27,000 data studies containing hundreds of thousands of individual data files, with over 850,000 downloads each year. As a strong supporter of replication in biomedical, behavioral, and social science research, ICPSR hosts more than 7,000 research replication packages in journal repositories on its self-publishing platforms. Additionally, for 63 years, successive generations of early-career scholars have received training in quantitative research methodology through courses in the ICPSR Summer Program, where they are exposed to best practices in research. Further, ICPSR promotes transparency and replicability by publishing extensive guidelines for data depositors on how to prepare data files and documentation to ensure their reuse (ICPSR, 2020). ICPSR strongly supports NIH's interest in identifying the "critical research and infrastructure needs necessary to advance rigorous and reliable scientific findings" (NIH, 2026). ICPSR further supports NIH's efforts to expand measures of scientific success through acknowledging, elevating, and rewarding scientists who share data. In tandem with NIH, ICPSR also recognizes the value in rewarding scholars who reuse shared data and then make adequate information and tools available to replicate their results.

In addition to serving as data stewards and supporting study replication, ICPSR has a long history of linking publication-associated replication materials to the curated data it distributes. Data distributed by ICPSR form the foundation for tens of thousands of research articles, reports, dissertations, books, and other works that advance science, and are collected in the ICPSR Bibliography of Data-related Literature (ICPSR, 2026), a one-of-a-kind searchable database that captures, organizes, and makes discoverable research findings stemming from ICPSR datasets. Each citation record in the database is enhanced with metadata linking the publication to the underlying data used by its author. The Bibliography plays a crucial role in demonstrating the long-term impact of NIH-funded datasets. However, a further step could be taken to recognize authors who reuse data and make it easier to test their methods and reproduce their findings.

Data repositories are well positioned to play a larger role in recognizing investigators who reuse data and provide replication packages when they publish their findings, since the platforms on which shared data are made available form a natural home for source data, published findings based on those data, and the tools essential to replicating study findings. Linking such

resources together makes each meaningful in context, multiplies the usefulness and impact of NIH investments, and helps recognize investigators' rigorous efforts to make results from publicly funded research reproducible.

Measurable indicators of science that should be recognized and incentivized:

- Researchers publish in journals or on platforms that assign scholarly works with persistent identifiers, e.g., DOIs, to ensure long-term accessibility.
- Researchers reuse archived data and include links to their replication packages that contain their analytic code, software, and other tools essential for replication.
- Data repositories flag or highlight publications in which authors include links to their replication packages.
- Data repositories encourage authors to deposit their replication packages, which are linked to the original dataset they reused.
- Data repositories that house replication packages requiring restricted access offer a streamlined process for granting access for testing replicability.
- Data repositories systematically collect and link their distributed data to the citing literature, and they also link findings, replication packages, and original archived data to disseminate them together, thereby simplifying and promoting the reproduction of results.

Implementation approaches:

- Trusted repositories should provide a data citation and an accompanying persistent data identifier for all deposited datasets, and require data reusers to cite the data in publications in which the data were analyzed.
- Publishers should require the explicit citation of source data and replication packages in scholarly works. Without explicit citation and persistent identifiers, automatic linking among data, literature, and replication packages is more difficult.
- NIH should support archival system infrastructure that links research data to the primary and secondary findings generated from those data.
- NIH should support efforts by archives and repositories to single out publications that provide access to replication packages and use their platforms to promote best practices.
- Investigators who have received recognition from trusted data repositories can include such accomplishments in their NIH grant applications and progress reports.
- NIH should encourage archives not only to collect links to data-related publications but also to find and link to, or even archive, the replication packages associated with those publications.
- NIH should encourage archives and repositories to reach out to authors whose replication materials are not available online but are available by request, and encourage authors to preserve them.
- NIH should support efforts by archives and repositories to disseminate data with the citing papers and the replication packages associated with them.

Potential benefits or unintended consequences:

- Authors may more frequently make use of provided citations and unique identifiers to formally cite data.
- It becomes easier to identify which shared datasets support which publications, analyses, and downstream discoveries.
- It becomes easier for researchers to build upon existing research, since the citing literature is identified and available for replication or extension.
- Transparency and replicability are prioritized by making replication materials available alongside the data.
- More authors will provide links to replication packages when publishing results.
- By collecting publications that reuse data and including replication packages, archives and repositories will be able to identify investigators who enable replication.
- Greater public trust in, and a stronger evidence base for, biomedical and behavioral science will result.
- A potential unintended consequence is that creating viable replication packages when restricted data were used can be difficult due to privacy concerns, indirectly penalizing researchers who reuse those data. Archives could mitigate this by providing secure options for replication testing. Also, by highlighting publications whose authors provided replication packages, repositories risk endorsing the content of their analysis rather than the practice of sharing the necessary tools to replicate the experiment or study using the same methods and conditions to achieve the same result.

Data, Software, and Model Sharing

Over the past 64 years, ICPSR has built infrastructure for researchers to share data with the academic research community, receiving significant funding from NIH and other federal agencies (e.g., the Office of Justice Programs), as well as private foundations and member institutions. Data sharing has become a core expectation for researchers conducting federally funded scientific research. Today, nearly every federal agency providing research funding requires a data management and sharing plan as a condition of receiving an award (e.g., DOE, 2023; NASA, 2022; NEH, 2025; NIH, 2023; NSF, 2024). Both funding agencies and scholarly journals recognize the value of publishing corroborating data, and they require authors to make their data publicly available in trusted repositories to ensure robust metadata adequately describe and give context to the data, provide systems that protect confidential and sensitive information, register data with persistent, machine-readable identifiers, make data available in formats that will be useable over time, and provide online catalogs and discovery tools to ensure the data can be found and reused. ICPSR supports NIH's efforts to realign its measures of success, in order to recognize scholarly contributions beyond traditional measures of productivity. Research data as a scholarly information object has measurable impact that informs scholarship in ways publication metrics, alone, cannot. ICPSR supports NIH in its efforts to give credit to investigators who do the hard work of preparing, documenting, and sharing data to extend its value for the future.

Tracking the use and reuse of these shared data collections is a practical way for data repositories to help data creators demonstrate the scientific value they have generated. Like many repositories and archives, ICPSR measures the number of accounts created, dataset page views, downloads, data-use agreements, and access requests. However, these metrics do not necessarily indicate that data were cited, analyzed in publications, or used to replicate or extend prior findings. A researcher may download a dataset but never use it, or multiple members of a research team may access data that results in one publication. Conversely, a dataset may be used extensively over time in ways that are not fully captured by download counts alone. To address this limitation, ICPSR supports creating linkages between shared datasets and publications based on those datasets. By linking datasets to downstream publications, ICPSR provides an infrastructure that gives investigators the credit they deserve for preparing, documenting, and sharing data. This architecture is the database known as the ICPSR Bibliography of Data-related Literature (Moss et al., 2015; ICPSR, 2026). A publicly available tool for discovering data via the citing literature, it serves as an example of how repositories can demonstrate the scientific value generated by shared data resources.

Continually expanding, the Bibliography's database currently contains nearly 130,000 citations to publications that meaningfully use data distributed at ICPSR. The collection represents over 60 years of scholarship, including in public health, behavioral health, and biomedical research funded by NIH. Often, output based on these data is published decades after the data were originally collected and shared, proving their continued usefulness. The Bibliography was built with support from the National Science Foundation (SES 9977984) under a continuing grant from 1999 to 2003. Thereafter, it has been funded by ICPSR's 800 member institutions, as well

as by foundations and federal agencies. In the past decade, thanks in part to increased support from several NIH-funded data repositories at ICPSR, the Bibliography has grown at an accelerated pace, adding 5,000 to 7,000 citations per year. To populate the Bibliography, a small team of librarians and information professionals set up manual or API queries within bibliographic databases to find evidence of data use in the scholarly literature. They collect citations to publications that use the data and enhance each citation record with links to the data in ICPSR's collection. All publications associated with a given dataset then appear displayed with the data on ICPSR's public websites, like any other important metadata element. Careful human curation is required in order to make the collection meaningful, and not diluted with publications that merely mention datasets but do not actually conduct analysis using them.

The Bibliography can be searched, returning relevant results that point to publications linked to data. In this way, the Bibliography serves as both a data discovery tool and a compilation of scholarly works based on each dataset. Funders, data creators, researchers, and students can see not only the available data in the Bibliography but also how those data were used by others. Each publication's citation links a site user to the full text if they have access to it, and to the underlying data held at ICPSR. Thus, site users can discover analyses of data to replicate, avoid duplicating analyses that have already been done, identify cross-disciplinary implications and uses of the data, study how data resources are used, conduct citation analyses, better understand the data life cycle, and learn of methodological issues associated with the data, some of which are covered solely in the published literature. Crucially, the Bibliography acts as a de facto reward mechanism for data creators. A list of citing works, permanently linked to their shared data, helps demonstrate its value and justify future support from funders.

As the Bibliography has grown, bibliometricians and other scholars have found the full collection of citations, with its highly curated linkages between data and the citing literature, to be a unique dataset (ICPSR, 2026) for conducting research. They take advantage of its rich citation metadata, often combining the Bibliography with other sources to better understand the range of scholarship enabled by shared data. Some researchers have used co-citation analysis to measure the diversity and novelty of research data reuse (Lafia et al., 2022b). Others take advantage of the fact that, by definition, the authors in the Bibliography have analyzed data. By accessing corresponding author information, researchers can contact authors who reuse data and survey them about their experiences working with secondary data (e.g., Million et al., 2025). Hence, having convenient access to a sample of this group of published authors can inform researchers about successful data reuse. Still other researchers have used the data-literature links in the Bibliography to study the downstream impacts of poorly reused or problematic data noted in Retraction Watch, drawing links between retracted papers and archived datasets (Narayan et al., 2026). With the increasing number of retractions in the biomedical literature (Hwang et al., 2023), it is more important than ever to have tools like the Bibliography to use in conjunction with other resources to help make flaws in data more visible to potential reusers.

Due to several factors, it can be difficult and costly to find the universe of published and unpublished works resulting from analyses of data held at ICPSR. For instance, librarians and information professionals who populate the Bibliography must make do with tools not designed

for data discovery and use. Most platforms that host bibliographic databases focus on scientific article retrieval and do not support field searching that can isolate search matches where they appear in the methods and data sections of publications. Ironically, due to the inconsistency in how data are described in works and tagged or linked where those works are hosted, the best source for accessing metrics of data use is considered to be the data repository (Apartis, et al., 2024). Poor citing practices also can be a barrier for repositories trying to track data reuse (Vannan, 2020). In ICPSR's case, each citation is evaluated to ensure it is linked accurately to a specific dataset(s), since authors can be imprecise, opaque, or negligent in how they cite research data (Moss & Lyle, 2018). Inevitably, some reuse goes undetected; therefore, the data creator never receives credit for it. More computational efforts are being developed to determine how often shared data are cited. To help in this endeavor, ICPSR supplies data-literature linkage metadata from the Bibliography to the Data Citation Corpus (DataCite & Make Data Count, 2024), which in turn enables linkages to be made by entities like OpenAlex (Priem et al.), a free, open-source catalog and database of the global research ecosystem. With data citation information supplied by repositories and publishers, their services enable tracking publications and data that are registered with Digital Object Identifiers (DOIs). But these services still depend heavily on repositories to provide vetted data citations. For these reasons and more, the cost of collecting and linking shared data to the literature using it can be too high. As a result, ICPSR is one of only a few large-scale domain repositories tracking data use with human review to ensure the accuracy and relevance of the linkages.

In the future, researchers might leverage machine learning and generative AI (GenAI) to reduce the costs and frustrations associated with manually curating a collection like the Bibliography. In one experiment using the Bibliography, machine learning models were trained to recognize data use in publications (Lafia et al., 2022a), in an effort to reduce the amount of human judgement required to identify actual data use, and to do so at scale. It may be possible to use GenAI to build a domain-agnostic prototype of a tool that other repositories could use. A dynamic bibliographic metadata service could identify candidate related publications from external open source corpora, evaluate likely dataset-publication relationships, and route recommendations for staff review. Other tools may be created using GenAI to mine collections like the Bibliography to reveal and highlight existing interdisciplinary collaborations and other unforeseen benefits of sharing and reusing data. GenAI may also help reveal unexpected aspects of the secondary research being conducted across the social and biomedical sciences, surfacing more ways in which those who share data or share replication packages deserve recognition for the scholarship they enable.

Measurable indicators of science that should be recognized and incentivized:

- Data creators prepare, document, and share data for reuse in trusted data repositories.
- Data repositories link shared data to works that reused the shared data, to the extent possible.
- Repositories and archives help demonstrate the scientific value generated by shared data.

- Funders and data creators can verify that their data are reused, by which researchers, and in what disciplines.
- Data repositories, data creators/agencies, data funders, and information scientists can determine whether reuse extends beyond the original research team, whether the data support new research questions, whether the data contribute to interdisciplinary science, whether the data are used in training, replication, or policy-relevant work, and whether investments in curation and metadata increase downstream reuse.

Implementation approaches:

- Trusted repositories should provide a data citation and an accompanying persistent data identifier for all deposited datasets, requiring data reusers to cite the data in publications in which the data were analyzed.
- NIH should support trusted repositories in their efforts to discover and make linkages between shared data and the literature that uses it.
- NIH should invest in the infrastructure of data repositories and build on existing tools to create additional metrics of downstream reuse, connecting datasets to researchers, institutions, grants, and publications.
- NIH should support repository efforts to enhance publication citations beyond standard citation elements by leveraging robust metadata and persistent identifiers available in open sources.
- NIH should support data repositories seeking to develop GenAI mechanisms to increase efficiency in finding data for reuse.
- NIH should invest in research to uncover networks of interdisciplinary data reuse hidden in the citing literature.

Potential benefits or unintended consequences:

- Data seekers may gain an understanding of the data by reading works that use it.
- Funders, investigators, and others have access to a metric of shared data reuse.
- High-value data may be recognized by reuse in publications, not simply by download metrics.
- Data reusers may gain a better understanding of the uses and limitations of datasets, avoid duplicating effort, ask new questions, apply new analytical methods, and extend findings from the original dataset, thereby increasing its long-term value.
- Data repositories may be able to measure the impact of NIH-funded data after grants are completed.
- Potential unintended consequences could include placing additional burdens on small data repositories. By providing links between data studies and the citing literature, data repositories risk prioritizing data reuse quantity over the quality of scholarship.

Dr. Jay Bhattacharya
National Institutes of Health
Re: Response to Request for Information on Measuring and Rewarding Scientific Impact
Via electronic filing
(<https://osp.od.nih.gov/comment-form-measuring-and-rewarding-scientific-impact/>).

Dear Dr. Bhattacharya,

We have spent much of our careers studying reproducibility, reliability, and the impact of scientific research -- as scientists who study the role of science in society, and who study how scientific information is produced and communicated. This comment is based on our evaluation of the current state of research and practice in the science of science and draws specifically on our prior research and commentary on these topics [1-6].

Given the breadth of the proposed RFI, we focus our comments on two topics central to our research expertise and to the RFI's core purpose: Systematically increasing rigor and reproducibility in NIH funding, and core requirements for reaping public benefit from scientific research.

Rigor and Reproducibility

One of the most substantial barriers to improved rigor and reproducibility in science is the lack of a systematic, scientific approach to 'operational science policies', defined as the policies and practices that effectively control the conduct and communication of formal, natural, and social sciences. [1-3] As one of the largest and most important science funders, NIH is in a uniquely influential position to advance rigor and reproducibility in this area – both through how NIH updates and evaluates its own policies and through the research NIH supports.

While many policies for grant review, scholarly publication, and research transparency have served science and society well, there is an increasing need to update these policies and practices. However, changes to new policies must be designed as experiments that incorporate evaluation by both NIH and the scientific community. In particular, every policy change should include an assessment of how that policy affects the cost of science, who participates in it, and the rigor, impact, and quality of the resulting science.

Furthermore, it is vital that the selection of goals for each policy change, the design of assessments of those policy changes, and the resulting evaluations be transparent and deliberative. Science is a collective activity that works best when the community engages systematically to reach consensus based on reason and evidence. [6] Because of this, developing a collective understanding of what operational science approaches work depends on systematic monitoring of and reporting on operational science policies, interventions, and

outcomes; common standards for communicating and measuring operational interventions and assessments; and support for infrastructure needed to collect, durably store, and transparently share data about new projects in a transparent way. [1-3]

Moreover, recent systematic reviews of the state of reproducibility and reliability of science across multiple fields emphasize the need to continue advancing the general theory, methodology, and evidence base of metascience research. [4] To support rigorous biomedical sciences and public health, NIH should make significant investments in basic and multidisciplinary metascience—including grant programs to support experimental reproducibility interventions; data-sharing and replication infrastructure; evaluation and evidence-synthesis methodologies; and theory development for the science of science.

Public Impact

Transparency and dissemination are essential for both scientific rigor and impact—and can be designed to reinforce each other. Science has the greatest impact when the results are shared, and rigor and reliability depend in substantial part on the extent to which materials, methods, and results are accessible for evaluation, critique, and reproduction. Contemporary advances in information technology and infrastructure have expanded both the scope of scientific knowledge and the social impact of science. Innovation in research practices, cultures, and infrastructure has the potential to enable substantially more open and durable access to all the components of science production – and to lower the barriers facing individuals who aim to learn from and participate in science. [5]

In particular, in order to achieve its public impact potential, science depends on durable, open infrastructure for publishing results and sharing evidence. [1,5] The history of science development in the U.S. and around the world shows that this infrastructure cannot survive without public funding – especially from major science funders such as the NIH. But we cannot assume that all investments provide the same incentives and benefits. NIH should leverage the tools and infrastructure it supports to collect, analyze, and share the evidence necessary to evaluate its policy changes. And it should set the tone by incentivizing a scientific approach to studying operational science policy, and by establishing a climate in which each intervention can contribute cumulatively to the collective public and scientific knowledge.

And, to a large extent, public impact depends on public trust. The public's confidence in science grows from a web of legitimacy, sewn together by signals such as degrees, publications, affiliations, and accreditations. This network reflects the evolution of norms and practices that together comprise scientific communities. Public agencies play a key role in supporting scientific communities while allowing the independence they require to thrive. That independence, in turn, reinforces public trust and protects the reputation of science from the threat of politicization. Democratic governments take the lead in determining which goals a society pursues – and how to balance competing values through public investment – but in the face of high-stakes issues involving complex systems and uncertain approaches, scientific expert consensus serves as an honest broker to assess likely consequences of public policies. Government should not restrict scientists' freedom to engage in policy discussions, and should support the collective processes

needed for science: including supporting the costs of scientific dissemination (e.g. journal publications), deliberation (e.g. conferences) and resource sharing (e.g. data archiving). [1,6]

Summary

Interventions in science policy and practice should be treated, at least in part, as scientific experiments—designed to incrementally add to our cumulative knowledge of how, and how well, science works.

We should not expect NIH's processes to be perfect. It is worth noting, however, that NIH has previously changed its operational policies substantially -- including three major changes to peer review in the last two decades -- and still lacks clear public assessments of what was learned from prior. The public should be able to rely on NIH to change policies with the goals of improving scientific rigor and public benefit; to design those policies for systematic measurement; and to transparently share these performance measurements and conclusions drawn from them. Scientists should be able to rely on the NIH to support independent research evaluating its operational policies and to fund basic meta-science research needed to advance rigor and public impact in biomedical science.

The last decade has seen an acceleration in the rate of new initiatives to innovate in how science operates. NIH is not alone in calling for major changes to operational science policy without supporting plans to study the effects of those changes — absence of evaluation is endemic. Making progress will require that we thoughtfully design operational science policies to enable public assessment. And requires resources and attention – to support internal evaluation, independent external evaluation, and a durable public knowledge infrastructure.

Sincerely,

Micah Altman, Research Scientist, MIT
Philip N. Cohen, Professor of Sociology, University of Maryland

251. Wiley

I am responding: On behalf of an organization

Name: Jessica Sebeok

Name of Organization: Wiley

Type of Organization: Publisher

Role: Organizational Official

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: Wiley is the largest U.S. scientific publisher and the largest scientific society partner publisher, as well as a global leader in research and learning. Wiley's story begins in 1807, when Charles Wiley opened a small print shop on Reade Street in New York City. In our young republic's era of invention, the shop became a conduit for pioneering American ideas, first through literature and then through technical, medical, and scientific works. After the Civil War, William H. Wiley, a former U.S. Representative oriented the family company toward the applied sciences that powered American industrial growth by putting practical, reliable knowledge into the hands of engineers, physicians, and educators. When scholarship moved online, Wiley modernized again, first to digitized journals and reference works, and more recently to integrated platforms that combine submission, screening, peer review, and the permanent curation and preservation of the Version of Record. Over more than two centuries we have published the work of U.S. Nobel Prize winners and partnered with hundreds of U.S. scientific societies, supporting thousands of federally funded authors each year.

That 200-year vantage point—spanning the full lifecycle of federally funded research, from submission and peer review through correction, preservation, and reuse—shapes how we approach NIH's questions on rigor and reproducibility. Reproducibility is not a property of a single experiment; it is a property of a research record reliable enough for others to test, correct, and build upon. As the steward of that record, the publisher sits at the center of any effort to measure and reward reproducible science.

The Version of Record (VoR) is the authoritative, final, and citable form of a scholarly work, reflecting completed peer review, verified methods and data-availability statements, disclosed conflicts of interest and funding, and any subsequent corrections or retractions. It is the only version guaranteed to be checked for accuracy and curated by experts over time, and it is what allows a finding to be located, interpreted, and independently reproduced years after publication. This is the publisher's core contribution to rigor: the peer review, integrity screening, metadata stewardship, and post-publication correction that make a result trustworthy enough to reproduce. As NIH designs indicators of reproducibility, it should treat the permanence and integrity of this record as foundational rather than ancillary, consistent with the tenets of Gold Standard Science articulated in Executive Order 14303.

To strengthen NIH's framework for rigor and reproducibility, we recommend the following approaches:

Recognize the Version of Record as the authoritative basis for reproducibility assessment. Preprints and

other non-peer-reviewed outputs play a useful role in rapid communication, but they are not substitutes for the peer-reviewed record and should not be treated as equivalent in metrics frameworks.

Credit negative and null results in funding and career-advancement review. Well-conducted studies that find no effect are essential to an honest and complete literature; their absence from the record is a root cause of the reproducibility problem.

Rely on publisher-led integrity infrastructure, including peer review, editorial assessment, research-integrity screening, corrections, retractions, and post-publication stewardship, as part of the reproducibility ecosystem rather than treating these as separate from NIH's priorities.

Recognize long-term and programmatic research contributions rather than rewarding the pace of publication. Metrics that prize rapid output can push researchers toward premature claims; NIH should credit sustained, careful work that genuine reproducibility requires.

Account for disciplinary variation, since replication looks different across fields. A flexible framework that adapts to field-specific norms and methods will be more effective than applying a single standard to all research.

Wiley and the broader publishing community welcome opportunities to collaborate with NIH on the standards, infrastructure, and incentives that make reproducible science possible.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: Advancing NIH's mission requires a stable and growing biomedical research workforce, supported by stronger measures of the impact of training and mentorship. In our experience across the U.S. research ecosystem, mentorship is not a supplementary benefit but the primary mechanism by which the tacit skills of rigorous science are transmitted from one generation to the next. Long-horizon discovery depends on giving young researchers the time, resources, and guidance to learn from lead researchers on projects that may not yield results for a decade or more.

Federal laboratories and NIH-supported training environments are uniquely positioned to serve as national training grounds, not only for technical excellence but for the standards of rigor, reproducibility, and responsible conduct that underpin Gold Standard Science. Protecting mentored time on long-duration projects is essential to sustaining the discovery pipeline and delivering public-health returns years after the initial investment. As Wiley noted in its response to the U.S. Department of Energy's Genesis Mission RFI, the durability of the U.S. research workforce also depends on distributing training opportunity broadly across institutions and regions. NIH should ensure that training and mentorship indicators capture participation from R1, R2, and R3 universities, Historically Black Colleges and Universities, Tribal Colleges, and community colleges, so that emerging talent is developed wherever it is found rather than only at the best-resourced institutions.

To assess and reward training and mentorship impact, NIH should consider the following approaches:

Track the longitudinal trajectories of researchers who receive mentored training: whether they go on to

win independent funding, publish as principal investigators, establish productive laboratories, and remain in the biomedical workforce.

Recognize peer review and editorial participation as a form of mentorship and professional development. Serving as a reviewer or early-career editor is one of the primary ways scientists learn to evaluate evidence, judge methodology, and communicate uncertainty.

Support structured mentorship programs that can be delivered in both in-person and hybrid formats to extend access to trainees who lack proximity to major research centers, strengthening geographic resilience in the national talent pipeline.

4. Collaboration: Biomedical progress increasingly depends on large, interdisciplinary teams working across institutions, sectors, and Federal agencies. However, traditional measures of scientific achievement, such as author position, publication counts, and citation totals, do not always capture the full range of contributions required to conduct complex collaborative research. Wiley has advocated for more comprehensive approaches to recognizing team-based science in prior submissions, including our response to the U.S. Department of Energy's Genesis Mission RFI, and we encourage NIH to adopt a framework that reflects the true architecture of modern biomedical collaboration.

Publishers can support this effort by preserving a clear and reliable record of who contributed to a study and how. Publication records can document contributions beyond writing and lead authorship, including data collection and curation, methodology, software development, project coordination, statistical analysis, mentoring, and research-resource sharing. This infrastructure already exists and can serve as the foundation for any NIH framework for recognizing collaborative contributions.

NIH should consider the following to assess and recognize collaboration:

Recognize outputs beyond traditional journal articles. Data, software, research methods, shared infrastructure, and reproducibility work can all provide substantial value to a collaborative project and should be considered when evaluating investigators and research teams.

Coordinate with other Federal research agencies and with publishers on common principles for documenting and attributing research contributions, using persistent identifiers such as ORCID and DOIs to link researchers to their outputs across institutions and over time.

Adopt the CRediT taxonomy, which attributes individual researcher contributions across the research pipeline in a standardized, machine-readable format at submission.

Assign weight to team-level and program-level outcomes in funding review, particularly for large-scale, inter-agency, or public-private initiatives where success depends on coordinated effort rather than the work of a single investigator.

Build safeguards against unintended incentives such as inflated authorship or exaggerated contribution claims, by relying on transparent contribution statements that are preserved as part of the published Version of Record and subject to post-publication correction.

A more complete approach to evaluating team science would allow NIH to recognize the researchers who generate, organize, validate, and translate biomedical knowledge, not only those whose names appear in the most prominent author positions.

5. Entrepreneurship and Translation: The translation of discovery from bench to bedside depends on a scientific record that industry, investors, clinicians, and regulators can trust, and that record is the publisher's product. The peer-reviewed Version of Record, with its verified methods, disclosures, and corrections, is the defensible foundation on which patents are filed, products are developed, and clinical decisions are made. A discovery that cannot be located, cited, and relied upon with confidence cannot be translated, however promising it may be.

The publisher's role in translation is therefore not incidental but enabling. Wiley's investments in metadata, persistent identifiers, taxonomy, and integrity screening allow a finding to be discovered and built upon by a start-up or research-and-development team years after it is first published. As AI accelerates the translational pipeline, rights-cleared and provenance-rich content becomes even more critical: products and regulated systems built on unverified or unlawfully obtained inputs carry commercial, regulatory, and litigation risk that deters investment. The Wiley AI Gateway demonstrates how licensed, peer-reviewed content can be embedded in AI-enabled discovery tools, for tasks such as biomarker discovery and clinical trial design, with full provenance and attribution, accelerating translation while preserving research integrity.

To assess and reward translational and entrepreneurial impact, NIH should consider these approaches:

Track patents and regulatory submissions that cite federally funded publications as a concrete, verifiable indicator of translational impact, and include these in the criteria used to evaluate investigators and programs.

Count licensing agreements and start-up formation arising from NIH-funded research as recognized outputs, with appropriate attribution to the researchers, institutions, and publishers whose work enabled them.

Monitor incorporation of NIH-funded findings into clinical guidelines, standards of care, and public health policy, recognizing that these outcomes often represent the most direct translation of research into health benefit.

Encourage Federal procurement and partnership mechanisms to favor AI systems and analytical tools built on licensed, verified, rights-cleared research inputs, providing industry the legal certainty it needs to invest in translation and ensuring that federally supported innovation rests on defensible scientific foundations.

6. Foundational Scientific Exploration: Basic research and high-risk, high-reward inquiry carry an inherent risk of failure alongside the potential for paradigm-shifting breakthroughs. Wiley is proud to sponsor the Golden Goose Award, which recognizes research that appeared obscure, or even accidental, that produced significant benefits for public health and the economy. The award illustrates a principle

that NIH's own mission embodies: the value of foundational science is often not visible at the outset and cannot be judged by short-horizon metrics. When research is evaluated only by how quickly it produces results or how many citations it earns, the slow, uncertain, exploratory work that leads to the most important discoveries tends to get left behind.

Publishers sustain this kind of exploration by preserving the complete record of inquiry, including incremental findings, detailed methods, and the negative and null results that keep a field honest and prevent duplicated effort. The permanence of the Version of Record and long-term archiving mean that a finding regarded as obscure today remains discoverable years later, when its significance becomes clear, so that other scientists can validate and build on it.

Therefore, NIH should consider the following to support the foundation of scientific exploration:

Evaluate high-risk, high-reward research over longer time frames rather than short productivity cycles and protect such programs from metrics that penalize delayed or uncertain returns. Review panels should be explicitly instructed that absence of near-term results is not evidence of failure in exploratory research programs.

Establish a recognition mechanism modeled on the Golden Goose Award that NIH administers or co-sponsors, identifying and celebrating federally funded research that produced unexpected or long-delayed breakthroughs.

Credit the publication of negative and null results and of replication studies as legitimate scientific contributions, recognizing that these outputs are the record through which foundational science accumulates over time.

Sustained federal funding is what makes this kind of research possible in the first place. NIH should make clear in its assessment framework that investing in research before its value is obvious is not a risk to be avoided, but a necessity for scientific discovery.

7. Public Impact: Publishing is the mechanism by which taxpayer investment becomes lasting public benefit: it converts funded research into a transparent, enduring, and accessible record that patients, clinicians, educators, and innovators can rely on. The returns are substantial: by widely cited estimates, every $1 invested by NIH yields roughly $2.56 in economic activity, and it is the published, curated record that makes those returns durable and verifiable.

Public trust is now inseparable from the reliability of that record, which increasingly feeds the AI systems Americans use every day. When an American turns to an AI tool to understand a family member's diagnosis and possible treatments, the value of the answer depends on whether the underlying model draws on the gold-standard, peer-reviewed content that Wiley and its society partners produce and curate. The publisher's integrity screening, corrections, and provenance tracking are, in this sense, public-trust infrastructure. Accessibility matters as well: the maintained Version of Record, together with public-access compliance, ensures that findings reach practitioners and the public in usable, citable form.

NIH should consider the following approaches to assess and recognize the impact of biomedical research:

Measure the accessibility and sustained reuse of the scholarly record and the availability of findings in PubMed Central and other trusted repositories.

Use responsible altmetrics, including media coverage, policy citations, and public engagement, as supplementary signals of broader reach. Publishers already collect this data through existing infrastructure: for example, NIH-funded papers published by Wiley generated more than 10,000 social media mentions and over 1,500 news articles worldwide in 2024. NIH should partner with publishers to leverage this data rather than building parallel collection systems.

Recognize publishers as part of the public-trust infrastructure for biomedical AI. NIH should require that AI systems used in research and clinical decisions are built on licensed, provenance-rich, peer-reviewed content rather than unverified inputs.

WILEY

Wiley Response to the National Institutes of Health Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Notice Number: NOT-OD-26-087

Rigor and Reproducibility. Reproducible and replicable biomedical approaches are foundational to rigorous research. New strategies are needed to identify areas ripe for replication and reproducibility efforts, as well as incentives and infrastructure to support the reproduction and replication of existing findings.

Wiley is the largest U.S. scientific publisher and the largest scientific society partner publisher, as well as a global leader in research and learning. Wiley's story begins in 1807, when Charles Wiley opened a small print shop on Reade Street in New York City. In our young republic's era of invention, the shop became a conduit for pioneering American ideas, first through literature and then through technical, medical, and scientific works. After the Civil War, William H. Wiley, a former U.S. Representative oriented the family company toward the applied sciences that powered American industrial growth by putting practical, reliable knowledge into the hands of engineers, physicians, and educators. When scholarship moved online, Wiley modernized again, first to digitized journals and reference works, and more recently to integrated platforms that combine submission, screening, peer review, and the permanent curation and preservation of the Version of Record. Over more than two centuries we have published the work of U.S. Nobel Prize winners and partnered with hundreds of U.S. scientific societies, supporting thousands of federally funded authors each year.

That 200-year vantage point—spanning the full lifecycle of federally funded research, from submission and peer review through correction, preservation, and reuse—shapes how we approach NIH's questions on rigor and reproducibility. Reproducibility is not a property of a single experiment; it is a property of a research record reliable enough for others to test, correct, and build upon. As the steward of that record, the publisher sits at the center of any effort to measure and reward reproducible science.

The Version of Record (VoR) is the authoritative, final, and citable form of a scholarly work, reflecting completed peer review, verified methods and data-availability statements, disclosed conflicts of interest and funding, and any subsequent corrections or retractions. It is the only version guaranteed to be checked for accuracy and curated by experts over time, and it is what allows a finding to be located, interpreted, and independently reproduced years after publication. This is the publisher's core contribution to rigor: the peer review, integrity screening, metadata stewardship, and post-publication correction that make a result trustworthy enough to reproduce. As NIH designs indicators of reproducibility, it should treat the permanence and integrity of this record as foundational rather than ancillary, consistent with the tenets of Gold Standard Science articulated in Executive Order 14303.

To strengthen NIH's framework for rigor and reproducibility, we recommend the following approaches:

- Recognize the Version of Record as the authoritative basis for reproducibility assessment. Preprints and other non-peer-reviewed outputs play a useful role in rapid communication, but they are not substitutes for the peer-reviewed record and should not be treated as equivalent in metrics frameworks.

- Credit negative and null results in funding and career-advancement review. Well-conducted studies that find no effect are essential to an honest and complete literature; their absence from the record is a root cause of the reproducibility problem.
- Rely on publisher-led integrity infrastructure, including peer review, editorial assessment, research-integrity screening, corrections, retractions, and post-publication stewardship, as part of the reproducibility ecosystem rather than treating these as separate from NIH's priorities.
- Recognize long-term and programmatic research contributions rather than rewarding the pace of publication. Metrics that prize rapid output can push researchers toward premature claims; NIH should credit sustained, careful work that genuine reproducibility requires.
- Account for disciplinary variation, since replication looks different across fields. A flexible framework that adapts to field-specific norms and methods will be more effective than applying a single standard to all research.

Wiley and the broader publishing community welcome opportunities to collaborate with NIH on the standards, infrastructure, and incentives that make reproducible science possible.

Training and Mentorship. NIH recognizes that advancing its mission requires promoting the growth and stability of the biomedical research workforce. While NIH supports training and protects time through existing policies and programs, additional indicators are needed to assess and quantify the impact of these efforts.

Advancing NIH's mission requires a stable and growing biomedical research workforce, supported by stronger measures of the impact of training and mentorship. In our experience across the U.S. research ecosystem, mentorship is not a supplementary benefit but the primary mechanism by which the tacit skills of rigorous science are transmitted from one generation to the next. Long-horizon discovery depends on giving young researchers the time, resources, and guidance to learn from lead researchers on projects that may not yield results for a decade or more.

Federal laboratories and NIH-supported training environments are uniquely positioned to serve as national training grounds, not only for technical excellence but for the standards of rigor, reproducibility, and responsible conduct that underpin Gold Standard Science. Protecting mentored time on long-duration projects is essential to sustaining the discovery pipeline and delivering public-health returns years after the initial investment. As Wiley noted in its response to the U.S. Department of Energy's Genesis Mission RFI, the durability of the U.S. research workforce also depends on distributing training opportunity broadly across institutions and regions. NIH should ensure that training and mentorship indicators capture participation from R1, R2, and R3 universities, Historically Black Colleges and Universities, Tribal Colleges, and community colleges, so that emerging talent is developed wherever it is found rather than only at the best-resourced institutions.

To assess and reward training and mentorship impact, NIH should consider the following approaches:

- Track the longitudinal trajectories of researchers who receive mentored training: whether they go on to win independent funding, publish as principal investigators, establish productive laboratories, and remain in the biomedical workforce.

- Recognize peer review and editorial participation as a form of mentorship and professional development. Serving as a reviewer or early-career editor is one of the primary ways scientists learn to evaluate evidence, judge methodology, and communicate uncertainty.
- Support structured mentorship programs that can be delivered in both in-person and hybrid formats to extend access to trainees who lack proximity to major research centers, strengthening geographic resilience in the national talent pipeline.

Collaboration. As biomedical research becomes increasingly interdisciplinary and convergent, collaboration is growing in both scale and complexity. NIH seeks new approaches for assessing and recognizing contributions to team-based science.

Biomedical progress increasingly depends on large, interdisciplinary teams working across institutions, sectors, and Federal agencies. However, traditional measures of scientific achievement, such as author position, publication counts, and citation totals, do not always capture the full range of contributions required to conduct complex collaborative research. Wiley has advocated for more comprehensive approaches to recognizing team-based science in prior submissions, including our response to the U.S. Department of Energy's Genesis Mission RFI, and we encourage NIH to adopt a framework that reflects the true architecture of modern biomedical collaboration.

Publishers can support this effort by preserving a clear and reliable record of who contributed to a study and how. Publication records can document contributions beyond writing and lead authorship, including data collection and curation, methodology, software development, project coordination, statistical analysis, mentoring, and research-resource sharing. This infrastructure already exists and can serve as the foundation for any NIH framework for recognizing collaborative contributions.

NIH should consider the following to assess and recognize collaboration:

- Recognize outputs beyond traditional journal articles. Data, software, research methods, shared infrastructure, and reproducibility work can all provide substantial value to a collaborative project and should be considered when evaluating investigators and research teams.
- Coordinate with other Federal research agencies and with publishers on common principles for documenting and attributing research contributions, using persistent identifiers such as ORCID and DOIs to link researchers to their outputs across institutions and over time.
- Adopt the CRediT taxonomy, which attributes individual researcher contributions across the research pipeline in a standardized, machine-readable format at submission.
- Assign weight to team-level and program-level outcomes in funding review, particularly for large-scale, inter-agency, or public-private initiatives where success depends on coordinated effort rather than the work of a single investigator.
- Build safeguards against unintended incentives such as inflated authorship or exaggerated contribution claims, by relying on transparent contribution statements that are preserved as part of the published Version of Record and subject to post-publication correction.

A more complete approach to evaluating team science would allow NIH to recognize the researchers who generate, organize, validate, and translate biomedical knowledge, not only those whose names appear in the most prominent author positions.

Entrepreneurship and Translation. To advance the translation of discoveries into products for people, NIH fosters the maturation of discoveries from bench to bedside and promotes innovation across sectors. More can be done to incentivize, assess, and integrate the impact of innovation and entrepreneurial efforts as critical to the NIH mission.

The translation of discovery from bench to bedside depends on a scientific record that industry, investors, clinicians, and regulators can trust, and that record is the publisher's product. The peer-reviewed Version of Record, with its verified methods, disclosures, and corrections, is the defensible foundation on which patents are filed, products are developed, and clinical decisions are made. A discovery that cannot be located, cited, and relied upon with confidence cannot be translated, however promising it may be.

The publisher's role in translation is therefore not incidental but enabling. Wiley's investments in metadata, persistent identifiers, taxonomy, and integrity screening allow a finding to be discovered and built upon by a start-up or research-and-development team years after it is first published. As AI accelerates the translational pipeline, rights-cleared and provenance-rich content becomes even more critical: products and regulated systems built on unverified or unlawfully obtained inputs carry commercial, regulatory, and litigation risk that deters investment. The Wiley AI Gateway demonstrates how licensed, peer-reviewed content can be embedded in AI-enabled discovery tools, for tasks such as biomarker discovery and clinical trial design, with full provenance and attribution, accelerating translation while preserving research integrity.

To assess and reward translational and entrepreneurial impact, NIH should consider these approaches:

- Track patents and regulatory submissions that cite federally funded publications as a concrete, verifiable indicator of translational impact, and include these in the criteria used to evaluate investigators and programs.
- Count licensing agreements and start-up formation arising from NIH-funded research as recognized outputs, with appropriate attribution to the researchers, institutions, and publishers whose work enabled them.
- Monitor incorporation of NIH-funded findings into clinical guidelines, standards of care, and public health policy, recognizing that these outcomes often represent the most direct translation of research into health benefit.
- Encourage Federal procurement and partnership mechanisms to favor AI systems and analytical tools built on licensed, verified, rights-cleared research inputs, providing industry the legal certainty it needs to invest in translation and ensuring that federally supported innovation rests on defensible scientific foundations.

Foundational Scientific Exploration. Basic research and high-risk, high-reward initiatives represent foundational scientific exploration with an inherent risk of failure but the potential for paradigm-shifting breakthroughs. Further embedding these approaches within the academic enterprise is essential to ensuring continued support for bold and innovative research directions.

Basic research and high-risk, high-reward inquiry carry an inherent risk of failure alongside the potential for paradigm-shifting breakthroughs. Wiley is proud to sponsor the Golden Goose Award, which recognizes research that appeared obscure, or even accidental, that produced significant benefits for public health and the economy. The award illustrates a principle that NIH's own mission embodies: the value of foundational science is often not visible at the outset and cannot be judged by short-horizon metrics. When research is evaluated only by how quickly it produces results or how many citations it earns, the slow, uncertain, exploratory work that leads to the most important discoveries tends to get left behind.

Publishers sustain this kind of exploration by preserving the complete record of inquiry, including incremental findings, detailed methods, and the negative and null results that keep a field honest and prevent duplicated effort. The permanence of the Version of Record and long-term archiving mean that a finding regarded as obscure today remains discoverable years later, when its significance becomes clear, so that other scientists can validate and build on it.

Therefore, NIH should consider the following to support the foundation of scientific exploration:

- Evaluate high-risk, high-reward research over longer time frames rather than short productivity cycles and protect such programs from metrics that penalize delayed or uncertain returns. Review panels should be explicitly instructed that absence of near-term results is not evidence of failure in exploratory research programs.
- Establish a recognition mechanism modeled on the Golden Goose Award that NIH administers or co-sponsors, identifying and celebrating federally funded research that produced unexpected or long-delayed breakthroughs.
- Credit the publication of negative and null results and of replication studies as legitimate scientific contributions, recognizing that these outputs are the record through which foundational science accumulates over time.
- Sustained federal funding is what makes this kind of research possible in the first place. NIH should make clear in its assessment framework that investing in research before its value is obvious is not a risk to be avoided, but a necessity for scientific discovery.

Public Impact. NIH seeks approaches for assessing and recognizing the broader public impact of biomedical research, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit.

Publishing is the mechanism by which taxpayer investment becomes lasting public benefit: it converts funded research into a transparent, enduring, and accessible record that patients, clinicians, educators, and innovators can rely on. The returns are substantial: by widely cited estimates, every $1 invested by NIH yields roughly $2.56 in economic activity, and it is the published, curated record that makes those returns durable and verifiable.

Public trust is now inseparable from the reliability of that record, which increasingly feeds the AI systems Americans use every day. When an American turns to an AI tool to understand a family member's diagnosis and possible treatments, the value of the answer depends on whether the underlying model draws on the

gold-standard, peer-reviewed content that Wiley and its society partners produce and curate. The publisher's integrity screening, corrections, and provenance tracking are, in this sense, public-trust infrastructure. Accessibility matters as well: the maintained Version of Record, together with public-access compliance, ensures that findings reach practitioners and the public in usable, citable form.

NIH should consider the following approaches to assess and recognize the impact of biomedical research:

- Measure the accessibility and sustained reuse of the scholarly record and the availability of findings in PubMed Central and other trusted repositories.
- Use responsible altmetrics, including media coverage, policy citations, and public engagement, as supplementary signals of broader reach. Publishers already collect this data through existing infrastructure: for example, NIH-funded papers published by Wiley generated more than 10,000 social media mentions and over 1,500 news articles worldwide in 2024. NIH should partner with publishers to leverage this data rather than building parallel collection systems.
- Recognize publishers as part of the public-trust infrastructure for biomedical AI. NIH should require that AI systems used in research and clinical decisions are built on licensed, provenance-rich, peer-reviewed content rather than unverified inputs.

Name of Organization: University of California, San Francisco | Academic Senate Committee on Library and Scholarly Communication and University Library

Type of Organization: Not Applicable

Role: Other

Role - Other: Chair, Committee on Library and Scholarly Communication (Oldham) and University Librarian (Shaffer)

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: Biomedical research increasingly depends on complex datasets, software, and computational workflows that cannot be fully reproduced from publications alone. NIH's Replication and Reproducibility Initiative presents an opportunity to redefine reproducibility around persistent, reusable research objects. Community-governed metadata standards, persistent identifiers, provenance, executable workflows, and interoperable packaging would allow analyses to be reproduced directly rather than reconstructed from narrative methods. Reproducibility should be viewed not as the endpoint of validation, but as the prerequisite for continuous optimization of scientific methods. NIH can accelerate this transition by investing in shared infrastructure while recognizing reproducible datasets, software, and workflows as first-class scholarly outputs.

Actions or initiatives to support and reward rigor and reproducibility:
- Require researchers to openly share all relevant research outputs, including research methods, protocols, and code; and to cite resources and activities using platforms like Research Resource Identification (RRID) (https://www.rrids.org/) and Research Activity Identifer (RAiD) (https://www.raid.org/) in all relevant outputs. Platforms should be identified and prioritized to ensure standardization amongst researchers (see PID-Optimized Research Lifecyle (https://doi.org/10.5281/zenodo.4991732)).
- Adopt or create a platform for NIH-funded researchers to share null and negative results at no cost, following a standardized template. Such a platform would benefit reproducibility efforts and provide a record of funded research results.

2. Data, Software, and Model Sharing: NIH has successfully established expectations for data sharing. The next step is rewarding quality rather than deposition alone. Curated datasets, software, and workflows should be standardized, richly annotated, uniquely identifiable, interoperable, and reusable. Shared community infrastructure – including metadata standards, registries, persistent identifiers, and governance – should be sustained centrally, while investigators build reusable scientific assets upon this

foundation. Assessment should emphasize reuse, interoperability, reproducibility, and downstream scientific influence rather than simple download counts.

Actions or initiatives to support and reward data, software, and model sharing:
- Support the Make Data Count (MDC) initiative (https://makedatacount.org/), implement interoperable MDC practices in NIH data repositories, and promote these practices in external databases to enable standardized, measurable indicators of data usage and interoperability.

3. Training and Mentorship: Future investigators require training in data stewardship, metadata harmonization, computational reproducibility, and collaborative software development alongside training in experimental science. NIH can recognize mentors who build laboratories that consistently produce reusable scientific assets and who prepare trainees to participate in open, reproducible, data-intensive research. NIH can also provide dedicated training on these topics through the Responsible Conduct of Research requirement and other channels.

Actions or initiatives to support and reward training and mentorship:
- The Researcher Impact Framework (https://www.tara.tcd.ie/tara8/server/api/core/bitstreams/ea53964f-1f06-459d-ba0d-4f4fab9352c8/content)from Trinity College in Dublin provides a model to help researchers cite their relevant scholarly activity and write an outcome statement and impact narrative for the impact area, Development of Individuals and Collaborations.

4. Collaboration: Modern biomedical science depends on interdisciplinary teams whose contributions extend far beyond manuscript authorship. Persistent identifiers and contributor taxonomies should be used to recognize contributions to datasets, software, workflows, metadata standards, and shared infrastructure. Assessment systems should value the creation and maintenance of reusable community resources alongside traditional publications.

Actions or initiatives to support and reward collaboration:
- Encourage recognition of all research outputs and those who contribute to them in grant applications and reports, including statements by awardees addressing the impact of these contributions to the research project. These contributors may include research staff and community members. For example, the HiddenREF (https://hidden-ref.org/) initiative in the UK hosts a competition and festival to build evidence about assessing research outputs and to develop a better understanding of inclusive approaches to research recognition.
- Researchers can demonstrate their collaborations and disciplinary focuses using free tools such as Google Scholar Profiles and campus profiling systems, as well as subscription resources such as Web of Science and Dimensions Analytics.
- Researchers' organizations can also help drive collaboration and team science approaches. Providing opportunities in grant applications and reports for researchers to cite team science-oriented groups and resources within their organization, and how they have been utilized in the research project to enhance collaboration, would emphasize their importance and provide evidence of their impact.

5. Entrepreneurship and Translation: Successful translation and entrepreneurship depend upon reproducible and interoperable scientific knowledge. Standardized datasets and executable workflows reduce barriers for biotechnology, regulatory science, and clinical implementation by making research

outputs easier to validate, compare, integrate, and extend. Investments in reusable research infrastructure, therefore, accelerate both innovation and translation.

Actions or initiatives to support and reward entrepreneurship and translation:

- Contributions to innovation and entrepreneurship through patents, clinical and research products on the market, and entrepreneurial endeavors contribute towards a researcher's impact just as publications and other research outputs. A narrative description of these contributions is a fitting representation, as well as citations to their research outputs from patents, clinical guidelines, and policy documents. Citations to a researcher's outputs from others' patents, clinical trials, and policy documents may also demonstrate the impact of the researcher's work.
- Researchers may use free tools such as the U.S. patents database (https://www.uspto.gov/patents/search) and free Altmetric records (https://help.altmetric.com/en/categories/2060609-sources-of-attention) for publication citations, as well as subscription sources such as Dimensions Analytics, Web of Science, and Altmetric Explorer for publication citations.
- The Researcher Impact Framework (https://www.tara.tcd.ie/tara8/server/api/core/bitstreams/ea53964f-1f06-459d-ba0d-4f4fab9352c8/content) from Trinity College in Dublin provides a model to help researchers cite their relevant scholarly activity and write an outcome statement and impact narrative for the respective impact area, Generation of Knowledge.

6. Foundational Scientific Exploration: High-risk research often produces enduring datasets, analytical methods, and software even when the original biological hypothesis is not confirmed. Assessment systems should recognize these reusable assets because they frequently become the foundation for future discoveries. Benchmark datasets and community workflows also enable continuing methodological innovation.

7. Public Impact: Scientific impact should increasingly be measured not by where investigators publish, but by the degree to which durable research objects can be discovered, reused, reproduced, validated, and built upon to improve health, accelerate discovery, strengthen public trust, and increase research efficiency. Whereas publications enable period reporting of scientific knowledge, durable research objects enable cumulative scientific progress by fostering continuous optimization of scientific knowledge.

Actions or initiatives to support and reward entrepreneurship and translation:
- Researcher contributions to public impact can be assessed through a number of methods. Attention to research articles on social media, blogs, Wikipedia, and in the news can be tracked and measured via publisher webpages and through services such as Altmetric and PlumX Metrics. While these services tally counts, the researcher still needs to tell the impact story of the public attention their work has received.
- Databases such as Dimensions and Scopus Author Profiles map publications to corresponding United Nations Sustainable Development Goals (SDG). These goals, such as No Hunger; Good Health and Wellbeing; and Gender Equality, when applied to publications, reflect a researcher's focus on work that impacts society.

8. Other Areas: Better measures of scientific impact require better scientific infrastructure. NIH is uniquely positioned to invest in shared national resources—such as metadata standards, registries, persistent identifiers, and interoperability frameworks—that individual projects cannot sustainably create. These public goods would enable responsible assessment based on creation, quality, dissemination, reuse, scientific influence, and public impact while supporting a long-term transition from a publication-centered enterprise to a cumulative knowledge ecosystem. Standardized datasets, software, and computational workflows can become measurable scholarly contributions once they are accompanied by common metadata standards, persistent identifiers, and infrastructure that tracks discovery, reuse, and reproducibility.

Other actions or initiatives:
- Metrics for article publication citations can be useful when used responsibly. A move towards field-normalized scoring systems, such as the Relative Citation Ratio (RCR) at the article level (instead of the ranking for the journal where the article was published), should be emphasized. Field-normalized scores simplify score interpretations and ensure that articles are ranked in comparison to their field of research.
- Diverse forms of contributions should be supported, so that a social sciences researcher's activities can be accommodated and evaluated just as the basic sciences researcher's are.
- Using metrics alone for any type of research output is insufficient for assessing the impact of the research. Researchers should be expected to accompany counts and rankings with descriptions of the work's impact.

Re: NIH Request for Information on Measuring and Rewarding Scientific Impact

To Whom It May Concern,

Pursuant to NIH Notice Number NOT-OD-26-087 (https://grants.nih.gov/grants/guide/notice-files/NOT-OD-26-087.html), "Request for Information on Measuring and Rewarding Scientific Impact", the UCSF Academic Senate Committee on Library and Scholarly Communication (COLASC) and the UCSF Library have prepared a joint response, which is included below. We thank you for drawing attention to this critical topic and the implications it carries for the future of biomedical research.

Sincerely,

[redacted]

Michael C. Oldham, PhD
Professor, Department of Neurological Surgery
Chair, Academic Senate Committee on Library and Scholarly Communication
University of California, San Francisco

[redacted]

Chris Shaffer, MS, FMLA, AHIP
University Librarian and Assistant Vice Chancellor
Adjunct Professor, Department of Medicine
University of California, San Francisco

Response to NIH Notice Number NOT-OD-26-087: Request for Information on Measuring and Rewarding Scientific Impact

https://grants.nih.gov/grants/guide/notice-files/NOT-OD-26-087.html

Rigor and Reproducibility

- Reproducible and replicable biomedical approaches are foundational to rigorous research. New strategies are needed to identify areas ripe for replication and reproducibility efforts, as well as incentives and infrastructure to support the reproduction and replication of existing findings.

Biomedical research increasingly depends on complex datasets, software, and computational workflows that cannot be fully reproduced from publications alone. NIH's Replication and Reproducibility Initiative presents an opportunity to redefine reproducibility around persistent, reusable research objects. Community-governed metadata standards, persistent identifiers, provenance, executable workflows, and interoperable packaging would allow analyses to be reproduced directly rather than reconstructed from narrative methods. Reproducibility should be viewed not as the endpoint of validation, but as the prerequisite for continuous optimization of scientific methods. NIH can accelerate this transition by investing in shared infrastructure while recognizing reproducible datasets, software, and workflows as first-class scholarly outputs.

Actions or initiatives to support and reward rigor and reproducibility:

- Require researchers to openly share all relevant research outputs, including research methods, protocols, and code; and to cite resources and activities using platforms like Research Resource Identification (RRID) (https://www.rrids.org/) and Research Activity Identifer (RAiD) (https://www.raid.org/) in all relevant outputs. Platforms should be identified and prioritized to ensure standardization amongst researchers (see PID-Optimized Research Lifecyle (https://doi.org/10.5281/zenodo.4991732)).
- Adopt or create a platform for NIH-funded researchers to share null and negative results at no cost, following a standardized template. Such a platform would benefit reproducibility efforts and provide a record of funded research results.

Data, Software, and Model Sharing

- Sharing scientific data and tools accelerates biomedical research discovery, in part, by enabling validation of research results, providing accessibility to high-value datasets, and promoting data reuse for future research studies. NIH seeks to incentivize and reward these activities to maximize the value of research investments, catalyze collaborations, and accelerate scientific impact.

NIH has successfully established expectations for data sharing. The next step is rewarding quality rather than deposition alone. Curated datasets, software, and workflows should be standardized, richly annotated, uniquely identifiable, interoperable, and reusable. Shared community infrastructure – including metadata standards, registries, persistent identifiers, and governance – should be sustained centrally, while investigators build reusable scientific assets upon this foundation. Assessment should emphasize reuse, interoperability, reproducibility, and downstream scientific influence rather than simple download counts.

Actions or initiatives to support and reward data, software, and model sharing:

- Support the Make Data Count (MDC) initiative (https://makedatacount.org/), implement interoperable MDC practices in NIH data repositories, and promote these practices in external databases to enable standardized, measurable indicators of data usage and interoperability.

Training and Mentorship

- NIH recognizes that advancing its mission requires promoting the growth and stability of the biomedical research workforce. While NIH supports training and protects time through existing policies and programs, additional indicators are needed to assess and quantify the impact of these efforts.

Future investigators require training in data stewardship, metadata harmonization, computational reproducibility, and collaborative software development alongside training in experimental science. NIH can recognize mentors who build laboratories that consistently produce reusable scientific assets and who prepare trainees to participate in open, reproducible, data-intensive research. NIH can also provide dedicated training on these topics through the Responsible Conduct of Research requirement and other channels.

Actions or initiatives to support and reward training and mentorship:

- The Researcher Impact Framework (https://www.tara.tcd.ie/tara8/server/api/core/bitstreams/ea53964f-1f06-459d-ba0d-4f4fab9352c8/content)from Trinity College in Dublin provides a model to help researchers cite their relevant scholarly activity and write an outcome statement and impact narrative for the impact area, Development of Individuals and Collaborations.

Collaboration

- As biomedical research becomes increasingly interdisciplinary and convergent, collaboration is growing in both scale and complexity. NIH seeks new approaches for assessing and recognizing contributions to team-based science.

Modern biomedical science depends on interdisciplinary teams whose contributions extend far beyond manuscript authorship. Persistent identifiers and contributor taxonomies should be used to recognize contributions to datasets, software, workflows, metadata standards, and shared infrastructure. Assessment systems should value the creation and maintenance of reusable community resources alongside traditional publications.

Actions or initiatives to support and reward collaboration:

- Encourage recognition of all research outputs and those who contribute to them in grant applications and reports, including statements by awardees addressing the impact of these contributions to the research project. These contributors may include research staff and community members. For example, the HiddenREF (https://hidden-ref.org/) initiative in the UK hosts a competition and festival to build evidence about assessing research outputs and to develop a better understanding of inclusive approaches to research recognition.
- Researchers can demonstrate their collaborations and disciplinary focuses using free tools such as Google Scholar Profiles and campus profiling systems, as well as subscription resources such as Web of Science and Dimensions Analytics.
- Researchers' organizations can also help drive collaboration and team science approaches. Providing opportunities in grant applications and reports for researchers to cite team science-oriented groups and resources within their organization, and how they have been utilized in the research project to enhance collaboration, would emphasize their importance and provide evidence of their impact.

Entrepreneurship and Translation

- To advance the translation of discoveries into products for people, NIH fosters the maturation of discoveries from bench to bedside and promotes innovation across sectors. More can be done to incentivize, assess, and integrate the impact of innovation and entrepreneurial efforts as critical to the NIH mission.

Successful translation and entrepreneurship depend upon reproducible and interoperable scientific knowledge. Standardized datasets and executable workflows reduce barriers for biotechnology, regulatory science, and clinical implementation by making research outputs easier to validate, compare, integrate, and extend. Investments in reusable research infrastructure, therefore, accelerate both innovation and translation.

Actions or initiatives to support and reward entrepreneurship and translation:

- Contributions to innovation and entrepreneurship through patents, clinical and research products on the market, and entrepreneurial endeavors contribute towards a researcher's impact just as publications and other research outputs. A narrative description of these contributions is a fitting representation, as well as citations to their research outputs from patents, clinical guidelines, and policy documents. Citations to a researcher's outputs from others' patents, clinical trials, and policy documents may also demonstrate the impact of the researcher's work.
- Researchers may use free tools such as the U.S. patents database (https://www.uspto.gov/patents/search) and free Altmetric records (https://help.altmetric.com/en/categories/2060609-sources-of-attention) for publication citations, as well as subscription sources such as Dimensions Analytics, Web of Science, and Altmetric Explorer for publication citations.

- The Researcher Impact Framework (https://www.tara.tcd.ie/tara8/server/api/core/bitstreams/ea53964f-1f06-459d-ba0d-4f4fab9352c8/content) from Trinity College in Dublin provides a model to help researchers cite their relevant scholarly activity and write an outcome statement and impact narrative for the respective impact area, Generation of Knowledge.

Foundational Scientific Exploration

- Basic research and high-risk, high-reward initiatives represent foundational scientific exploration with an inherent risk of failure but the potential for paradigm-shifting breakthroughs. Further embedding these approaches within the academic enterprise is essential to ensuring continued support for bold and innovative research directions.

High-risk research often produces enduring datasets, analytical methods, and software even when the original biological hypothesis is not confirmed. Assessment systems should recognize these reusable assets because they frequently become the foundation for future discoveries. Benchmark datasets and community workflows also enable continuing methodological innovation.

Public Impact

- NIH seeks approaches for assessing and recognizing the broader public impact of biomedical research, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit.

Scientific impact should increasingly be measured not by where investigators publish, but by the degree to which durable research objects can be discovered, reused, reproduced, validated, and built upon to improve health, accelerate discovery, strengthen public trust, and increase research efficiency. Whereas publications enable period reporting of scientific knowledge, durable research objects enable cumulative scientific progress by fostering continuous optimization of scientific knowledge.

Actions or initiatives to support and reward entrepreneurship and translation:

- Researcher contributions to public impact can be assessed through a number of methods. Attention to research articles on social media, blogs, Wikipedia, and in the news can be tracked and measured via publisher webpages and through services such as Altmetric and PlumX Metrics. While these services tally counts, the researcher still needs to tell the impact story of the public attention their work has received.
- Databases such as Dimensions and Scopus Author Profiles map publications to corresponding United Nations Sustainable Development Goals (SDG). These goals, such as No Hunger; Good Health and Wellbeing; and Gender Equality, when applied to publications, reflect a researcher's focus on work that impacts society.

Other Areas

Better measures of scientific impact require better scientific infrastructure. NIH is uniquely positioned to invest in shared national resources—such as metadata standards, registries, persistent identifiers, and interoperability frameworks—that individual projects cannot sustainably create. These public

goods would enable responsible assessment based on creation, quality, dissemination, reuse, scientific influence, and public impact while supporting a long-term transition from a publication-centered enterprise to a cumulative knowledge ecosystem. Standardized datasets, software, and computational workflows can become measurable scholarly contributions once they are accompanied by common metadata standards, persistent identifiers, and infrastructure that tracks discovery, reuse, and reproducibility.

Other actions or initiatives:

- Metrics for article publication citations can be useful when used responsibly. A move towards field-normalized scoring systems, such as the Relative Citation Ratio (RCR) at the article level (instead of the ranking for the journal where the article was published), should be emphasized. Field-normalized scores simplify score interpretations and ensure that articles are ranked in comparison to their field of research.
- Diverse forms of contributions should be supported, so that a social sciences researcher's activities can be accommodated and evaluated just as the basic sciences researcher's are.
- Using metrics alone for any type of research output is insufficient for assessing the impact of the research. Researchers should be expected to accompany counts and rankings with descriptions of the work's impact.

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: As has been widely discussed, and as acknowledged in the recently announced NIH initiative on replication and reproducibility, low rates for replication attempts reflect the current incentive structure for scientists. In most fields, scientists do not get credit for replications in the way they do for new findings, and universities do not reward scientists for replicating other studies. In many fields, there is also an asymmetry, where a successful study is perceived to reflect investigator skill, whereas a failed replication (or failed initial study) may be seen as evidence that the investigator conducting the replication is less skilled. It is challenging to directly intervene on scientific culture and biases among P&T committees, ranking organizations, and peer reviewers. But there are other incentives – most notably, large federal research grants – that influence perceived stature and provide independent financial benefits, which may affect investigator behavior. Grant RFPs specifically targeting systematic replication efforts would likely impact on the number of replications attempted, as well as the reputation of scientists who focus primarily on replicating other studies. Ultimately, this will require a significant and focused financial investment.

Additionally, a mechanism should be developed to highlight and reward especially careful replications conducted by scientists with strong reputations for excellent analysis and experimental skill. The best way to do this would be to identify or develop a new publication venues with very high editorial standards that could play a role comparable to Cell, Science, and Nature for replications.

Finally, I note that replication is valuable even in cases where replications succeed, and efforts to support replication should not focus entirely on areas that are, for one reason or another, perceived to be suspect or likely to have replication attempts fail. Failed replications, and incorrect findings, should also be recognized as a normal part of science, and the choice of whether to attempt replication within some field should not be presented, or treated, as a potential indictment of results or researchers in that field. Instead, the NIH should consider an inductive risk approach, where the primary consideration behind replication efforts is an assessment of the overall strength of existing evidence along with the potential harms of adopting policies or practices based on incorrect findings. Emphasis should also be placed on publicly-funded, highly transparent replications of high-impact research previously funded by private groups with financial conflicts.

2. Data, Software, and Model Sharing: Norms around data stewardship and open data are important, and rapidly evolving. In addition to requiring data and sharing management plans, the NIH can promote

improved data practices by better auditing past practices as part of the grant proposal process, making availability of past data a criterion for assessment of future proposals, providing support for data maintenance, and providing ombudsman resources for cases where requests for data from NIH-supported research are not granted in a timely manner.

3. Training and Mentorship: The single-most important factor in building and maintaining a strong scientific workforce is funding stability and longitudinal support for early-career and untenured researchers. Funding uncertainty makes research careers less attractive, and disruptions to funding often force researchers who have already benefited from past public investments to leave the field, with minimal prospect of returning. This reduces the overall skilled workforce and it blunts the possible impact of past investment. The NIH should perform an internal audit of grant cancelations, award delays, and other funding disruptions over the past several years to identify the impact of those actions on the size and quality of the scientific workforce, especially by age cohort, to identify ways in which its own past practices have harmed its stated goals. This audit should then be the basis for new safeguards to protect the long-term stability of the scientific workforce.

4. Collaboration: There are challenging issues related to how to assess the size and importance of individual contributions to team science, and to assign credit and other resources on the basis of those contributions. I do not have specific proposals for how to do this, but I do note that similar issues arise in physics, related to very large experiments (such as particle accelerator experiments and large astronomical instruments), and that it may be possible to adapt best-practices from that context to the biomedical sciences.

5. Entrepreneurship and Translation: Translational science is crucial for realizing the public impacts of federal science funding, and it is right for the NIH to support entrepreneurship and the bench-to-bedside pipeline. Currently, federal law incentivizes institutional recipients of federal grants to commercialize federally funded research, via the Bayh-Dole act, which permits non-profits to hold patents on inventions developed with federal funds. However, there is a gap between development of the underlying technology / intellectual property to the patent stage, and further development of viable commercialization strategies that can attract private funding and ultimately reach consumers.

Moreover, the current risk/reward structure for developing private companies to commercialize research is the same as for other start-ups, where early assessments of long-term market demand determine what IP is commercialized. This does not reflect the past public investment in that IP nor the public benefits of its broad availability. Structures should be developed to permit prolonged incubation under, or in close partnership with, non-profit entities, and the NIH should provide mechanisms for early-stage venture capital funding in cases where public benefit is high but market demand may be insufficient to recover costs. Public investment in later-stage commercialization could be reflected in reduced prices, or preferred pricing for federal buyers (such as Medicare). The existing SBIR and STTR programs are good models for this, but funding levels are very low compared to private capital.

That being said, independent market mechanisms exist for rewarding successful commercialization, and the NIH should maintain its focus on basic science. Ultimately, the need for public support is greater the earlier in the development pipeline. Basic science, with no obvious commercial applications, is where public funding is most justified (as supporting a collective good) and most needed.

6. Foundational Scientific Exploration: I fully agree with the NIH's statement on this topic. One particular concern is that, while expert peer review remains the best way to assess the quality of proposals, it can select for relatively safe / conservative projects, especially in a resource-strained environment where reviewers are asked to comment on the likelihood that an award will result in specific benefits. For this reason, the NIH should consider lottery-based funding mechanisms, for high-risk proposals from researchers with an established track record who meet other criteria of quality, such as past research success.

7. Public Impact: Public Impact must be assessed holistically, with no expectation that individual projects will result in easily quantified, short-term effects. Instead, the NIH should conceive of itself as supporting a large portfolio of activities that, on the whole, will make a significant public impact over time. The history of scientific research shows that broad support for basic science will yield significant public benefits. Narrow focus on short-term indicators and individual projects, without tolerance for failure (a consequence of risk-taking) or long horizons, will ultimately reduce the public impact of the NIH's investments.

8. Other Areas: Overall, scientific researchers should be assessed holistically, with easily quantified measures like citation counts, patents, previous grants, and publications balanced against more subjective and difficult to measure qualities such as creativity, quality of past research, indirect impact, and intellectual humility. This is necessary to properly reward activities such as replications (which are less likely to be cited or published in especially high-status journals, especially when successful), commercialization (which does not show up in citations or publications), risk-taking (which may not have immediate benefits), and highly original contributions that are not immediately recognized as such. However, holistic assessment is often unstable, and can quickly collapse into either bean-counting or lowered standards. One mechanism to protect against instability is to target grant opportunities for researchers who are especially strong in valuable but difficult to quantify dimensions, and either focus evaluation of proposals on specific criteria or use lottery-based mechanisms to avoid biases.

RE: Request for Information on Measuring and Rewarding Scientific Impact

Dear Colleagues,

I write this memo in a personal capacity. For identification and contextualization purposes, I note that I am Chancellors Professor in the Department of Logic and Philosophy of Science at UC Irvine and I currently serve as Chair of the University Committee on Research Policy (UCORP), a standing committee of the systemwide Academic Senate of the University of California. In that capacity, and in my prior capacity as Chair of UC Irvine's Council on Research, Computing, and Libraries, I have had opportunities to participate in many discussions across disciplines and across UC campuses on topics related to this request for information. Additionally, my primary academic field is philosophy of science, and I have previously written and taught on issues related to science in public discourse, the credit economy of science, and scientific best-practices. This submission is partially informed by feedback from colleagues on UCORP and others in my local community whose research concerns these topics.

Rigor and Reproducibility.
As has been widely discussed, and as acknowledged in the recently announced NIH initiative on replication and reproducibility, low rates for replication attempts reflect the current incentive structure for scientists. In most fields, scientists do not get credit for replications in the way they do for new findings, and universities do not reward scientists for replicating other studies. In many fields, there is also an asymmetry, where a successful study is perceived to reflect investigator skill, whereas a failed replication (or failed initial study) may be seen as evidence that the investigator conducting the replication is less skilled. It is challenging to directly intervene on scientific culture and biases among P&T committees, ranking organizations, and peer reviewers. But there are other incentives – most notably, large federal research grants – that influence perceived stature and provide independent financial benefits, which may affect investigator behavior. Grant RFPs specifically targeting systematic replication efforts would likely impact on the number of replications attempted,

as well as the reputation of scientists who focus primarily on replicating other studies. Ultimately, this will require a significant and focused financial investment.

Additionally, a mechanism should be developed to highlight and reward especially careful replications conducted by scientists with strong reputations for excellent analysis and experimental skill. The best way to do this would be to identify or develop a new publication venues with very high editorial standards that could play a role comparable to Cell, Science, and Nature for replications.

Finally, I note that replication is valuable even in cases where replications succeed, and efforts to support replication should not focus entirely on areas that are, for one reason or another, perceived to be suspect or likely to have replication attempts fail. Failed replications, and incorrect findings, should also be recognized as a normal part of science, and the choice of whether to attempt replication within some field should not be presented, or treated, as a potential indictment of results or researchers in that field. Instead, the NIH should consider an inductive risk approach, where the primary consideration behind replication efforts is an assessment of the overall strength of existing evidence along with the potential harms of adopting policies or practices based on incorrect findings. Emphasis should also be placed on publicly-funded, highly transparent replications of high-impact research previously funded by private groups with financial conflicts.

Data, Software, and Model Sharing.
Norms around data stewardship and open data are important, and rapidly evolving. In addition to requiring data and sharing management plans, the NIH can promote improved data practices by better auditing past practices as part of the grant proposal process, making availability of past data a criterion for assessment of future proposals, providing support for data maintenance, and providing ombudsman resources for cases where requests for data from NIH-supported research are not granted in a timely manner.

Training and Mentorship.
The single-most important factor in building and maintaining a strong scientific workforce is funding stability and longitudinal support for early-career and untenured researchers. Funding uncertainty makes research careers less attractive, and disruptions to funding often force researchers who have already benefited from past public investments to leave the field, with minimal prospect of returning. This reduces the overall skilled workforce and it blunts the possible impact of past investment. The NIH should perform an internal audit of grant cancelations, award delays, and other funding disruptions over the past several years to identify the impact of those actions on the size and quality of the scientific workforce, especially by age cohort, to identify ways in which its own past practices have harmed its stated goals. This audit should then be the basis for new safeguards to protect the long-term stability of the scientific workforce.

Collaboration.
There are challenging issues related to how to assess the size and importance of individual contributions to team science, and to assign credit and other resources on the basis of those contributions. I do not have specific proposals for how to do this, but I do note that similar issues arise in physics, related to very large experiments (such as particle accelerator experiments and large astronomical instruments), and that it may be possible to adapt best-practices from that context to the biomedical sciences.

Entrepreneurship and Translation.
Translational science is crucial for realizing the public impacts of federal science funding, and it is right for

the NIH to support entrepreneurship and the bench-to-bedside pipeline. Currently, federal law incentivizes institutional recipients of federal grants to commercialize federally funded research, via the Bayh-Dole act, which permits non-profits to hold patents on inventions developed with federal funds. However, there is a gap between development of the underlying technology / intellectual property to the patent stage, and further development of viable commercialization strategies that can attract private funding and ultimately reach consumers.

Moreover, the current risk/reward structure for developing private companies to commercialize research is the same as for other start-ups, where early assessments of long-term market demand determine what IP is commercialized. This does not reflect the past public investment in that IP nor the public benefits of its broad availability. Structures should be developed to permit prolonged incubation under, or in close partnership with, non-profit entities, and the NIH should provide mechanisms for early-stage venture capital funding in cases where public benefit is high but market demand may be insufficient to recover costs. Public investment in later-stage commercialization could be reflected in reduced prices, or preferred pricing for federal buyers (such as Medicare). The existing SBIR and STTR programs are good models for this, but funding levels are very low compared to private capital.

That being said, independent market mechanisms exist for rewarding successful commercialization, and the NIH should maintain its focus on basic science. Ultimately, the need for public support is greater the earlier in the development pipeline. Basic science, with no obvious commercial applications, is where public funding is most justified (as supporting a collective good) and most needed.

Foundational Scientific Exploration.
I fully agree with the NIH's statement on this topic. One particular concern is that, while expert peer review remains the best way to assess the quality of proposals, it can select for relatively safe / conservative projects, especially in a resource-strained environment where reviewers are asked to comment on the likelihood that an award will result in specific benefits. For this reason, the NIH should consider lottery-based funding mechanisms, for high-risk proposals from researchers with an established track record who meet other criteria of quality, such as past research success.

Public Impact.
Public Impact must be assessed holistically, with no expectation that individual projects will result in easily quantified, short-term effects. Instead, the NIH should conceive of itself as supporting a large portfolio of activities that, on the whole, will make a significant public impact over time. The history of scientific research shows that broad support for basic science will yield significant public benefits. Narrow focus on short-term indicators and individual projects, without tolerance for failure (a consequence of risk-taking) or long horizons, will ultimately reduce the public impact of the NIH's investments.

Other Areas.
Overall, scientific researchers should be assessed holistically, with easily quantified measures like citation counts, patents, previous grants, and publications balanced against more subjective and difficult to measure qualities such as creativity, quality of past research, indirect impact, and intellectual humility. This is necessary to properly reward activities such as replications (which are less likely to be cited or published in especially high-status journals, especially when successful), commercialization (which does not show up in citations or publications), risk-taking (which may not have immediate benefits), and highly original contributions that are not immediately recognized as such. However, holistic assessment is often

unstable, and can quickly collapse into either bean-counting or lowered standards. One mechanism to protect against instability is to target grant opportunities for researchers who are especially strong in valuable but difficult to quantify dimensions, and either focus evaluation of proposals on specific criteria or use lottery-based mechanisms to avoid biases.

Thank you for the opportunity to comment.

Sincerely,

Chair, University Committee on Research Policy

Chancellor's Professor and Department Chair
Logic and Philosophy of Science

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: As much as feasible, biomedical research should rely on accepted and standardized methods for experimental design. Such methods should be developed by experts within disciplines, as a partnership between educational institutions and the private sector; these efforts are often coordinated through professional societies. This will enhance reproducibility by standardizing methods and data handling, through supporting disciplinary norms and best practices.

It will be essential for NIH to recognize and reward investments in open infrastructure. Local repositories make outputs like articles, data, and code openly available, with persistent identifiers. The University of Illinois Urbana-Champaign (Illinois) has invested in such infrastructure, including our institutional repository IDEALS and the Illinois Data Bank. These are two examples of efficient and open means to make federally funded research available. They are critical infrastructure, not just in fields where no readily available disciplinary repositories exist. For example, they support reproducibility where the costs of open access publication in commercial journals are prohibitive (and becoming more so). Assessment models that measure and reward the impact of research distributed through these open access repositories can and should be part of processes that assess impact and support rigor.

As a related point, the winners of NIH's recent S-index competition demonstrate growing interest in developing better measures of data-sharing value and impact. NIH should build on this momentum by developing richer measures of dataset value. Download counts are increasingly difficult to interpret as AI agents and automated systems generate substantial repository traffic. Metrics should capture citations, reuse, downstream publications and software/models, FAIRness, and other evidence of scientific impact—and should recognize the institutional infrastructure and professional curation that make such reuse possible.

A supercomputing center, like the National Center for Supercomputing Applications (NCSA), can support reproducible and replicable biomedical approaches by providing version-controlled code, documented computational environments, reproducible/archived workflows and pipelines, containerized software, and persistent storage. These practices will help independently rerun analyses and arrive at the same result. Small research groups may be overburdened if they need to do those things at the group level. Centralized infrastructure makes these practices accessible across disciplines and institutions.

2. Data, Software, and Model Sharing: Academic library data services, such as the Illinois Research Data Service, support researchers in identifying and using the most appropriate data-sharing venue. However, NIH's data-sharing policies encompass data for which no disciplinary repository exists. Domain repositories are also notoriously difficult to sustain and fund over the long term; there will never be a repository for every data type or research area subject to NIH's policies. Universities, including Illinois, make up for this structural gap by investing in library services and infrastructure to provide long-term access, preservation, and curation for data that have no disciplinary repository home.

Principal Investigators should be incentivized to publish original data and software via public repositories, including those maintained by individual institutions. Education and Professional Development of Open Science best practices should be encouraged at all levels of education for students and faculty.

The potential benefits of data sharing include democratization of science and greater access to data. This is especially important for early career scientists or researchers with limited resources. Sharing data in an open way can engage a broader community in research and increase collaborative opportunities.

Some of the measurable indicators can be the number of datasets, software packages, models deposited in recognized repositories, number of downloads. A supercomputer center like NCSA can provide secure data storage and data engineering, mechanisms for metadata standardization, computing environments, software management, etc.

Institutional data repositories are vital infrastructure for the long-term stewardship and reuse of research data (Darragh et al., 2024, Science 385(6714):1174; DOI: 10.1126/science.adr0789). The value of institutional repositories is demonstrable at scale. For example, a dataset in the University of Illinois, Illinois Data Bank, ranks 4th among approximately 45 million datasets indexed by S-index winner, scholarly.data.io. This illustrates the reach and impact that professionally curated institutional repositories can provide and underscores why the infrastructure and expertise supporting them should be recognized as an essential part of the research enterprise.

3. Training and Mentorship: NIH should incentivize non-academic mentors for trainees, including those in non-academic institutions and industry. As part of this, NIH should develop mentor training resources for those in non-academic institutions. This will provide a broader perspective on career options and development.

Measurable indicators could be the number of researchers and students trained, repeat use of training resources, etc.. Implementation approaches should offer tiered training, from introductory computing to advanced AI & HPC workflows. This will broaden access to advanced infrastructure.

4. Collaboration: As research becomes more collaborative, it will be helpful if NIH moves away from using proxies to assess impact. Historically, these proxy measures have included publication counts and journal prestige (e.g. impact factor), which are at best directional, fuzzy indicators. They are widely recognized as poor substitutes for assessing research quality, rigor, and real-world impact. Accordingly, assessing the impact or quality of research using these metrics can incentivize poor research practices, such as rewarding volume over quality, while disincentivizing replication and the adoption of open

research practices that increase impact and rigor.

Metrics that capture citations, reuse, downstream publications and software/models, FAIRness, and other evidence of scientific impact—and the open institutional infrastructure and professional curation that make such reuse possible through library and other services—are better measures of impact.

Similarly, it will be helpful for NIH to make clear that contribution-based credit models, as opposed to author-order driven credit, reflect the very real and deep collaboration that underlies much scientific research and innovation. Contribution-based credit also better supports replication and reproducibility. Metrics should recognize different roles and levels of contribution (not just rely on # of grants or publications). For example, when researchers collaborate with a supercomputer center, the contributions from computational scientists, research software engineers, data scientists, and infrastructure experts are often overlooked in the publication of IP invention disclosures. We need to look into the number and diversity of disciplines, number of new interdisciplinary collaborations, computational/data contributions to publications and funded grants, etc.

NIH should encourage and incentivize programs for academic institutions to partner and collaborate with industry to enhance interdisciplinary innovation. As part of this, NIH should develop template collaboration guides that outline best practices for team science, authorship, data management, sharing and ownership, and handling of intellectual property. Such materials should include guidance on obtaining oversight and administrative approval.

The benefits and unintended consequences of interdisciplinary team science have been studied for large and small teams (e.g., https://journals.plos.org/plosone/article?id=10.1371/journal.pone.0322943). The evidence shows that access to interdisciplinarity and team science improves the diversity of collaboration without impacting a researcher's productivity.

5. Entrepreneurship and Translation: NIH should encourage and incentivize programs for academic institutions to partner and collaborate with industry to enhance interdisciplinary innovation.

Metrics could include the number of invention reports and the number of interdisciplinary creators/inventors on those reports, to an office like Illinois' Office of Technology Management (OTM). OTM protects and licenses intellectual property to bring Illinois innovations to the world. One could also track computational contributions to translational projects and provide access to HPC, AI, data, and technical expertise early in the process.

6. Foundational Scientific Exploration: NIH should encourage the dissemination of all results and outcomes from scientific research, regardless of successful findings.

The Beckman Institute for Advanced Science and Technology at the University of Illinois Urbana-Champaign shows how foundational, high-risk science can be embedded in the academic enterprise. Its model — a theme-organized institute offering seed grants for exploratory interdisciplinary projects, independent postdoctoral fellowships, and shared open-access instrumentation — suggests implementation approaches NIH could scale: institute-based set-asides for no-preliminary-data seed awards; person-based fellowships freeing early-career scientists from PI-defined aims; and physical co-

location of disciplines. Measurable indicators: share of seed projects maturing into extramural awards; new cross-departmental collaborations formed; fellows' time to independent positions; publication of null results; and field-normed novelty metrics tracked alongside citations. Benefits: paradigm-shifting discovery at disciplinary interfaces, faster course correction through published failure, and retention of creative early-career scientists. Unintended consequences to guard against: "risk-washing" of incremental work, metric gaming, and concentration of such institutes at wealthy universities — NIH-funded institute set-asides for MSIs and emerging institutions are essential. Feasibility spans career stages if fellows earn tenure credit for exploratory work and senior investigators face renewal criteria tolerant of partial failure.

7. Public Impact: NIH should encourage the dissemination of academic and private sector partnerships that have led to successful development of clinical innovation, diagnoses, and health therapeutics.

1. Rigor and Reproducibility: NIH should establish the reproducibility of patient-level data linkage as a measurable dimension of research rigor and invest in shared infrastructure that makes reproducible linkage a standard capability rather than a burden each laboratory must shoulder alone.

A frequently overlooked dimension of reproducibility in research that relies on real-world data is whether the same patient population, defined using the same criteria, can be identified consistently across datasets and research teams. Privacy-preserving record linkage (PPRL) makes this measurable. Consistent, de-identified tokens generated from standardized inputs produce linkage that is documentable, independently validatable, and reproducible across research groups, in contrast to ad hoc data pulls in which cohort construction is undocumented and cannot be replicated. This is a proven approach at national scale: Datavant processes roughly 2.2 trillion records for linkage each year and has supported more than 180 clinical trials and observational programs covering over 800,000 patients.

To institutionalize this as a discipline, NIH could require or incentivize a small set of measurable practices: documentation of linkage methodology in study protocols, including the provenance of the real-world data source and the token-generation approach; reporting of false-positive and false-negative match rates and their effect on study conclusions; validation of the linkage method through peer-reviewed publication, performance testing against known datasets, or independent expert review; and use of shared, centrally governed data enclaves built on common data models.

Infrastructure to support this already exists within NIH's own portfolio. The N3C Data Enclave and the All of Us Center for Linkage and Acquisition of Data demonstrate reproducible, harmonized, privacy-preserving linkage at scale, using linkage infrastructure that Datavant provides and governs. NIH could designate them as reference implementations and as a central locus for reproducible-linkage methods. Recognizing this infrastructure also creates a natural set of incentives: NIH could reward documented, validated linkage in application scoring, recognize teams that contribute reusable linkage methods or replication studies conducted on shared enclaves, and engage the research community in selecting data-intensive areas that are ripe for replication.

Because the cost of building linkage infrastructure falls hardest on smaller institutions and early-career investigators, providing reproducible linkage as a centralized, shared service rather than a capability each laboratory must fund is what keeps reproducibility feasible across career stages and institution types. The N3C enclave is an existing example of this shared-service model.

One caution: mandating a single method or platform would risk entrenching incumbent providers and crowding out novel approaches. NIH can avoid this by specifying the reproducibility outcomes it wants, namely documented, validated, auditable, and interoperable linkage, rather than a named technology, keeping the standard method-neutral.

2. Data, Software, and Model Sharing: NIH should reward investment in the privacy infrastructure that makes data sharing compliant and reusable, and should measure the downstream reuse of shared data rather than only its initial deposit.

The barriers to compliant data sharing are rarely philosophical; they are technical and legal. Researchers who want to share data often cannot, because they lack the means to de-identify it at sufficient quality, link it to other datasets in a privacy-compliant manner, or certify that downstream use meets HIPAA's De-Identification Standard. Incentives should therefore reward investment in privacy-enabling infrastructure, not only the act of deposit.

First, NIH should recognize HIPAA Expert Determination as a measurable indicator of data-sharing readiness. Expert Determination is the statistical, risk-based method for certifying that a dataset meets the Privacy Rule's De-Identification Standard, and datasets certified this way can be shared, reused, and linked across institutions without exposing patient identity. NIH could reward this certification as a condition of data-sharing credit. The capacity to perform it already exists in the ecosystem, including Datavant's disclosure-risk analysis practice, which certifies de-identification across dozens of jurisdictions.

Second, NIH should measure downstream reuse rather than deposit alone. A dataset that has been tokenized and linked to other datasets, enabling patient-level follow-up, external validation, or meta-analysis, represents a higher scientific contribution than one that is deposited but never accessed, and it directly serves NIH's interest in enabling validation of results. Reuse of this kind is quantifiable: token-based overlap analyses yield counts of patients matched across datasets. This is established practice; Datavant has tokenized nearly 300 clinical trials to link them to real-world data without unblinding studies or exposing participant identity.

Third, NIH should sustain shared, standardized data infrastructure and hold it up as a benchmark. The N3C model combines electronic health record, imaging, mortality, genomic, Medicare and Medicaid, and social-determinants data, all de-identified and linked through common privacy-preserving infrastructure, as part of an NIH-CMS interagency effort led by NCATS and a reference implementation for the NAIRR pilot. NIH could position it as a reference framework for cross-institutional, disease-area data sharing.

As with reproducibility, feasibility varies across institutions: Expert Determination and high-quality de-identification are unevenly distributed. To keep the incentive from rewarding only the already-capable, NIH should pair it with funded, shared de-identification and linkage services so that a researcher at a

smaller institution can meet the standard without building it alone.

Finally, two consequences to manage. A reuse metric can be gamed through superficial or low-value linkages, and a certification requirement can itself become a barrier if it is treated as a precondition rather than a supported service. NIH should combine quantitative reuse measures with qualitative review of scientific contribution, and fund the shared infrastructure rather than only mandating the standard.

8. Other Areas: We appreciate the opportunity to comment on how to better define, measure, recognize, and incentivize the qualities of modern biomedical research, particularly on the topics of Rigor and Reproducibility as well as Data, Software, and Model Sharing. Datavant supports the Agency's efforts to create measurable indicators and incentives as part of NIH's broader Replication and Reproducibility Initiative and its Plan to Drive Gold Standard Science.

Datavant is the data collaboration platform trusted for healthcare, working with more than 80,000 hospitals and clinics, every health insurance company in the U.S., all 20 of the top 20 pharmaceutical companies, government agencies, and more than 300 real-world data partners. We are a company of health information interoperability, privacy, security, and pharmacoepidemiology experts, on a mission to make the world's health data secure, accessible, and actionable. Through our acquisition of Aetion, we also provide scalable, transparent, and scientifically rigorous analysis of real-world data (RWD), applying causal-inference and epidemiologic methods that support reproducible, auditable research.

Datavant appreciates the Agency's leadership in incentivizing and rewarding rigorous research that delivers value to the American public, and we stand ready to serve as a resource as NIH advances replication and reproducibility.

Please contact us at governmentaffairs@datavant.com.

Thank you.

1. Rigor and Reproducibility: I write from the perspective of a PI performing investigator-initiated clinical research. I have a prior history of basic bench science, but this proposal applies mostly to translational and clinical research.

I propose that NIH lead the way toward UNTETHERING IDEA GENERATION FROM PROTOCOL EXECUTION.

Research HUBS would focus on protocol execution and reproducibility, while SPOKES focus on idea generation and pilot testing.

An Idea Spoke-Execution Hub model would counter the disincentives that drive irreproducibility:

SECRECY: Researchers currently hoard their ideas in secret until they can get funded to actually test those ideas. That day only rarely comes.

CREDIT: Academic credit currently focuses on first/senior-author papers (too easy to achieve in the swamp of crappy publishers) and grant indirects (too difficult to earn in the current funding landscape).

HOLDING THE FORT: Once academic researchers get funded for a particular line of research, they're subconsciously pressured to defend the hypotheses underlying that line of research (and the results of initial experiments) forever. Academia incentivizes us to maintain funding, not to get it right.

PART-TIME: Most academic researchers, myself included, lose research time to clinical, teaching, and/or administrative duties (not to mention frequent grant writing/editing). Less time devoted to research (especially when individual labs with varying levels of experience, resources, and time attempt to execute complicated research protocols) means less focus on research reproducibility.

Academic institutions have invested too much in the irreproducible status quo to lead the way towards necessary change. Hopefully, NIH can lead this effort, like it has done with so many other initiatives over the years.

Research Spokes would be the descendants of current academic research centers. Research Hubs would be regional centers staffed by experienced FULL-TIME RESEARCHERS with well-equipped facilities and

stable rather than cyclical funding. Kind of like the ALLEN INSTITUTE.

Rather than managing all logistical, administrative, and regulatory aspects of taking a project from idea to full translation, Spoke investigators would focus on generating ideas and early-stage testing. This would relieve financial pressure on each Spoke to obtain all the space and equipment necessary for advanced protocol execution, thereby democratizing the idea landscape to give lesser-resourced Spokes a more equal footing.

More importantly, focusing on (and giving sufficient credit for) earlier stage research would also reduce Spoke investigators' incentive to massage data and exaggerate results to survive in the publish-grant-perish model.

This system could also reduce duplicative administrative infrastructures by enabling smaller-sized Grants and Contracts Offices, Offices of Sponsored Research, etc. Therefore, the government's overall bill for indirects would decrease without requiring an overnight imposition of greatly reduced indirect rates.

Meanwhile, Hubs would be freed of the grant hamster wheel and the pressures of academic credit. Stable long-term staffing and greater focus on protocol execution would likely increase efficiency and reliability of sophisticated outcome testing.

For patient stakeholders, participation in clinical trials run by Hubs will be more likely to contribute to reliable progress (and participant travel and lodging could easily be covered by savings on administrative costs).

Obviously, this is an idealized vision. Executing it will be very disruptive and difficult.

There would be far fewer Hubs than Spokes. Academic institutions driven by indirects will obviously oppose giving up any aspects of the current research funding model towards full-time protocol execution Hubs. Conversely, a centralized network of fewer Hubs executing large government-sponsored projects will be more susceptible to political interference.

NIH needs to discuss some key issues with stakeholders:

How to fund Spokes? Whereas the process for funding Hubs seems self-evident, Idea-generators will still need funding for their time and for pilot testing. Inevitably this will be at least partially grant-driven. But ideally, grants would fund people, not projects.

Notably, this model would also push academic institutions to (finally) evolve towards giving credit for SHARING ideas rather than hoarding them in a rarely used file cabinet.

How to develop graduate students and postdocs in this landscape? Presumably, they would still be based at academic Spokes, but perhaps they could each have sponsored years at a Hub as well.

How to protect IP for ideas that eventually succeed in the real world? I am delighted to not have any

expertise or opinions on this key issue.

How, and by whom, would Spoke ideas and preliminary data be vetted for potential Hub execution? One approach could be via depositing ideas into a publicly accessible centralized proposal repository (CPR).

The CPR would function like a “Common App” for college or AMCAS for medical school. It would allow proposal submission at any time (no deadlines). One generalized format. Funders (not just NIH) could search through submissions for proposals matching their missions. If a funder(s) like(s) a proposal, they contact that PI to develop a secondary application (red tape only when necessary).

This would mean one portal for one idea (instead of repackaging ideas across multiple grant mechanisms), no deadlines, less red tape. Applicants would have a larger audience. Funders would have a larger pool of ideas from which to pick.

Unfortunately, Funders would also surely have more spam to sift through. And peer review panels do not currently work on a rolling basis. But this would open up jobs for full-time paid reviewers (hopefully mostly human!?) and thereby free up time spent by excessively burdened volunteer reviewers.

It would be great if NIH would convene a stakeholder meeting to discuss how a pilot Hub might look?

For more detailed expression of some of these arguments, please see past editorials at these PMIDs: 18368097, 30776062, 36113101. Also attached.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

8. Other Areas: Thank you to NIH for understanding the inherently fluid nature of spending research budgets. At the VA, we have great difficulty spending VA research dollars due to impossibly dumb HR practices, as you are surely aware. VA researchers have to use separate nonprofit Foundations to more easily spend non-VA dollars. Most of us would rather go for non-VA than VA grants.

If only the NIH could somehow take over control of VA ORD administrative logistics (not its mission or scope). And if only there were a way to bring some sense into VA research HR and onboarding…I’d be happy to provide some absurd examples, but surely you’re already aware of many. The rumors are true.

VIEWPOINT

Untethering Idea Generation From Protocol Execution in Neurorehabilitation Research

Noam Yehezkel Harel, MD, PhD
Icahn School of Medicine at Mount Sinai, New York, New York; and James J. Peters Veterans Affairs Medical Center, New York, New York.

Proficient conduct of human research is difficult. The difficulty is magnified in neurorehabilitation research; function is difficult to quantify, large numbers of participants are required to distinguish statistically significant effects of an intervention from rates of natural recovery, nonpharmacological interventions garner less industry funding and are harder to apply in a standardized fashion, and so on.[1,2] Overcoming these challenges requires resources and trial experience that are simply not available to most would-be clinician-investigators who have limited protected research time.

As a result, when an investigator has a novel idea but lacks the time or resources to experimentally pursue it, what happens? Often, nothing. To preserve the opportunity for academic credit, the idea is privately hoarded for a future implementation that may never occur. When an investigator with suboptimal experience does get the opportunity to test a novel idea, what happens? Usually, an unreliable pilot study that muddies the field. This writer can attest to the latter scenario through personal experience. Neurorehabilitation studies often suffer from serious flaws in study design, conduction, analysis, and/or reporting.[2,3] It is no surprise that rehabilitation manuscripts have significantly lower odds of acceptance in *Stroke*.[4]

Unexplored ideas and inexpert investigation contribute to a bottleneck in effective clinical translation and a crisis of irreproducible results in neurorehabilitation and beyond. Commendable initiatives like the National Institutes of Health Network for Excellence in Neuroscience Clinical Trials (NeuroNEXT) and StrokeNet are not enough to surmount the immense barriers facing most clinical investigators. To reap more health benefits from basic biomedical advances, clinical research needs radical reengineering.

Ironically, to facilitate greater idea propagation and participation in clinical research, fewer investigators should conduct their own studies. Each investigator should not need to initiate, own, operate, and maintain all aspects of a project to earn full academic credit. Societal resources would be more efficiently used if academic investigators—and their institutions—specialized into complementary roles. Untether idea generation from protocol execution.

Rather than shelve untested ideas or inadequately perform early-stage clinical neurorehabilitation studies, idea generators in a synergistic system would collaborate remotely with experimentalists at high-volume protocol execution hubs. Governments, foundations, and industries will be motivated to generously fund protocol execution hubs, as further outlined below. In this fashion, the best ideas would be tested by the most experienced practitioners at properly equipped and staffed facilities. Investigators at idea-generating and protocol execution hubs would share academic credit. Their institutions would share potential royalties. This would increasingly democratize the scientific enterprise among academics in developing and wealthy countries alike.

Of course, not all biomedical research can or should be dichotomized into idea generation and protocol execution at separate locations. Clinical neurorehabilitation research, with its difficulty in standardizing procedures, would be an obvious place to start. Rather than focusing only on randomized clinical trials, neurorehabilitation protocol execution hubs would be essential for performing reliable early-phase studies—points at which funders make critical decisions on investing further resources.[3] Conducting studies exclusively through regional hubs would increase savings through economies of scale; improve study quality, objectivity, and reliability; and provide multifaceted opportunities for mentoring in protocol execution methodology—goals shared by all stakeholders.

Consolidating protocol execution at high-throughput centers would also reduce competitive recruiting among disparate teams for studies with overlapping inclusion criteria. Instead, potential participants could enlist with protocol execution centers and undergo thorough baseline characterization. They would then be offered participation in studies that best match their inclusion criteria. With suitable washout periods, participants could choose to participate in more than 1 study at the same center. Execution teams would thereby collect multidimensional data and metadata on each participant. Housing a wider selection of studies under one or a few roofs would thus improve experimental reliability and participant equity.

Patients would benefit the most from synergistic specialization in clinical research. A larger crop from which to efficiently harvest the best ideas for testing at the most experienced clinical research centers would make medical progress faster, more reliable, and more impactful. This approach could enhance progress in all medical fields, not just neurorehabilitation.

Talk of reorganizing institutional resources could raise concerns of socialist idealism. Idealist, yes; socialist, no. Rather than imposing a plan from the top down, multiple interesting market-based scenarios could transpire in a synergistically specialized ecosystem. How and by whom would proposals be vetted? How and by whom would idea-generating scholars and their institutions be compensated? Would Uber-like intermediaries arise to match proposals with execution teams? Would career prospects improve for legions of discouraged postdocs and junior faculty? In one envisioned model, investigators would deposit proposals into a publicly accessible centralized repository[5,6]—perhaps bioRxiv could ex-

Corresponding Author: Noam Yehezkel Harel, MD, PhD, James J. Peters Veterans Affairs Medical Center, 130 W Kingsbridge Rd, Ste 7A-13G, New York, NY 10468 (noam.harel@mssm.edu).

Downloaded from jamanetwork.com by Mount Sinai School of Medicine user on 02/19/2019

pand its current scope of archiving completed study preprints. Trial hubs would bid to execute the best proposals. Academic and financial bonuses would be given for meritorious ideas and reproducible study results. Stable contracts underwriting personnel at idea-generating and protocol execution hubs would partially replace cyclical grant writing. This would reduce pressure on investigators to aggrandize or even distort results of premature pilot studies. Market-based interplay between academia, governments, and industries at multiple nodes in this environment could stimulate innovative approaches to technology transfer, a goal of governments and industries around the world.

Talk of unleashing market forces on academia may raise concerns of capitalist idealism and libertarian dystopia. Might disputes arise when similar research designs are enacted in parallel by competing experimental hubs? Yes. But many such disputes already rage today. With broader exchange of ideas independent of execution, disputes would occur in the context of a more transparent system, with financial and academic incentives that better align with the societal imperative of reproducibility.[7]

Inevitably, many academic institutions will resist abandoning aspirations to maintain a full in-house clinical trial apparatus. Most of the academic biomedical community continues to function analogously to brick-and-mortar stores, which fell behind Amazon by stubbornly trying to produce, warehouse, and sell products all by themselves. Forward-thinking retailers prosper by specializing in what they do best without investing massive effort on infrastructure activities they do less well. Likewise, a network of clinical research hubs would provide the optimal platform for the best products (ie, ideas) to be sold (ie, tested).

Gradually, the advantages of institutional specialization and the disadvantages of clinging to an older research model will become more evident. Nonhub institutions would expend fewer resources on administrative overhead and capital. Funders will need to help these institutions revise spending priorities and soften the blow of lost indirect costs. Funds reinvested in teaching, idea development, and mentoring would be far more beneficial than funds wasted on duplicative research administrative duties. This would further incentivize funders to financially support all academic institutions, not just those that become experimental hubs.

Disruption almost never occurs suddenly. Many key aspects of the new research ecosystem have been advancing for years—for example, greater emphasis on research transparency, data reproducibility, and credit attribution for team science.[7] Forward-thinking funders need to play a financially reassuring, decisive role in pushing many institutions to take the next leap of ceding clinical research efforts.

As with so many debates, everyone knows the system for translating biomedical research into clinical advances needs to improve, and everyone has different opinions on how to do so. In neurorehabilitation and beyond, untethering idea generation from protocol execution could allow investigators, institutions, and funders to find common ground for patients' benefit.

1. Rigor and Reproducibility: AERA supports the ongoing efforts that NIH has taken to promote the importance of reproducibility and replication research as part of NIH's research portfolio. Some additional actions that NIH can take to build incentives and provide infrastructure for reproducibility research include:

• Provide funding support for research activities that explicitly support replication and reproducibility studies, as well as secondary data analyses, of prior NIH-funded research. Such activities also could include using technological innovations to develop new methodological approaches for conducting reproducibility and replication studies. These activities would also align with recent priorities from the White House Office of Science and Technology (OSTP) to invest in replication work. To achieve such a rigorous replication research ecosystem, it is also critical to support the foundational research necessary to establish baselines for replication studies.

• Through its positionality, collaborate with scientific societies and academic publishers to pursue strategies to promote publication of research that note null or negative effects for different education and health interventions, including through replication and reproducibility studies. Such studies would be able to describe barriers to implementation among other contexts that may affect replicable results.

• Invest in training and professional development opportunities for graduate students and early career researchers that would promote and develop skills for innovative methods to facilitate replication and reproducibility studies that build upon prior NIH-funded research.

2. Data, Software, and Model Sharing: We appreciate the ongoing work that NIH has undertaken to promote the characteristics of repositories for data sharing that reflect the Findable, Accessibility, Interoperability, and Reuse (FAIR) principles as well as efforts across federal scientific agencies – including NIH – to enable public access to data from federally funded research publications for future use. At the same time, we recognize the challenges and barriers that exist in the broader scientific enterprise, including in education research, to fully facilitate data sharing practices.

Recent research related to the sharing of data in education research has indicated several barriers that include the lack of shared data management frameworks in addition to lack of training on data sharing and concerns on participant identification and being scooped, among other concerns. At the same time,

researchers have noted the importance of developing and maintaining shareable datasets in education research to maximize the value of longitudinal data in important topics such as examining factors that lead to understanding teacher effectiveness.

Even with NIH's efforts to promote and educate the importance of data sharing with NIH-funded researchers, more can be done to recognize the value of how shared data and other products are integrated into future basic and applied research activities:

• Promote the NIH data management and sharing policy and implementation of the FAIR principles, alongside training efforts for peer reviewers, grant applicants, and grant recipients on how NIH's data management and sharing policies should be considered during the review of grant proposals and as a result of funded research.

• Invest in infrastructure to enable the storage and sharing of data from NIH-funded research with considerations of privacy and confidentiality for research involving human subjects. The OSTP Desirable Characteristics of Data Repositories for Federally Funded Research serves as one source of core guidance to develop secure and accessible data repositories.

• Invest in predoctoral and postdoctoral professional development and training to support data sharing – including developing codebooks, incorporating metadata, and ensuring privacy and confidentiality of human subjects.

• Develop procedures that would enable the use of clinical trial data from NIH-funded research under a restricted use basis. Frequently used and cited datasets could be made available for further research use through the National Secure Data Service. Practices undertaken by the National Center for Education Statistics to provide restricted-use access to evaluation data from evaluations conducted by the Institute of Education Sciences could be a model for NIH procedures.

• Recognize the curation and accessibility of NIH-funded datasets through citations of direct object identifiers submitted into data repositories and used in future research.

3. Training and Mentorship: In addition to the training and mentorship opportunities noted previously for rigor and reproducibility and for data, software, and model sharing, NIH is encouraged to undertake activities to examine impact of its own funded training and mentorship opportunities:

• Collaborate with NSF on work Congress authorized under the CHIPS and Science Act to conduct a study examining the impact of different funding mechanisms on graduate student experiences and outcomes, including whether such mechanisms have differential impacts on sub-sets of the student population.

• Develop measures that describe the impact of NIH-funded training and mentorship activities for participants in assessing longitudinal success that include:

o Number of training and mentorship participants.
o Future training and mentorship activities developed or provided by prior participants in NIH-funded training and mentorship activities.

o Linkages between NIH-funded training and mentorship programs and citations and success in receiving future federal research grants
o Recognition for engagement with practitioners, policymakers, and other public audiences in advancing NIH-funded research.

4. Collaboration: We recognize the tradition – even within AERA's own activities – of honoring individual accomplishments and contributions to advancing scientific knowledge. At the same time, researchers increasingly must engage in interdisciplinary partnerships to address complex problems that require different expertise (e.g., disease treatment that requires a deep understanding of both biological/physiological mechanisms and behavioral/social science mechanisms that determine health outcomes). Further, research funding entities may be requiring interdisciplinary teams in ways that do not align with institutional rewards and advancement for "independent" scientific contributions. NIH could serve as a leader in collaboration with the broader scientific community and practice/policy-oriented partners to develop recognitions of high quality, high impact team-based science in work developed through NIH funding.

Such an effort would require consideration of how to recognize both the contributions that individual team members make to knowledge and practice and the synergistic impacts that would not be possible without the team members' collaboration. An additional consideration is how to best assess and honor high-quality team coordination leadership and the infrastructure needed to foster effective, impactful collaboration among teams. This could be an opportunity for NIH to partner with other federal agencies to engage with scholars who are the forefront of interdisciplinary "team science" to understand its value and the different factors that lead to or challenge successful research and its application for societal impacts.

5. Entrepreneurship and Translation: The National Center for Advancing Translational Sciences (NCATS) has as its mission "to transform the translational process so that new treatments and cures for disease could be delivered to patients faster." NCATS funds translational science but could also play a significant role in synthesizing evidence on effective health and education practices that can be produced in accessible formats for practitioners.

As one example, NCATS would be an appropriate partner with NICHD to both support NIH-funded syntheses and to produce evidence-based recommendations in plain language from NICHD-funded research that would support the cognitive and behavioral development of students with intellectual and developmental disabilities. NCATS would have the capability to monitor and track use and adoption of recommendations to assess broader impact of NIH-funded research.

6. Foundational Scientific Exploration: AERA has had a longstanding appreciation for the role that basic and fundamental research has in building the evidence base for its application in evidence-based policy and practice as well as the role that basic research has in generating cumulative knowledge. We encourage NIH to ensure continued investment in basic and fundamental research as it is essential to generating tools, interventions, and strategies that improve health outcomes, including those at the intersection of education.

We recommend that NIH build upon prior research and evidence-based strategies that have shown evidence of effectiveness in incorporating high-risk, high-reward activities within the NIH portfolio. In

addition to ongoing work within the Advanced Research Projects Agency-Health, other federal research agencies are taking steps to implement high-risk, high-reward activities. The Institute of Education Sciences (IES) has funded the first round of Seedlings to Scale, which promotes the development of quick-turnaround high-reward, scalable solutions intended to improve education outcomes for all learners. Seedlings to Scale projects are focused on an identified need with funding conducted in three phases. This is an example of one model that NIH could pursue.

7. Public Impact: NIH could model actions that institutions, including scientific societies, are taking to recognize high-quality translation, synthesis, knowledge mobilization, and other public engagement activities that are results of NIH-funded research:

• The NIH Office of Behavioral and Social Science Research honors a distinguished researcher who has made transformative impact on NIH research as a Matilda White Riley Honoree. A criterion for this honor is conducting "behavioral and social sciences research that improvs the lives of individuals and society." This award is an example that could be a model for similar awards and honors for NIH-funded researchers – either within specific institutes or NIH-wide – that would recognize public impact of NIH-funded research to improving overall societal outcomes.

• As an example from a scientific society, AERA established the Exemplary Contributions to Practice-Engaged Research Award in 2016, which recognizes an education research scholar or scholars in recognition of collaborative project(s) between researchers and practitioners that have had sustained and observable effects on contexts of practice. Recipients of this award have demonstrated impact of their work in connection to the communities with which they conduct research and provide guidance for developing and implementing evidence-based practice. NIH could honor similar connections of researchers with patients, health practitioners, and other communities that use NIH-funded research in their work.

NIH could also incorporate non-publication impact, dissemination, and knowledge mobilization as part of consideration of grants in the peer review process and for highlighting long-term grant success. One resource for assessing public impact that could be a model for NIH from education research is a recent report from IES describing the development and validation of measures for research evidence use, research capacity, and partner experiences with the Regional Educational Laboratories. Constructs that could be applied to NIH-supported research-practice partnerships include usefulness of research evidence, relevance of evidence and services, and accessibility of evidence and services. Additional metrics that NIH could use to measure public impact include:

• The number of people who are served from the interventions, diagnostics, and treatments (among other tools) funded by NIH.

• The number of practitioner-oriented resources (e.g., curricular materials for medical schools, professional development for health practitioners, assessments, evidence-based health and/or education practices) that are developed as a result of NIH investment, along with the number of people using those resources.

• The number of research-practice partnerships that enable intentional connections between basic

health and behavioral research with intermediaries that translate and use research findings in practice. These types of partnerships would help promote continuous improvement among communities of practice and inform practice-informed research questions within basic biomedical and behavioral research.

Bethesda, MD 20817
Comments submitted through NIH website

Re: NOT-OD-26-087, Request for Information on Measuring and Rewarding Scientific Impact

On behalf of the American Educational Research Association (AERA), thank you for the opportunity to provide comments on the Request for Information (RFI) on Measuring and Rewarding Scientific Impact. AERA is the major national scientific association of 22,000 faculty, researchers, graduate students, and other distinguished professionals dedicated to advancing knowledge about education, encouraging scholarly inquiry related to education, and promoting the use of research to improve education and serve the public good. AERA members include NIH principal investigators who receive funding for research on human development and cognition, including from the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), the National Institute of Mental Health (NIMH), and the National Institute on Aging (NIA).

We appreciate NIH's consideration of innovative ways to measure and reward the scientific impact of NIH-funded research. Overall, we encourage NIH to consider investment in professional development activities and infrastructure to educate and promote best practices that would enable assessment and measurement of the impact of NIH-funded research beyond publication citations and patents.

NIH has been a leading federal scientific agency in advancing rigorous research and practices for facilitating public access to NIH-funded research and datasets that are the basis behind research publications. As NIH considers new measures and rewards for scientific impact, AERA also encourages NIH to adopt practices that highlight the public impact of the agency's funded research and to reward public engagement of its work with communities and practitioners that benefit from the application of NIH-funded research. This response reflects the categories included in the online form for comment.

• ***Rigor and Reproducibility***. *Reproducible and replicable biomedical approaches are foundational to rigorous research. New strategies are needed to identify areas ripe for replication and reproducibility efforts, as well as incentives and infrastructure to support the reproduction and replication of existing findings.*

AERA supports the ongoing efforts that NIH has taken to promote the importance of reproducibility and replication research as part of NIH's research portfolio. Some additional actions that NIH can take to build incentives and provide infrastructure for reproducibility research include:

- Provide funding support for research activities that explicitly support replication and reproducibility studies, as well as secondary data analyses, of prior NIH-funded research. Such activities also could include using technological innovations to develop new methodological approaches for conducting reproducibility and replication studies. These activities would also align with recent priorities from the White House Office of Science and Technology (OSTP) to invest in replication work. To achieve such a rigorous replication research ecosystem, it is also critical to support the foundational research necessary to establish baselines for replication studies.
- Through its positionality, collaborate with scientific societies and academic publishers to pursue strategies to promote publication of research that note null or negative effects for different education and health interventions, including through replication and reproducibility studies. Such studies would be able to describe barriers to implementation among other contexts that may affect replicable results.[1]
- Invest in training and professional development opportunities for graduate students and early career researchers that would promote and develop skills for innovative methods to facilitate replication and reproducibility studies that build upon prior NIH-funded research.

• ***Data, Software, and Model Sharing****. Sharing scientific data and tools accelerates biomedical research discovery, in part, by enabling validation of research results, providing accessibility to high-value datasets, and promoting data reuse for future research studies. NIH seeks to incentivize and reward these activities to maximize the value of research investments, catalyze collaborations, and accelerate scientific impact.*

We appreciate the ongoing work that NIH has undertaken to promote the characteristics of repositories for data sharing that reflect the Findable, Accessibility, Interoperability, and Reuse (FAIR) principles as well as efforts across federal scientific agencies – including NIH – to enable public access to data from federally funded research publications for future use. At the same time, we recognize the challenges and barriers that exist in the broader scientific enterprise, including in education research, to fully facilitate data sharing practices.

[1] Kim, J. S. (2019). Making Every Study Count: Learning From Replication Failure to Improve Intervention Research. *Educational Researcher*, *48*(9), 599-607.

Recent research related to the sharing of data in education research has indicated several barriers that include the lack of shared data management frameworks[2] in addition to lack of training on data sharing and concerns on participant identification and being scooped, among other concerns.[3] At the same time, researchers have noted the importance of developing and maintaining shareable datasets in education research to maximize the value of longitudinal data in important topics such as examining factors that lead to understanding teacher effectiveness.[4]

Even with NIH's efforts to promote and educate the importance of data sharing with NIH-funded researchers, more can be done to recognize the value of how shared data and other products are integrated into future basic and applied research activities:

- Promote the NIH data management and sharing policy and implementation of the FAIR principles,[5] alongside training efforts for peer reviewers, grant applicants, and grant recipients on how NIH's data management and sharing policies should be considered during the review of grant proposals and as a result of funded research.
- Invest in infrastructure to enable the storage and sharing of data from NIH-funded research with considerations of privacy and confidentiality for research involving human subjects. The OSTP *Desirable Characteristics of Data Repositories for Federally Funded Research*[6] serves as one source of core guidance to develop secure and accessible data repositories.
- Invest in predoctoral and postdoctoral professional development and training to support data sharing – including developing codebooks, incorporating metadata, and ensuring privacy and confidentiality of human subjects.
- Develop procedures that would enable the use of clinical trial data from NIH-funded research under a restricted use basis. Frequently used and cited datasets could be made available for further research use through the National Secure Data Service. Practices undertaken by the National Center for Education Statistics to provide restricted-use access to evaluation data from evaluations conducted by the Institute of Education Sciences could be a model for NIH procedures.
- Recognize the curation and accessibility of NIH-funded datasets through citations of direct object identifiers submitted into data repositories and used in future research.

• ***Training and Mentorship****. NIH recognizes that advancing its mission requires promoting the growth and stability of the biomedical research workforce. While NIH supports training and protects time through existing policies and programs, additional indicators are needed to assess and quantify the impact of these efforts.*

In addition to the training and mentorship opportunities noted previously for rigor and reproducibility and for data, software, and model sharing, NIH is encouraged to undertake activities to examine impact of its own funded training and mentorship opportunities:

- Collaborate with NSF on work Congress authorized under the CHIPS and Science Act to conduct a study examining the impact of different funding mechanisms on graduate student experiences and outcomes, including whether such mechanisms have differential impacts on sub-sets of the student population.[7]
- Develop measures that describe the impact of NIH-funded training and mentorship activities for participants in assessing longitudinal success that include:
    - Number of training and mentorship participants.
    - Future training and mentorship activities developed or provided by prior participants in NIH-funded training and mentorship activities.
    - Linkages between NIH-funded training and mentorship programs and citations and success in receiving future federal research grants
    - Recognition for engagement with practitioners, policymakers, and other public audiences in advancing NIH-funded research.

• ***Collaboration****. As biomedical research becomes increasingly interdisciplinary and convergent, collaboration is growing in both scale and complexity. NIH seeks new approaches for assessing and recognizing contributions to team-based science.*

We recognize the tradition – even within AERA's own activities – of honoring individual accomplishments and contributions to advancing scientific knowledge. At the same time, researchers increasingly must engage in interdisciplinary partnerships to address complex problems that require different expertise (e.g., disease treatment that requires a deep understanding of both biological/physiological mechanisms and behavioral/social science mechanisms that determine health outcomes). Further, research funding entities may be requiring interdisciplinary teams in ways that do not align with institutional rewards and advancement for "independent" scientific contributions. NIH could serve as a leader in collaboration with the broader scientific community and practice/policy-oriented partners to develop recognitions of high quality, high impact team-based science in work developed through NIH funding.

Such an effort would require consideration of how to recognize both the contributions that individual team members make to knowledge and practice and the synergistic

---

[7] 42 USC 18993(c)

impacts that would not be possible without the team members' collaboration. An additional consideration is how to best assess and honor high-quality team coordination leadership and the infrastructure needed to foster effective, impactful collaboration among teams. This could be an opportunity for NIH to partner with other federal agencies to engage with scholars who are the forefront of interdisciplinary "team science" to understand its value and the different factors that lead to or challenge successful research and its application for societal impacts.

• ***Entrepreneurship and Translation****. To advance the translation of discoveries into products for people, NIH fosters the maturation of discoveries from bench to bedside and promotes innovation across sectors. More can be done to incentivize, assess, and integrate the impact of innovation and entrepreneurial efforts as critical to the NIH mission.*

The National Center for Advancing Translational Sciences (NCATS) has as its mission "to transform the translational process so that new treatments and cures for disease could be delivered to patients faster." NCATS funds translational science but could also play a significant role in synthesizing evidence on effective health and education practices that can be produced in accessible formats for practitioners.

As one example, NCATS would be an appropriate partner with NICHD to both support NIH-funded syntheses and to produce evidence-based recommendations in plain language from NICHD-funded research that would support the cognitive and behavioral development of students with intellectual and developmental disabilities. NCATS would have the capability to monitor and track use and adoption of recommendations to assess broader impact of NIH-funded research.

• ***Foundational Scientific Exploration****. Basic research and high-risk, high-reward initiatives represent foundational scientific exploration with an inherent risk of failure but the potential for paradigm-shifting breakthroughs. Further embedding these approaches within the academic enterprise is essential to ensuring continued support for bold and innovative research directions.*

AERA has had a longstanding appreciation for the role that basic and fundamental research has in building the evidence base for its application in evidence-based policy and practice as well as the role that basic research has in generating cumulative knowledge. We encourage NIH to ensure continued investment in basic and fundamental research as it is essential to generating tools, interventions, and strategies that improve health outcomes, including those at the intersection of education.

We recommend that NIH build upon prior research and evidence-based strategies that have shown evidence of effectiveness in incorporating high-risk, high-reward activities within the NIH portfolio. In addition to ongoing work within the Advanced Research Projects Agency-Health, other federal research agencies are taking steps to implement high-risk, high-reward activities. The Institute of Education Sciences (IES) has funded the first round of Seedlings to Scale, which promotes the development of quick-

turnaround high-reward, scalable solutions intended to improve education outcomes for all learners.[8] Seedlings to Scale projects are focused on an identified need with funding conducted in three phases. This is an example of one model that NIH could pursue.

• ***Public Impact****. NIH seeks approaches for assessing and recognizing the broader public impact of biomedical research, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit.*

NIH could model actions that institutions, including scientific societies, are taking to recognize high-quality translation, synthesis, knowledge mobilization, and other public engagement activities that are results of NIH-funded research:

- The NIH Office of Behavioral and Social Science Research honors a distinguished researcher who has made transformative impact on NIH research as a Matilda White Riley Honoree. A criterion for this honor is conducting "behavioral and social sciences research that improvs the lives of individuals and society." This award is an example that could be a model for similar awards and honors for NIH-funded researchers – either within specific institutes or NIH-wide – that would recognize public impact of NIH-funded research to improving overall societal outcomes.
- As an example from a scientific society, AERA established the Exemplary Contributions to Practice-Engaged Research Award in 2016, which recognizes an education research scholar or scholars in recognition of collaborative project(s) between researchers and practitioners that have had sustained and observable effects on contexts of practice.[9] Recipients of this award have demonstrated impact of their work in connection to the communities with which they conduct research and provide guidance for developing and implementing evidence-based practice. NIH could honor similar connections of researchers with patients, health practitioners, and other communities that use NIH-funded research in their work.

NIH could also incorporate non-publication impact, dissemination, and knowledge mobilization as part of consideration of grants in the peer review process and for highlighting long-term grant success. One resource for assessing public impact that could be a model for NIH from education research is a recent report from IES describing the development and validation of measures for research evidence use, research capacity, and partner experiences with the Regional Educational Laboratories.[10]

1. Rigor and Reproducibility: NIH has already advanced beyond raw publication and citation counts through tools such as iCite and the Relative Citation Ratio (RCR), which provide useful field-normalized indicators of scientific influence. The next opportunity is not to replace these measures with another universal score, but to consider portfolios of contribution that capture how research, resources, people, and collaborations generate downstream scientific and public value.
Rigor, reproducibility, and reuse
NIH should distinguish compliance with reproducibility requirements from evidence that research products are actually reusable or independently replicated. Particularly useful indicators include:
• availability of protocols, analytic documentation, code, metadata, provenance, and versioning; and
• successful reuse, adaptation, or independent replication by researchers outside the originating team.
Independent replication is especially important but often outside the control of the original investigator. NIH could strengthen incentives by supporting dedicated opportunities to replicate influential findings and protocols and by recognizing successful replication as a scientific contribution.

2. Data, Software, and Model Sharing: For datasets, software, models, instruments, and other shared resources, deposit alone should not constitute impact. Greater weight should be given to whether resources are discoverable, documented, maintained, and reused. NIH could also promote minimum metadata and implementation standards that make shared research products easier to compare and adopt.

3. Training and Mentorship: Training outcomes should be assessed longitudinally and should not be reduced to publications or attainment of an independent R01. Relevant indicators could include:
• progression from career-development or pilot support to subsequent research, implementation, collaboration, or funding.
This approach would recognize scientific contribution without assuming that becoming an independent principal investigator is the only meaningful outcome of research training.

4. Collaboration: Coauthorship counts alone are insufficient measures of collaboration. NIH should consider both the structure and consequences of collaborative work. Useful evidence could include:
• formation and persistence of cross-disciplinary or cross-organizational collaborations; and
• documented contributor roles and evidence that methods, data, expertise, or perspectives were

meaningfully integrated.
Network analysis can help identify collaboration patterns, but network breadth should not automatically be interpreted as quality. NIH should also recognize the contributions of connectors, translators, infrastructure builders, and boundary-spanners who enable team science.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: Translation should be evaluated as progression through multiple possible pathways rather than solely commercialization or immediate population-health change. Frameworks such as the Translational Science Benefits Model illustrate how research may generate clinical, community, economic, and policy impacts.
Examples include:
• adoption of research findings, methods, tools, or workflows in clinical, community, organizational, or policy settings; and
• patents, products, partnerships, follow-on funding, cost savings, increased efficiency, or sustained use of research-derived resources.
Follow-on funding and return on research investment can demonstrate leverage and stewardship, but they should not become stand-alone proxies for scientific value. Foundational, qualitative, prevention-oriented, and community-engaged research may produce substantial benefit without generating large near-term financial returns.

6. Foundational Scientific Exploration: N/A

7. Public Impact: It is proposed that a metric be implemented in the review process to assess the beneficial impact both to individuals and society as a whole. This proposed metric follows the methodology of the United Nations' Human Development Index (HDI). For further information on that index, please see https://hdr.undp.org/data-center/human-development-index#/indicies/HDI.

The metric I am proposing in these comments utilizes five factors, beginning with median life expectancy and years of education which are included in the HDI. The poverty rate replaces HDI factor for Income. To these factors, the maternal mortality rate and incarceration rate are added.

The rubric for the proposed metric begins with the percent change expected in the base numbers that could result from the research. These numbers are then normalized to 100% and then combined using the geometric mean, in the same manner as the HDI. Most factors will of course be 1 for most most research. Use of this metric provides a data-driven assessment of human and societal benefit from scientific research.

1. Rigor and Reproducibility: Rigor, reproducibility, replicability and transparency are baseline expectations of all research and scholarship. However, standards and practices that contribute to these essential characteristics, including reporting guidelines, are not always available or in wide use, especially for emerging technologies and disciplines. NIH should support dedicated research studies on the development of reproducible, replicable and transparent approaches in the use of new technology in biomedical and behavioral research, e.g., AI-guided drug discovery, new approach methodologies (NAMs) for drug testing, LLM-guided analysis of electronic health records. Such studies would elucidate how research design and disclosure practices affect the rigor, reproducibility, replication and robustness of research results, improve methodology and reporting, and enable development of rubrics and evidence-based practices for use of new technologies. Supplements to these or other NIH awards could support testing and validation of the practices in different research studies. NIH funding and supplements for these studies would reward the efforts of those who devote energies to developing rigorous research approaches and provide incentives for other researchers to utilize those approaches.

Development of evidence-based practices should be accompanied by support for dissemination and implementation studies, to ensure these practices are translated into active research settings, including academic, industry and clinical sites. Studies that can reveal the barriers and facilitators to rigorous and reproducible research approaches will provide further information on what actions NIH and institutions can take to incentivize these approaches.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: Recipients of NIH training and career development awards will pursue varied career paths, and the appropriate indicators of success and performance metrics for these individuals will vary depending on desired career path. Reflecting this, it has become standard practice to use Individual Development Plans (IDPs) to set personalized outcomes and indicators for graduate students, while training and career development grants require plans for didactic and experiential training to advance stated career objectives. Mentor history is evaluated during grant review, but difficulties in matching outcomes for prior trainees with their career objectives mean success is generally defined after the fact. That is, a former training who remains a research scientist is considered a success, even if they aren't content in their position, weren't well trained for it or if their career path was torturous. This suggests assessing workforce mentorship may require aggregate indicators, where trainee outcomes for programs are judged not only as individual placements but by the mix of career

outcomes and its relation to the stated goals of the program and judged needs of the research ecosystem.

For research training outside of dedicated training grants, inconsistent use of IDPs and adherence to their goals and misalignment of training goals and practices have been identified as persistent challenges. [Coop] NIH could and perhaps should collect outcomes for all trainees supported through its grants and assess PI mentorship readiness in evaluating proposals. However, these issues may reflect a mismatch between the model of a trainee supported by the focused research project of an academic advisor and the career development needs of trainees and workforce training needs of the biomedical research system. Considering alternative models to support research training may better serve NIH's mission of preparing the biomedical research workforce than adding or altering indicators and metrics of research program grants. Models could include institutional training grants offered in partnership with states, regional alliances or industry, such as NSF's pilot Industry-Integrated PhD Program, with indicators established in advance for each training model for both individual trainees, e.g., career placement satisfaction, and the program as a whole, e.g., workforce needs met, local economic stimulus. Any new model or program trial should include support for program evaluation and implementation studies, so that barriers, facilitators and outcomes are identified and tracked.

Even in traditional modes of research training, such as graduate student support through an R grant, NIH support for scholarship of teaching and learning studies applied to research training, scientific mentorship and graduate education would help provide an evidence base for the indicators and metrics that correlate with desired outcomes.

Coop A, Early J, et al. Supporting Research and Graduate Education in a Troubled Landscape: Report of the 2025-2026 AACP Research and Graduate Affairs Committee. Am J Pharm Educ. 2026 Jul 16;90(9):102056. doi: 10.1016/j.ajpe.2026.102056.

4. Collaboration: Recognizing the breadth of and the unique contributions made by different disciplines and research endeavors is critical to activate collaborations and spur innovation. To illuminate the relationships between types of research and enable identification of opportunities for collaboration, the 2024-2025 American Association of Colleges of Pharmacy (AACP) Research and Graduate Affairs Committee developed a unified definition of research and scholarship for pharmacy that captured different research pursuits, e.g., the scholarships of discovery, integration, application, and teaching, while supporting the purposes such a definition would serve, e.g., regulatory and ethical oversight, research impact and career development assessment. [Chahine] Relevant to this RFI, the Committee developed distinct definitions for research and scholarship to capture the broadest range of scholarly activities that should be recognized as advancing or contributing to the body of knowledge and improvement of health and wellbeing.

Both research and scholarship demand high standards of intellectual honesty, methodological rigor, ethical consideration, and transparency and should be subject to peer-review or recognition and publicly shared. Traditional research assessment focuses on basic discovery and the publications, citations and funding that accrue to it. The Committee recognized that scholarship, often centered on practice and including integrative, systemic or scoping reviews, commentaries/editorials, invited lectures/podium presentations, case reports/series, community engagement and real-world studies, is crucial to

translating discoveries to practice and ensuring successful implementation of evidence-based interventions. Scholarship will often represent the collaborative effort of many individuals and organizations spanning research, clinical practice and social engagement. Metrics to capture impact of scholarship can include changes in operating procedure in a clinic or health center due to case reports, numbers of community members who benefit from a public health campaign, or number of patients or cost savings due to a successful implementation study. These metrics are often collected at an institutional level, but individual effort can be assigned and credited. However, traditional research metrics may accord more impact to the outputs of basic or translational science researchers, e.g., publications, than to the work of community liaisons and clinical practitioners, e.g., clinical trial accrual or patient explainers. Both are crucial to project outcomes, though, so that impact may be measured at the project or team level and individual outputs mapped to project outcomes to assess individual contributions.

As research increasingly occurs in the context of collaborations, both near and distant, NIH should recognize the value of scholarship of integration and the key contributions made by research center and community managers, particularly with larger and multidisciplinary teams. NIH should support studies of successful interdisciplinary and interprofessional collaborations to build on the existing evidence base for effective practices in research collaboration management and community engagement. Studies of collaborations would also provide insights into metrics and indicators of successful integration that could be used to assess future research collaborations and provide insight into the conditions under which individual efforts can be recognized and accounted for in the context of collaborations and team science.

Chahine E, Cole J, Ogunsanya M et al. Advancing Research and Scholarship: Report of the 2024–2025 AACP Research and Graduate Affairs Committee. Am J Pharm Educ. 2025 Sep;89(9):101471. doi: 10.1016/j.ajpe.2025.101471. Epub 2025 Jul 20. PMID: 40692110.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: Broader impact of biomedical and behavioral research is already being recognized in faculty evaluations at many institutions and by NIH, e.g., through inclusion in the “Contributions to Science” section of the biosketch. Examples include including regulatory approvals or commercialization of new therapies or technologies, business startups, creation of intervention protocols and their adoption in health care, educational or other settings, and creation of data resources or research tools for use by the research community. In many instances, though, these appropriately capture effort but not necessarily impact. Metrics that rely on counting, e.g., number of patients who are treated with a new product or protocol or number of researchers who access a resource, are valuable but may undervalue innovations in rare diseases or emerging research areas. NIH should support studies of research translation that explore the value and weighting of different indicators of success and impact and how contributions to successful translation can be identified and recognized.

The AACP Research and Graduate Committee has recognized that the education of the public, including policymakers, and clinicians on how to evaluate and use evidence is a core scientific contribution that is frequently underappreciated. [Coop] Although some metrics for evaluating efforts in communication, community engagement and related endeavors exist, e.g., altmetrics including media mentions, social

media footprint and references in policy documents, further development of metrics is needed. NIH should support studies of scientific communications, public health campaigns and community engagement to elucidate measures that go beyond counting contacts or impressions, as valuable as those may be, and indicate positive effects on health outcomes and societal wellbeing.

Coop A, Early J, et al. Supporting Research and Graduate Education in a Troubled Landscape: Report of the 2025-2026 AACP Research and Graduate Affairs Committee. Am J Pharm Educ. 2026 Jul 16;90(9):102056. doi: 10.1016/j.ajpe.2026.102056.

8. Other Areas: Given the considerable interest in research and researcher assessment and the current lack of consensus metrics and indicators beyond traditional bibliometrics and funding, NIH should share its findings through this RFI or follow-on efforts, to help the community identify and investigate those measures that may be pertinent to their own assessment needs.

We appreciate the opportunity to provide comments in response to NOT-OD-26-087, *Request for Information on Measuring and Rewarding Scientific Impact*.

As NIH develops such approaches, we encourage the agency to distinguish between established practices for conducting high-quality research which already exist and measures of scientific impact. Rigor, reproducibility, transparent reporting, appropriate experimental design, and data sharing are essential components of responsible biomedical research and are already reflected in NIH policies and guidance. Rather than creating additional layers of requirements to document these practices, NIH should focus on appropriately recognizing investigators and teams, and the organization's environment and capacity that make meaningful contributions to reproducibility, resource sharing, collaboration, training, translation, and public benefit.

Biomedical advances frequently result from decades of cumulative, collaborative work involving numerous investigators, institutions, funders, and sectors. Models that facilitate sharing of data, methods, resources, and expertise can amplify scientific impact and enable validation and extension of findings. NIH should therefore recognize collaborative infrastructure and shared resources while remaining cautious about assigning a specific economic or health outcome to an individual award or investigator.

NIH has established substantial expectations concerning rigor and reproducibility in grant applications, including consideration of the rigor of prior research (published and unpublished), rigorous experimental design, relevant biological variables, and authentication of key resources. Discipline-specific standards, such as the ARRIVE guidelines for animal research, similarly provide detailed expectations concerning experimental design, statistical analysis, minimization of bias, and transparent reporting. We therefore encourage NIH to build upon and harmonize existing frameworks rather than introduce duplicative requirements. Additional requirements should have a clearly demonstrated benefit and should avoid increasing administrative burden without a corresponding improvement in research quality.

Importantly, reproducibility should not be reduced to a binary indicator or a requirement that every study be independently replicated. NIH could instead recognize meaningful contributions to a reproducible research ecosystem, including:

- publication of sufficiently detailed methods and protocols;
- availability and documented reuse of datasets, software, models, and other research resources;
- development and validation of methods or resources used by other investigators;
- well-designed replication or validation studies, including studies that do not confirm an original finding; and
- adoption of and training in rigorous experimental-design and statistical practices appropriate to the field.

Because judgments about rigor, reproducibility, and scientific impact are inherently field- and context-dependent, NIH should also ensure that review panels include sufficient breadth of scientific, methodological, and statistical expertise to evaluate these dimensions appropriately.

NIH should minimize new reporting requirements. Wherever possible, indicators should be derived from information already available through NIH systems, publications, repositories, persistent identifiers, or other established sources rather than requiring investigators and institutions to create additional reports.

We encourage NIH to pilot proposed indicators before incorporating them into funding decisions and to evaluate those pilots for validity, administrative burden, unintended incentives, and effects across disciplines, career stages, and institution types.

Name: Stanford Program on Research Rigor and Reproducibility (SPORR), , composed of Steven N. Goodman, MD, MHS, PhD, Ruth O'Hara, John Borghi, PhD, and Dr. Mario Malicki, MD, MA, PhD.

Name of Organization: Stanford University

Type of Organization: Not Applicable

Role: Investigator/Researcher

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: The Stanford Program on Research Rigor and Reproducibility (SPORR) is a Stanford School of Medicine hub for promoting and implementing best practices in research rigor and reproducibility (hereafter abbreviated "R&R"). SPORR has been supported by CTSA grants UL1TR003142 and UM1TR004921 (PI: Ruth O'Hara, PhD). Our philosophy is that measurement and rewards, or incentives, cannot just be at the end of the process (e.g. at promotion), but must be embedded at multiple stages throughout a scientific career. And we must build incentives that are aligned with the ultimate purpose of biomedical research, the advancement of human health.

Promotion incentives at Stanford:

1) Our Stanford CTSA SPORR program has developed a new optional Rigor and Reproducibility (R&R) CV template for researchers (https://med.stanford.edu/sporr/rewards/CVTemplate.html) that allows the highlighting of R&R practices, making it possible to evaluate faculty not just on research reports, but on how they do the research. The new additions include listing (and linking) the availability of protocols; analysis plans; analytic code; data; public accessibility of results for research outputs; registration number and result reporting for clinical trials; details of peer review activities; and the candidate's persistent identifier (e.g., ORCIDiD). We also have a list of R&R practices that can be described in a candidate's narrative statement. Details of the template can be found in our recent publication (PMCID: PMC13239307, https://doi.org/10.1111/cts.70575).

We worked closely with the Office of Academic Affairs and Academic Vice Dean to incorporate this CV template into promotion review. This format was enthusiastically received and this coming year we have permission to promote the use of the new CV template amongst department chairs and promotion committees, as well as highlighting the practices in early faculty orientations. This is critical, as the practices highlighted therein need to be adopted early in a research career; a candidate up for promotion cannot go back in time to employ procedures that can be featured on an academic CV.

2) These R&R CV practices are also embedded in the education and training of graduate students, which in turn affects the faculty. This is done via a suite of courses offered to these audiences (some encouraged by the NIH T32 requirements). This year we will try to incorporate reporting on these practices in PhD students' Individual Development Plans (IDP), a formal annual review of progress for

each student that is filled out after a structured meeting with their research advisor. This ensures that both faculty and trainees are continually aware of and accountable for the kinds of practices needed to support R&R, encouraging its incorporation into the normal work flow.

3) SPORR issues annual Rigor and Reproducibility Researcher awards (RaRe) to individuals and teams who have demonstrated the use of R&R practices in a manner that demonstrably accelerates the research process, with a clear connection to improving human health. The list of winners and the reasons for the awards can be found at https://med.stanford.edu/sporr/rewards/RaRe.html.

We have also awarded seed grants for Stanford researchers to improve their R&R practices with support from the Office of the Senior Associate Dean for Research. The first round of these grants has just concluded, and the initial reports are that research processes have been demonstrably improved.

4) We are working with AI scientists to extract open science indicators (e.g., sharing of data, meta-data, code, protocols, statistical analysis plans, etc.) from all published work published by Stanford scientists and developing dashboards that could display them. Furthermore, as part of the effort of our CTSA we are also developing methods to assess the computational reproducibility of research by Stanford scientists.

We are monitoring all corrections and retractions from biomedical publications by Stanford researchers, not as an indicator of problematic research, because these can exemplify laudable self-correction practices, but as the basis for root-cause analyses, so we can see if these arise from scientific or data management procedures that the institution can help improve.

5) We are instituting an institution-wide monitoring program of the fate of all IRB-approved research. This will provide key evidence related to selective reporting. We are initiating a program to encourage all Stanford researchers conducting human subjects research to report the IRB protocol number in their publication, a practice that required by few journals. This will provide the institution, journals, and the funders and ability to confirm that any reported research is an authentic product of research that was actually approved and conducted at an institution. In the current environment where a large and rapidly increasing proportion of biomedical research reports are AI-produced fakes, this could be a critical tool to weed out such false reports, which undermine confidence in the entire enterprise. We are also working with journals to require this reporting.

Part of the Stanford CTSA networking mission is to disseminate across the CTSA Consortium, and it is our goal to do so for these practices.

1. Rigor and Reproducibility: Under half of NIH-funded research articles are reproducible – not because of methodological flaws, but because the datasets needed for the re-analysis are not publicly available*. One cannot check the reproducibility of an article without access to the underlying datasets.

In other words, the biggest single piece of infrastructure supporting 'Rigor and Reproducibility' is the same infrastructure supporting 'Data, Software, and Model Sharing'. Having access to the datasets that underpin an article allows others to begin checking reproducibility, so any actions that improve data and code sharing necessarily improve Reproducibility and Rigor. Analysis code is particularly important: our earlier study (https://peerj.com/articles/1137/) found that reproducibility was much higher when a) author provided their data and code, and b) the code reads in the provided datasets.

Only once researchers' data and code are routinely available alongside NIH-funded articles will other incentives that encourage researchers to test reproducibility of others' work be worthwhile.

*see 'Data, Software, and Model Sharing' section for more explanation

2. Data, Software, and Model Sharing: Step 1 in incentivizing the sharing of datasets, code, and software is monitoring compliance. NIH-funded researchers currently make promises about data sharing in their grant proposals, around half break those promises when the resulting research is published or when the grant ends.

How do we know? DataSeer has the most advanced Open Science monitoring system available, and we supply Open Science metrics to publishers like PLOS, Taylor & Francis, and AAAS, along with funders like the Michael J Fox Foundation and UK Research & Innovation.

Some preliminary results for data and code sharing among 1213 NIH funded articles can be found here:

https://dataseer.ai/nih/

For articles that generate new data, only 48% share any data from their article online. For articles that use command line software (and hence generate shareable code), only 38% share code on an online

repository.

The current absence of compliance monitoring has generated a downward spiral – researchers know that their data sharing is not being monitored, and hence there is no incentive to share data from subsequent articles or subsequent grants. Institutions know that they will continue to receive NIH grant money regardless of their researchers' data sharing efforts and make no effort to promote data sharing.

The widespread availability of compliance monitoring data rapidly inverts this spiral. First, monitoring generates accountability – it is immediately clear which institutions and which researchers are not complying with the data sharing expectations of their NIH grants. Complacency at the institutional level is replaced with action, particularly if the funders themselves gets in touch to ask for an explanation.

Second, monitoring also empowers intervention, as then stakeholders (including the NIH and the grantee institutions) can target their efforts to promote better data and code sharing with the groups that most need help.

Lastly, as pointed out above, the upward spiral in the sharing of research data created by compliance monitoring efficiently enables the NIH to push for and achieve progress towards greater Reproducibility and Rigor.

1. Rigor and Reproducibility: Score rigor from what a paper says, not from where it was published. A Scientific Reasoning Quality Index scores the nine steps of the scientific method, from observation through reporting. At the analysis step, fixed statistical rules do the checking. Does the test match the data type? Does the analysis account for repeated measures on the same animals or cells? Are the reporting elements the field requires present? Those checks need no training corpus, because statistics already fixes the right answer.

Reproducibility needs a reward, so a calibration axis credits a correctly-reported negative result and a candidly-stated limitation as much as a positive finding. Citations accumulate for clean positive results, and that is how nulls get buried and claims get stretched. Crediting honest reporting supplies what citation counts leave out. On feasibility, these scores read the paper text, so they work in any field. Where a literature is thinly indexed, the score comes with lower confidence attached.

2. Data, Software, and Model Sharing: A shared dataset, reagent, or tool is invisible to current metrics unless someone wraps it in a citable paper. A researcher who releases a widely-used resource therefore earns less credit than one who publishes small papers steadily. We propose crediting shared artifacts by how much independent reuse they generate, counting use by people who have never co-authored with the originator, so reuse inside one's own group cannot inflate the number. Credit then follows the use an artifact earns in other laboratories. This needs persistent identifiers and a way to track reuse. Both work well for data and software and less well for physical reagents, so the score reports its coverage rather than pretending to be uniform.

3. Training and Mentorship: Mentorship is hard to measure because the product is a person, not a paper. Doing science means running the scientific method, all nine steps from observation to reporting. A trainee grows as a scientist as they run more of those steps without help. So measure progression toward independent fundability. Track how many steps a trainee executes alone, and track movement toward a body of work a review panel would judge independent. This makes the middle steps visible, meaning design, execution, and analysis. Those are the steps that connect ideas to written results, and many trainees never watch a mentor perform them. A mentor who produces independent scientists then scores above a mentor who produces skilled hands. Because the measure reads change over time rather than total output, it works at every career stage.

4. Collaboration: Team science breaks author-level credit, because a citation counts a paper the same way no matter who did what. A Co-Author Contribution Index credits each author for the scientific-method steps that author actually engaged. It reads contribution structure, not author position and not demographics, so credit follows the distribution of real work. An Independent Recognition Indicator then separates citations from strangers from citations by former collaborators. It computes this per paper and takes the median, so one heavily-cited paper cannot dominate. Both report a distribution rather than a rank, so a researcher with a large network is described, not punished.

5. Entrepreneurship and Translation: Translation matters, and this framework credits it by rewarding methods and tools that other groups adopt. One unintended consequence needs attention. NIH is moving toward holistic, priority-aligned funding. If a measure treats near-term translational appeal as impact, it will over-reward work that pays off soon and cut support for the basic research that later translation depends on. So translational consequence is scored on the same forward-looking axis as foundational consequence, with wide uncertainty and an explicit allowance for work a field has not absorbed yet. Translation gets credit without becoming the only kind of impact the system can see.

6. Foundational Scientific Exploration: This category is the one the framework addresses most directly, and current funding conditions make it urgent. Before NIH stopped publishing cutoffs, institute paylines sat near the 5th percentile. Success rates for R01 grants now run below 8%, and the data are still incomplete. In November 2025, NIH replaced fixed score-based paylines with holistic decisions that weigh how well an application aligns with agency priorities.

Under that combination, scarcity plus priority weighting, review favors work that pays off soon and reads as mission-relevant. Support for deep, slow work then disappears at the priority step rather than at a published cutoff, where nobody can see it happen. Three measurable indicators address this:

A Sleeping-Beauty Trajectory Index scores the chance that a paper will be recognized late. Katalin Karikó's messenger RNA work is the anchor case, since the field ignored it for two decades.
A consequence axis predicts how much a contribution will change the field, and reports that prediction with wide uncertainty. Under the rule that incomputability scores high, work too far ahead of its field is flagged as possibly dormant, not as minor.
A Lifetime Foundational Impact Indicator, scored once at the end of a career, credits origination, delayed payoff, risk-taking, and infrastructure. Annual metrics never measure those things.

The design principle is that evaluation should push against the translational preference the funding system already applies, rather than adding to it. Foundational capacity is also a competitive position. A bipartisan national-security commission has told Congress that China's biotechnology expansion is a direct security concern. Cutting foundational funding degrades an ecosystem of trained scientists, and a competitor cannot rebuild that quickly, so the loss compounds.

CRISPR shows what these indicators would credit. In the late 1980s, federally funded scientists studied strange repeated sequences in bacterial genomes for no applied reason. The National Science Foundation gave Jennifer Doudna's laboratory more than 1.5 million dollars over her career. That work produced the gene-editing methods behind Casgevy, the first CRISPR medicine, approved in December 2023 for sickle cell disease. A metric that treated impact as near-term translational appeal would have

scored the 1990 version of that work low and ended its support. The two-axis design and the delayed-recognition index exist to prevent that outcome.

7. Public Impact: Public impact includes whether the public understands why federally funded research matters, because that understanding is what sustains funding across political cycles. A public-engagement indicator credits substantive research communication and treats it as protection for everything else, not as a vanity score. It measures verifiable engagement with the research and its consequences rather than follower counts. This is the one place the framework credits work outside the paper record. Health outcomes, clinical practice, and economic growth enter through the same forward-looking consequence axis, reported with the wide uncertainty those slow outcomes deserve. Return on public investment belongs here too, and the consequence axis is what lets a review system credit value that arrives late and compounds, rather than only the near-term output a translation-appeal proxy can register.

8. Other Areas: Two design choices apply everywhere. The framework has two arms. One diagnoses, scoring quality that current metrics do not measure. The other sets incentives, using metrics built so that the cheapest way to score well is to do the wanted thing. Every indicator advises human reviewers rather than deciding for them. Human review comes last and handles only what the automated checks cannot reach. Every score arrives with its supporting evidence and a confidence flag, so a reviewer can inspect it and overrule it.

One limit belongs in the record. The consequence axis protects basic research, and it also holds the widest uncertainty in the framework, because at review time contribution magnitude is a prediction rather than a measurement. It is reported with that uncertainty, and it needs both retrospective and forward validation before anyone uses it in a funding or promotion decision.

Measuring and Rewarding Scientific Impact

A Framework of AI-Enabled Indicators for 21st-Century Biomedical Research Assessment

Submitted by Takashi D. Y. Kozai, PhD

Ernest E. Roth Professor of Bioengineering, University of Pittsburgh

Director, B.I.O.N.I.C. Lab and UP NExT (University of Pittsburgh Neural Engineering Cross-Translation)

Date: August 18, 2026

Preface: What This Framework Is Weighed Against

In 1995, the University of Pennsylvania demoted Katalin Karikó. Her grants were unsuccessful and her papers were not cited. Over the next two decades, the messenger RNA chemistry she developed became the COVID-19 vaccines and won the 2023 Nobel Prize. The metrics used at her evaluation predicted failure at the moment her most consequential work was beginning. Her case is not an anomaly in an otherwise sound system. It is one visible instance of a baseline that routinely misvalues the science with the longest payoff. The case for a new framework rests on how bad that baseline is.

The case does not rest on the proposed metrics being good in the abstract. It rests on what they are weighed against. Three observations, taken together, decide whether building this helps or harms.

First, the status quo is not thoughtful human judgment that a flawed metric might displace. Evaluators under time pressure reach for the two most misleading numbers available. One is the raw h-index. The other is a count of papers in high-prestige journals such as Nature, Science, and Cell. The h-index is the largest number h for which a researcher has published at least h papers, each cited at least h times. It is a single figure, and it rewards steady citation accumulation. It also excludes delayed, foundational, and corrective work. Both defaults suppress the slow, foundational, corrective, and exploratory work with the longest eventual payoff. Removing a computable score does not produce careful qualitative evaluation. It produces the h-index. The choice is therefore not metric versus judgment. The choice is which computable default a busy committee reaches for.

Second, and deeper, human committee judgment is itself biased by relationship, and the current system rewards that bias. Outcomes are shaped by who trained whom, who publishes with whom, who sits on study section, and which institution and nation a researcher belongs to. A convenient number is then used to ratify a judgment already made on social grounds. This is the Matthew Effect working through networks, and its errors are not random. They are structured by who you know. Structured errors accumulate across a career and concentrate advantage in the already-advantaged, rather than averaging out the way random noise would. A content scorer reads only what is in the paper. It deliberately excludes the collaboration graph, institutional prestige, and training lineage. That trade replaces structured relationship bias with unstructured noise, which lowers total unfairness across many decisions even when any single score is imperfect.

Third, the bar a new metric must clear is not high absolute accuracy. It has two parts. The metric must predict real contribution better than the h-index does. It must also fail more gracefully, meaning its errors must not fall hardest on foundational, slow, and corrective work, as the incumbent metrics do. The incumbent is a scorer with almost no accuracy for long-term contribution, trusted mainly because habit has made it familiar. Beating that while failing more gracefully is an achievable bar, and it is the bar this framework sets for itself.

Against this baseline, the framework proposes two arms. One arm diagnoses. It scores the content of papers to detect quality the current metrics miss. The second arm sets incentives. Its metrics reward foundational exploration, replication, correction, data sharing, mentorship, public understanding, and lifetime contribution, and they are built so that gaming them produces the behavior the enterprise requires. Many of these incentive reforms need no artificial intelligence at all. They could run on human judgment and verified counts. The AI content scorers are the more powerful layer, and the riskier one.

One risk survives every argument in favor, and it must be stated. A content scorer inherits the biases of its training data. If the relationship-biased system it would replace generates its labels, it will reproduce that bias in a form that is harder to contest, because it looks objective. Whoever controls the scorer's training and calibration would then control scientific careers. The people who benefit from relationship bias now are the senior figures best placed to capture that calibration, and they could use it to confirm the existing hierarchy while appearing neutral. Governance language does not answer that risk. Architecture does. Scorers must be open-source and independently reproducible. The computation must not build lasting dossiers on individuals. No scorer should be deployed unless its training and calibration can be independently audited and reproduced.

The downside is asymmetric, and that shapes how any of this should be deployed. A poorly built or captured content scorer does not fail by doing nothing. It fails by doing harm with false authority. It encodes bias or noise and presents the result as objective computation, which is harder to contest than a human judgment. History warns that the discipline needed to keep such a system advisory is unreliable. Both the h-index and the journal impact factor arrived as one input among many. The impact factor is the average citation rate of a journal's recent articles, and it is widely used as a stand-in for the quality of any single paper published there. Habit and workload then made both of them decisive. A promise to deploy only after accuracy and openness gates are met is therefore not self-enforcing. The gates must be architectural, meaning reproducibility, no lasting dossiers, and network-blindness, rather than procedural assurances. Where a gaming or bias mode cannot be closed, this document names it rather than presenting the metric as sound, so evaluators can weight it appropriately and later work can address it.

The recommendation is deliberate and staged. The incentive-structure reforms are the primary contribution and should come first. Most need no AI and can run on human judgment and verified counts. They credit high-risk work including its failures, replication, correction, verified reuse of data and tools, trainee independence, and, at the end of a career, origination and delayed impact. The content-scoring layer is more powerful and riskier. It warrants deployment only as a gated pilot, and only where the graceful-failure and open-reproducibility preconditions are demonstrably met. If those conditions are not met, it should not be deployed at all. Section 8 states the staged recommendation in full.

The comparison that matters is against the applicable baseline, not an imagined one. Consider deploying a network-blind, gracefully-failing, openly-built scorer alongside long-horizon incentive metrics. That is more likely than not a positive contribution, because it partly dismantles the system that currently converts relationships into judgments and misallocates careers and resources. The contribution is real. The principal risk is capture of the scorer's training, and open, reproducible construction answers that risk better than promises do. This framework should be judged on that comparison, not against a baseline of neutral expert judgment that the evidence does not support.

1. Problem Statement

Current impact metrics count papers and citations for individual researchers. They do not measure what modern biomedical research actually looks like, which is collaborative, long-horizon, and mission-driven. Two failure types occur.

False negatives are work whose impact arrives decades after publication, where short-window indicators cannot see it. Karikó's demotion, described in the preface, is one instance. Tom Brock sampled Yellowstone's thermal pools in 1966 because one question interested him. How could anything live above 70 C? He isolated the microbe Thermus aquaticus. The Taq polymerase from that organism made PCR possible, and PCR in turn made the Human Genome Project possible. Richard Normann built the Utah intracortical microelectrode array at the University of Utah through the late 1980s, with NIH and DARPA support. It sat in academic laboratories for two decades before the BrainGate clinical trials began in 2004. The same architecture now restores speech in patients with ALS, and Pat Bennett reached 62 words per minute in 2023. Carl Sagan published roughly 500 peer-reviewed papers over 39 years, about one a month. Harvard denied him tenure in 1968, and the National Academy of Sciences blocked his 1992 nomination, because colleagues treated his public communication as evidence that he was not a serious scientist.

False positives are volume-first publication patterns. They produce high paper counts without durable contribution. The strategies include single-test analyses, papers that reuse public databases, papers with no primary data, and first-author output above ten papers a year. These accumulate counts that look like productivity while generating nothing the field builds on. The current proxy counts them equally with substantive work.

Both failure modes share one root cause. The metrics are pseudo-metrics, meaning indirect proxies for something no one can observe directly, long-term scientific impact. Using a proxy is not the problem. Mistaking the proxy for the thing is the problem. This proxy excludes delayed translation, deep mechanistic work without translational hooks, failure analysis, replication, and public engagement, and it rewards the gameable volume patterns described above.

The most favorable version of the incumbent does not rescue it. Consider the m-index, which divides a researcher's h-index by the number of years since their first publication. That normalization accounts for career length, so a productive early-career researcher is not penalized against a senior one. It is the closest existing metric to a rate of impact rather than a cumulative count. It still fails on delayed impact, because it depends on citations that have already accumulated. Katalin Karikó's m-index at her 1995 demotion would have been near zero, since her foundational messenger RNA work had not yet been cited. The metric would

have delivered the same verdict the raw h-index did. Normalizing for time does not help when the impact itself is delayed by decades. The failure is not that incumbent metrics ignore career stage. Every citation-based metric, whether cumulative or rate-based, cannot register impact that has not yet arrived.

Funding pressure compounds this failure. NIH funding notices fell from 756 in 2024 to about 120 in 2025, and to 14 by mid-March 2026, with competitive awards down 74%. Under that pressure, principal investigators pursue short-term translational framings and positive results to stay publishable. That shift defunds the deep characterization, failure analysis, and replication that future translation depends on.

Funding pressure has since changed form. In November 2025, NIH moved away from fixed, score-based paylines. Funding decisions are now holistic, weighing how well an application aligns with agency priorities alongside its peer-review score. Before NIH stopped publishing cutoffs, institute paylines sat near the 5th percentile. R01 success rates on incomplete current data run below 8%, down from the low 20s several years earlier. Under a holistic regime the translational preference relocates rather than disappearing. The priority-alignment step rewards payoff that is soon and mission-legible over work whose value is deep but distant. Whatever proxy stands in for impact and priority now determines funding directly. A proxy that treats near-term translational legibility as impact therefore removes support for basic research at the priority-alignment step, where no published cutoff makes the loss visible. Two separated axes address this. A consequence axis predicts contribution magnitude with wide uncertainty, and it scores work the field has not yet absorbed as unresolved rather than as minor. A calibration axis cannot raise the consequence read, so foundational research is not penalized for lacking a near-term application.

Foundational capacity is also a competitive position. Every intracortical brain-computer interface now in human trials rests on neuroscience from the 1990s and early 2000s. United States investment in extending that base slowed while the devices that depend on it remain in clinical use. The durable advantage is the research ecosystem rather than the publication count. That ecosystem means trained scientists, interdisciplinary density, and cross-institutional capacity, and a centralized, state-directed program replicates those slowly. A bipartisan national-security commission has reported to Congress that China's biotechnology expansion presents a direct security concern. An impact measure that reduces foundational funding degrades that ecosystem rather than one budget line, and ecosystem losses take a scientific generation to reverse. Measuring impact so that foundational capacity stays funded is therefore an economic and security question as well as a scientific one.

Venue prestige is the dominant informal proxy in hiring, promotion, and award decisions, and it is decoupling from scientific contribution under two pressures at once. The first is cost. Publishing gold open access in Nature currently costs $12,850, or 9,390 pounds, in article-processing charges, so venue access increasingly reflects institutional wealth and funder policy rather than the quality of the work. United States public-access policy and current grant-cost restrictions are moving to limit whether federal grants can pay those charges. The second pressure is national policy. Some countries have rewarded publication in high-impact venues directly. China offered institutional cash bonuses for Nature and Science papers until 2020, when the Ministry of Education and the Ministry of Science and Technology ordered institutions to stop the practice and to stop evaluating researchers on publication count or venue alone. As

a result, evaluation based on impact factor measures who can pay and which national policy regime a researcher sits inside, not what the work contributes. Indicators that read the paper directly would let hiring, promotion, and award committees evaluate the science rather than the venue. That is among the principal justifications for the framework proposed here.

A deeper problem sits beneath the measurement failures. Study sections reward near-term clinical translation, because it is fundable and demonstrable within a grant cycle. Public sentiment rewards the same thing, because visible cures arrive during the appropriations window that funds them. Both forces push toward the short horizon. Basic and foundational science has the opposite profile, the longest impact horizon and the weakest political constituency. Its payoff arrives after the appropriations cycle, after the administration, and sometimes after the researcher's lifetime. An evaluation system that scores all work on the same near-term axis does not stop at missing foundational science. It systematically under-invests in it, because it adds to a pressure that already over-rewards translation instead of counterbalancing it. Correcting this takes more than better measurement. It takes metrics that actively reward long-horizon, high-risk work whose returns no one can capture privately, which is the work only public funding will ever support.

This response proposes a two-arm framework, responsive to both jobs the RFI names, measuring scientific impact and rewarding it. The diagnostic arm has fourteen top-level AI-enabled indicators that detect quality the existing metrics miss. They score content rather than metadata, through computational analysis of full text and citation networks. Two of the fourteen are meta-indices, the Scientific-Reasoning Quality Index and the Engineering-Method Index, and each composes named step-level sub-indices. The incentive arm has indicators built so that the cheapest way to score high is to perform the wanted behavior, which makes them resistant to the gaming that degrades proxy metrics. This arm leads with foundational and exploration incentives. It ends with career-terminal metrics, scored once and late, that measure what no annual metric measures. Those are the fields a researcher originated, the delayed payoffs realized, the risks taken, the scientific lineage launched, the errors corrected, and the shared infrastructure built across an entire career. The incentive arm should receive heavier evaluative weight than the diagnostic arm, and the foundational and career-terminal metrics within it should receive the most. Weighting long-horizon incentives corrects a standing imbalance toward near-term impact. Only a public funder with a multi-decade mission has the mandate to correct it.

The diagnostic arm is organized into four operational groups. First, foundational-exploration indicators, meaning sleeping-beauty trajectory, mechanism-graph centrality, field-define, and gap. Second, rigor and reasoning indicators, meaning assumption-addressing, the paper-substance score, and two meta-indices. The Scientific-Reasoning Quality Index composes eleven scientific-method step-indices, and the Engineering-Method Index composes six engineering-method step-indices, since much NIH-funded work builds things rather than discovering them. Third, collaboration and integration indicators, meaning cross-field integration, co-author composition, and independent recognition. Fourth, impact-direction indicators, meaning verifiable public engagement, citing breadth, and the data-driven innovation composite. Section 5 specifies the incentive arm.

2. Notation

Throughout this document, p denotes a paper, a denotes an author, and t denotes time, typically a year. The term c(x, y) denotes a citation from x to y, and refs(p) denotes the reference list of p.

AI components are of three kinds, distinguished throughout because they differ in what they require. Rule-based checks have a fixed ground truth and need no training corpus, and the statistical-validity checks are of this kind. Corpus-relational pattern detectors have the existing literature's structure as their ground truth, and they need the corpus for retrieval but no annotation, covering novelty, field-distance, provenance, and design-overlap. Graded scorers map computed features to a scale anchored to the reference-population distribution of those same features, and the meta-index step-indices are of this kind, with structural feature detection and a scale mapping that uses no expert quality-labels. Model architecture is noted where it constrains implementation.

Each standalone indicator reports on the scale native to what it measures. That may be a probability where a probability is interpretable, as with SBTI and DDIC. It may be a field-relative z-score for standing against a reference distribution. It may be a bounded 0-to-1 factor for component scores that combine. Or it may be a raw or log-transformed count where magnitude is informative. These standalone outputs are deliberately not rescaled onto one common band. They feed calibrated committee decisions and an ensemble model rather than a single-number comparison, and forcing a fixed bounded band would compress genuine outliers, discard tail information, and reintroduce the false precision of the one legible index this framework replaces. Preserving native scale and reported uncertainty is more informative than cosmetic uniformity.

One class of indices is an explicit exception. The step-level sub-indices of the two meta-indices, meaning SRQI in Section 3.5 and EMI in Section 3.5E, must be commensurable with one another. A meta-index composite is a committee-weighted average across its step-scores, and an average is coherent only when the terms share a scale. Otherwise whichever sub-score has the largest numeric range dominates the weighting. Each step-index therefore reports on a common anchored 1-to-10 rubric, where 3 is deficient, 7 is solid, and 10 is excellent within the field's normal range. The top is left uncapped, so documented work beyond the field's normal range scores above 10 and the composite average preserves the outlier rather than compressing it. The 1-to-10 anchoring matches the range reviewers already reason in, and the uncapped top keeps a ceiling from flattening the foundational-outlier signal this framework preserves.

3. Indicator Specifications

This section specifies the diagnostic arm, the AI content-scoring layer. Per the recommendation in the preface, this arm is the more powerful and the riskier component and should be treated as a gated, optional experiment, deployed only where the graceful-failure and open-reproducibility preconditions of Sections 6 and 7 are demonstrably met. The incentive-structure reforms of Section 5, most of which require no artificial intelligence, are the primary contribution and do not depend on any indicator in this section being built.

Each indicator section presents seven parts. These are a definition of what the indicator measures, the motivation explaining why current metrics fail at this measurement and what gap the new indicator fills, a mathematical formulation, the AI specification including model architecture and training requirements, numbered implementation steps, failure modes and mitigations, and the RFI category alignment.

One distinction governs how every indicator should be read, and it is the distinction the current metrics collapse. Quality and impact are independent axes.

The quality axis is whether the work was done as science. That means the observation was real, the hypothesis falsifiable, the design controlled, the execution reproducible, the analysis sound, and the reasoning traceable. All six are assessable at publication time from the paper itself. Impact is whether the work eventually changed the field, which is knowable only later and only from what the field does with it. A careful scientist can produce high-quality work that turns out wrong or inconsequential, and careful-but-wrong is still good science, just not consequential science. An incautious one can stumble onto high-impact results through low-quality work.

The scientific-reasoning indices of Section 3.5 and the paper-substance score measure quality, meaning the reasoning was sound at publication. The trajectory and recognition indices, meaning SBTI, IRI, and the citation-structure measures, together with the career-terminal incentives, measure impact, meaning the work mattered over time. Separating the two axes is the point. The current citation-and-venue metrics conflate them, treating eventual citation as if it certified quality and treating quality as if it guaranteed impact, when neither implication holds. The reasoning score must therefore never be read as a claim about truth or importance. It measures only that the work was done as science, which is the most any at-publication metric can measure, and the thing citation and venue do not measure at all.

3.1 Sleeping-Beauty Trajectory Index (SBTI)

Definition.

A sleeping beauty, in bibliometrics, is a paper that goes largely uncited for years or decades and then accumulates citations rapidly once the field catches up to it. This index estimates the probability that a paper will follow that trajectory, computed at publication time from early-trajectory features and content-level scoring rather than waiting for the delayed citations to appear.

Formally, it is the probability that a paper's downstream citation accumulation will exceed a field-specific threshold beyond a horizon Δt years from publication, computed from early-trajectory features and content-level scoring.

Motivation.

Current metrics rely on cumulative citations within a 5-to-7-year window, which dominates h-index calculation (Hirsch 2005) and grant-review evaluation. Karikó's 1995 mRNA chemistry work had near-zero early citation despite eventually founding the COVID-19 vaccine platform, and the current metric system would have predicted her career failure at her 1995 evaluation. The Sleeping-Beauty Trajectory Index fills this gap by scoring publication-time features that predict long-horizon citation accumulation, providing decision-relevant signal during evaluation rather than waiting decades for the citation pattern to emerge.

Formulation.

$$SBTI(p,\ t) = P(\ C(p,\ t + \Delta t) > k \mid F(p,\ t)\ )$$

where $C(p, t + \Delta t)$ is cumulative citations to p by year $t + \Delta t$, k is the 90th percentile of the field-specific citation distribution at the chosen horizon, and $F(p, t)$ is the feature vector at publication time including early citation trajectory shape, mechanism-graph centrality, methodological specificity, and gap-filling status.

AI specification.

A gradient-boosted decision tree or LSTM model, trained on historical late-blooming papers. Training targets come from computed disruption indices rather than human annotation. Those indices measure whether a paper eclipses the prior work it builds on, since a disruptive paper is cited in place of its own references while an incremental one is cited alongside them. The targets are the Funk and Owen-Smith 2017 CD index and the Wu and colleagues 2019 disruption score in Nature, both computed from citation structure. Retrospective validation requires reproducing the late-blooming signal on three papers held out of training, Karikó and Weissman 2005 in Immunity, Brock and Freeze 1969 in J Bacteriol, and Maynard and colleagues 1997 in Electroencephalogr Clin Neurophysiol.

The feature vector combines content-scored inputs with early-trajectory shape. The content-scored inputs are mechanism-graph centrality, methodological specificity, and gap-filling status. The trajectory inputs are citation velocity and citing-field breadth at two and five years. The model predicts the disruption label from these features rather than from author, institution, or venue identity, which are excluded so a prestigious byline cannot lift the score. This index is difficult to game directly, because its target realizes 10 or more years out and its content features depend on other researchers' independent downstream choices rather than on anything the author writes. The only path to a high score is producing work with genuine mechanistic centrality and specificity that later matures. The output is a calibrated probability with a 90% confidence interval.

Implementation.

1. Construct training corpus from Web of Science, OpenAlex, or Microsoft Academic with full-text access.
2. Label papers by disruption score at 20-year horizon (where possible) or by curated panels of foundational and non-foundational exemplars.
3. Extract early-trajectory features at t+2 and t+5 years post-publication.

4. Train model to predict 10-year and 20-year citation accumulation conditional on early features.
5. Apply to new submissions with calibrated probability output and 90% confidence intervals.

Failure mode and mitigation.

The model can over-fit to obscurity itself, generating false positives for unimportant work with low early citation. Mitigation requires joint conditions with mechanism-graph centrality and paper-substance score above field-median thresholds. A paper qualifies as a sleeping-beauty candidate only when low early citation pairs with high content scoring on independent dimensions.

RFI category alignment.

Foundational Scientific Exploration.

3.2 Mechanism-Graph Centrality Index (MGCI)

Definition.

Centrality of a paper's contributed concepts within a knowledge graph of mechanistic relationships extracted from biomedical literature.

Motivation.

Current metrics treat all citations equally, counting a citation to a deep mechanism paper the same as a citation to a translational hook paper. This treats foundational mechanistic characterization as equivalent to shallow translation when in fact the mechanism work is the substrate downstream applications require. The Mechanism-Graph Centrality Index fills this gap by scoring how foundational a paper's contributed concepts are within the knowledge graph of mechanistic relationships, distinguishing structural contributions from incremental elaboration.

Formulation.

$$MGCI(p) = \Sigma \text{ over } c \in Concepts(p) \text{ of } PageRank(c, G_mech) \cdot attribution(p, c)$$

where *G_mech = (V, E)* is the knowledge graph with vertices *V* (mechanistic concepts extracted from full-text papers via biomedical LLM) and edges *E* (causal and dependency relationships extracted from text), and *attribution(p, c)* is the fraction of paper *p*'s contribution to concept *c* (1 if origination, decreasing for elaboration).

AI specification.

A two-stage system. First, a biomedical LLM (BioGPT, PubMedBERT, or domain-tuned successor) performs semantic relation extraction on full text to identify causal and dependency edges between mechanistic concepts. Second, a graph neural network computes centrality with PageRank or eigenvector-centrality variants. Edge extraction uses dependency-parsing plus relation-classification, with confidence thresholds for edge inclusion.

Parameters and thresholds.

Edges enter the graph only above a relation-classification confidence of 0.7. That threshold is set so extraction precision against a held-out gold-reference edge set exceeds 0.8, since a false edge distorts centrality more than a missed one, so precision is favored. The gold reference checks factual extraction correctness, meaning whether the stated mechanistic relation is actually present in the text, rather than any judgment of the relation's importance. PageRank uses the standard 0.85 damping factor over the directed mechanism graph, recomputed quarterly as new papers add edges.

Attribution is set to 1.0 for the originating paper of a concept, and decays for elaborating papers by their semantic distance from the originating definition, so centrality credit concentrates on origination rather than restatement. Paper-level centrality is the sum of attributed centrality across the concepts a paper contributes, field-normalized to a z-score against same-field same-era papers. An audit samples 10% of extracted subgraphs each year against a gold reference, which bounds drift in edge extraction and checks the factual correctness of extracted relations rather than scoring importance. Centrality outputs are reported with confidence intervals derived from edge-confidence propagation.

Implementation.

6. Build candidate concept dictionary from UMLS, MeSH, Gene Ontology, and field-specific ontologies.
7. Run LLM relation extraction across full-text corpus to populate edges with confidence scoring.
8. Compute centrality scores per concept at quarterly intervals.
9. Aggregate concept-level centrality back to papers as their concept-weighted contribution.
10. Update graph as new papers add edges, with concept disambiguation across emerging fields.
11. Calibrate centrality outputs against the NIH-funded reference population stratified by field per Section 3.5.0 Element 4, so a paper's mechanism-graph centrality is scored relative to its own field's connectivity norms rather than a global standard.

Failure mode and mitigation.

Concept extraction errors propagate to graph structure, particularly in emerging fields where terminology has not stabilized. Two steps mitigate this. Audit extraction accuracy each year against a gold reference on a 10% sample of subgraphs, and report confidence intervals on centrality outputs. Flag low-confidence extractions and down-weight them rather than letting a human scorer override them, so the mitigation stays computational and adds no per-paper judgment.

Direct gaming is limited, because a concept's centrality is determined by how the rest of the literature connects to it rather than by anything the author writes, so an author cannot inflate the score by asserting importance. The residual vector is manufactured citation to a coined concept by a coordinated group. That is handled as in the field-define indicator, by weighting concept connections toward independent sources with no co-authorship tie, so within-clique reinforcement does not raise centrality.

RFI category alignment.

Foundational Scientific Exploration.

3.3 Assumption-Addressing Indicator (AAI)

Definition.

A publication-time score of how well a paper identifies an incorrect or unexamined assumption in the prior literature and addresses it, across three modes, demonstrating that a prior approach or premise fails, correcting a wrong assumption directly, or building a new approach past a documented failure. It replaces the separate failure-analysis and corrective-contribution indicators of earlier framework versions, whose cores were the same act viewed two ways, and it scores the quality of the engagement rather than any downstream effect on the field.

Motivation.

Current metrics systematically penalize the work that confronts a field's mistakes. High-impact journals select against negative and corrective findings, and the resulting citation metrics follow, so incorrect assumptions go unexamined and failure modes go uncharacterized. Framing this contribution as field-killing, meaning whether the work ended a line of inquiry, sets the wrong and unmeasurable bar. The right bar is how well the work addresses an incorrect assumption, which is the ordinary and essential mechanism of scientific self-correction, and which no current metric credits. This indicator is deliberately publication-time and corpus-relational. It reads the paper's own engagement with the prior literature rather than waiting on downstream citations, and it credits the common high-value case that pure-correction framing missed, a paper that takes a documented failure and builds a new design past it.

Formulation and AI specification.

This indicator applies the Section 3.5.0 Element 2 machinery to the paper's target assumption, scores three features, and then classifies the mode.

Assumption identification locates a specific assumption, premise, or approach in the same-year-and-prior corpus that the paper treats as incorrect or unexamined. Credit requires showing the assumption was actually present and supported in the prior corpus, rather than characterized as prevailing by the paper itself, which blocks the strawman vector. Confrontation quality scores whether the paper engages that assumption directly with evidence, by testing it, showing where it breaks, or identifying the variable that invalidates it, reusing the conflict-resolution and dogma-engagement machinery, as against asserting the assumption is wrong. Resolution scores what the paper does about it and classifies the mode as one of three. Failure-demonstration shows empirically that the premise does not hold. Correction overturns the assumption with a replacement. Building-past is the therefore-we-tried-this-new-design case, where the paper takes the documented failure as a premise and constructs a new approach.

The building-past mode is first-class, since building forward on a corrected assumption is the common workhorse the field advances on. The strength of the addressed assumption is weighted by its recency and support in the corpus, so confronting a well-supported recent assumption scores above knocking down a fringe one.

Implementation.

12. Extract the paper's target assumption, its confrontation, and its resolution using the Element 1 extraction model.
13. Verify the assumption is actually present and supported in the same-year-and-prior corpus via Element 2 retrieval, weighting by its recency-and-citation support and rejecting assumptions the corpus shows were already doubted.
14. Score confrontation quality by the conflict-resolution and dogma-engagement checks, requiring direct evidence-based engagement rather than assertion.
15. Classify the resolution mode (failure-demonstration, correction, building-past) and score the resolution, crediting building-past as a first-class mode.
16. Map the three features to the score and normalize against the Element 4 reference stratum, reporting the mode alongside the score. The correctness of the challenge is not scored here and is deferred to the career-terminal Assumption-Correctness Indicator (Section 5.4.2).

Failure mode and gaming defense.

Manufacturing a strawman assumption that nobody actually held is the dominant gaming vector. It is blocked because assumption identification uses the corpus support for the targeted assumption rather than the paper's characterization of it, so an assumption the corpus shows was already contested cannot be dressed as prevailing dogma. Framing an ordinary incremental disagreement as addressing a wrong assumption is the second vector, defended by the confrontation-quality requirement of direct evidence-based engagement. One boundary is intrinsic and stated. This indicator measures the quality of the assumption-addressing act, not whether the assumption was in fact wrong, since a paper can confront an assumption well and still be mistaken. Correctness is therefore deferred to the career-terminal metric and to eventual replication.

RFI category alignment.

Rigor and Reproducibility (primary), Foundational Scientific Exploration (secondary).

3.4 Paper-Substance Score (PSS)

Definition.

A composite score of methodological complexity, data novelty, statistical rigor, and primary-data ratio, calibrated to distinguish substantive contributions from volume-first publication patterns.

Motivation.

Current metrics count papers regardless of underlying methodological substance. A paper with a single statistical test on a reused public dataset therefore counts the same as a paper with extensive primary data collection, multiple independent analyses, and rigorous statistical correction.

That produces the volume-first failure mode, where high-output strategies accumulate paper counts, ten or more first-author papers a year, without contributing substantive work the field builds on. This score measures methodological complexity, data novelty, statistical rigor, and

primary-data ratio as content-level features, which distinguishes substantive contribution from publication-velocity gaming.

Formulation.

$$PSS(p) = w_1 \cdot M(p) + w_2 \cdot D(p) + w_3 \cdot S(p) + w_4 \cdot R(p)$$

where *M(p)* is methodological complexity (LLM-evaluated breadth and depth of methods in the Methods section), *D(p)* is data novelty (proportion of dataset newly generated versus reused from public sources or collaborator data), *S(p)* is statistical rigor (number of independent tests, multiple-comparison correction reporting, effect-size reporting, and pre-registration where applicable), *R(p)* is the primary-data ratio (fraction of analyses based on newly collected versus retrieved data), and weights $w_1 \ldots w_4$ are tuned empirically against retrospective disruption signal.

AI specification.

A composite whose four components are computed from structural evidence and fixed rules rather than from a human-labeled quality corpus, so this score detects the volume-first pattern computationally rather than reproducing expert taste.

Data novelty is computed by matching the paper's datasets against public-repository fingerprints and collaborator-data provenance. A reused GEO or dbGaP dataset is therefore detected as reuse regardless of how the methods describe it, and the primary-data ratio follows from the same provenance matching rather than from the paper's self-description. Methodological complexity counts the number and interdependence of distinct experimental or analytic procedures actually executed, which is a structural count from the methods. Statistical rigor reuses the analysis-rigor checks of Section 3.5.8 in full, meaning the test-to-data-type match, dependence-structure and pseudoreplication detection, claim-alignment, and the silence-counts-as-deficiency disclosure audit, rather than re-specifying a weaker parallel version.

The volume-first archetype is a single test on a reused public dataset with no primary collection. It is caught by the conjunction of low data novelty, low primary-data ratio, low methodological complexity, and a thin disclosure profile. None of the four components requires an annotated good-versus-bad training corpus, since each reads provenance, structure, or the fixed rules of statistics. For a theory, review, or perspective paper the primary-data-ratio and statistical-rigor components are not scored, per the analytical-mode specification of Section 3.5A, so a synthesis paper's substance is measured by its gap, novelty, and integration signals rather than penalized for primary-data collection it did not involve.

Implementation.

17. Compute data novelty and primary-data ratio by matching the paper's datasets against public-repository fingerprints and collaborator-data provenance (Element 2 corpus).
18. Compute methodological complexity as the structural count of distinct executed procedures extracted from the methods.
19. Compute statistical rigor by invoking the analysis-rigor checks of Section 3.5.8, reusing that index's output rather than a separate scorer.

20. Combine the four components, publish per-component sub-scores for transparency, and apply PSS as a calibrator across other indicators.
21. Calibrate each component against the NIH-funded reference stratum per Section 3.5.0 Element 4, so substance is scored relative to field norms rather than a global standard.

Failure mode and mitigation.

Engineering a paper to score well without substance is the gaming vector, and the components constrain it because they read provenance and structure. Raising data novelty or the primary-data ratio requires actually generating primary data rather than describing it. Raising methodological complexity requires actually executing more interdependent procedures. Raising statistical rigor requires actually satisfying the Section 3.5.8 checks, including full disclosure. The residual vector is manufacturing apparent methodological complexity through procedures that add count without contribution. Weighting complexity by interdependence rather than raw count mitigates that, as does conjunction with the other components, so complexity without novelty or primary data does not lift the composite. Periodic external audit by an independent bibliometric panel, together with public per-component sub-scores, keeps the composite inspectable.

RFI category alignment.

Cross-cutting calibrator applicable to all RFI categories, with primary alignment to Rigor and Reproducibility and Foundational Scientific Exploration.

3.5 Scientific-Reasoning Quality Index (SRQI), a meta-index over scientific-method steps

Definition.

A meta-index that composes eleven named step-level indices into a reported profile of the scientific reasoning a paper demonstrates. Nine of the eleven correspond to the canonical steps of the scientific method, meaning observation, question, hypothesis, prediction, experimental design, execution, analysis, interpretation, and reporting. Two capture reasoning qualities that cut across those steps and are also scored at the network level by standalone indicators. Those two are gap identification, paired with the Gap Index of Section 3.7, and synthesis, paired with the Cross-Field Integration Index of Section 3.9.

This meta-index stands to its step-indices as the Data-Driven Innovation Composite stands to the diagnostic arm, meaning a composite over independently-specified sub-indices. It is reported as the vector of its eleven step-scores rather than collapsed into a single number.

Motivation.

Current metrics measure the outcome of reasoning, meaning the citations a paper eventually receives, but never the reasoning itself. A paper with rigorous hypothesis structure, adequate controls, and calibrated interpretation is therefore scored identically to a paper with the same eventual citation count and weaker reasoning. Venue prestige operates as the informal proxy for reasoning quality, and venue prestige is decoupling from contribution under the pay-to-play pressures described in Section 1. This meta-index scores the reasoning operations directly from the paper text.

Decomposing into named step-indices rather than a flat multi-component score is deliberate. Each step of the scientific method is a distinct operation that a paper can perform well or poorly independent of the others. Each therefore warrants its own definition, formulation, evidence rubric, and gaming defense, rather than being buried as an unnamed component.

A single collapsed number would reward proximity to one template and homogenize the field toward one reasoning style. Step-level reporting instead preserves the legitimacy of different scientific modes. An exploratory foundational study can score high on gap identification and synthesis while scoring lower on immediate analytic closure.

Formulation.

$$SRQI(p) = (SObs, SGap, SQ, SHyp, SPred, SDes, SExec, SAna, SInt, SSyn, SRep)$$

reported as the vector of the eleven step-indices defined in Sections 3.5.1 through 3.5.11, each on the common anchored 1-to-10 rubric (uncapped above 10 for documented beyond-normal work) specified in the Notation section, with a confidence interval. The common scale is required because the composite is a committee-weighted average across steps, which is coherent only when the steps share a scale. No canonical weighting across steps is specified. Evaluating committees select role-appropriate weights, so a theory-focused search weights question formulation and synthesis while a methods or core-facility hire weights design and execution, which converts the anti-homogenization safeguard (Section 6.7) into a structural feature of the meta-index rather than an external qualification. The composite reports the weighted average alongside the full step vector, never in place of it, and any above-10 step-scores are surfaced so a committee sees where a paper broke the field's normal range.

AI specification (shared across step-indices).

Each step-index is a scorer that keys on the structural evidence the step requires rather than on claim language, field-stratified because step norms differ across experimental, computational, and theoretical work, and outputting the common anchored 1-to-10 score (uncapped above 10) with a confidence interval. The scale is anchored to the reference population, not to expert opinion, so a 7 is the median computed feature value in the field stratum. A 10 is the 95th percentile, and above-10 is beyond the observed range. That score reports where a paper's computed features fall relative to the field's actual distribution of those same features rather than where an annotator judged it to sit. Surface features that are cheap to fabricate (claim phrases, section headers, boilerplate) are held out of every step-index feature set, so the cheapest path to a high score is to perform the operation rather than name it. The step-index specifications below give the step-specific evidence each scorer uses, the feature-to-score mapping, the rubric anchors, and the step-specific gaming defense.

Failure mode and mitigation (meta-index level).

The meta-index inherits the correlation among its steps, since design and analysis co-vary, as do gap identification and synthesis. The composite must therefore report per-step sub-scores and attribute shared signal transparently, rather than presenting correlated steps as independent evidence. Homogenization is addressed by mandatory per-step reporting and committee-selected weighting. Gaming is addressed at the step level, since each step-index requires its own structural evidence, and a paper cannot raise the composite without performing the steps it claims.

RFI category alignment.

Rigor and Reproducibility (primary), Foundational Scientific Exploration (secondary), cross-cutting content calibrator.

3.5.0 Shared Implementation and Calibration Protocol

Every step-index in Sections 3.5 and 3.5E uses the common protocol specified here. Each step section below states only its own features and rubric, and inherits the seven elements defined once here. The components and thresholds named below are starting values, chosen because they can be built today. They are calibratable rather than fixed, and each should be tuned during calibration against the acceptance criteria.

Element 1, unit of analysis and extraction.

The scored unit is the claim, meaning a single asserted empirical or reasoning statement. A paper is broken into its claims before scoring, rather than scored as one undifferentiated whole. A claim-extraction model segments the full text into candidate claims. It tags each claim by type, meaning observation, gap, hypothesis, prediction, design, execution, analysis, interpretation, synthesis, or reporting, and by the section it came from. That model is a fine-tuned long-context transformer, either GPT-4-class or a domain-adapted open model such as a biomedical Llama variant. Each step-index scores only the claims of its own type. The paper-level step-score is then the weighted aggregate of its claim scores, weighted by citation or salience, with the primary claim, meaning the abstract's central assertion, weighted highest. Before scoring proceeds, extraction is validated for boundary agreement, meaning where one claim ends and the next begins. That is a mechanical text-structure task rather than a quality judgment, and it must reach an F1 above 0.80.

Element 2, reference corpus and retrieval.

The reference corpus is OpenAlex, which holds roughly 250 million works under an open license, with abstracts, citation edges, and institution and author metadata. It is mirrored locally for the compute described in Element 7. PubMed supplies biomedical abstracts, and Semantic Scholar supplies citation-context sentences. Retrieval works as follows. Each claim is embedded with a scientific sentence-embedding model, either SPECTER2 or a comparable citation-informed encoder. The system retrieves the 50 nearest prior claims by cosine similarity, and counts as near neighbors those above a cosine threshold of 0.75, tuned per field during calibration. A natural-language-inference model then classifies each neighbor as entailing, contradicting, or neutral to the claim. That model is a fine-tuned DeBERTa-v3 or a biomedical equivalent. A claim counts as already present when any prior neighbor entails it with confidence above 0.85. A claim counts as linked to a gap when a prior neighbor leaves the claim's target open. Field distance is the shortest path between the claim's field and each connected field in the OpenAlex concept co-citation graph, normalized to the distribution of field-pair distances. An embedding-cosine distance is reported alongside it as a robustness check.

Grounding-evidence requirement (applies across all elements).

No step may assign a score by pattern-matching to summary features, surface templates, or presumed absence. Scoring the summary of the evidence, rather than the evidence, repeats the error this framework indicts in the h-index, substituting a countable proxy for the thing

measured. Each score must instead be grounded in the primary evidence its claim rests on. That evidence is emitted and checked before the score issues. Three hard gates follow:

22. A novelty score is invalid unless two things happened. The same-year-or-prior neighbor set of Element 2 was actually retrieved, and its grounding sentences were emitted. Novelty is therefore never asserted from presumed absence of prior work. That is the false-novelty failure the Section 6.8 check catches, prevented here at the scorer's own hand.
23. A fidelity score is invalid unless the scorer examined a sample of the primary data, meaning the traces, waveforms, or images the summary statistics come from, and judged it physically and physiologically plausible. A recording claim therefore earns no credit from yield, signal-to-noise, and amplitude-stability summaries alone, because the underlying waveforms may be non-physiological in shape or may lack refractory-period validation. Sometimes a paper supplies too little primary data to support the claim it makes. That insufficiency is scored as a deficiency rather than assigned to cannot-verify, because the burden of evidence sits with the paper, and an unsupported claim is a shortfall the paper owns. The size of the debit tracks the gap between how strong the claim is and how much evidence supports it. A modest claim on modest data is not penalized, while a categorical claim on the same data is. Cannot-verify is reserved for one narrow case, where the paper contains sufficient evidence but the scorer cannot reach it, for example inside a figure it cannot parse. Even then, cannot-verify caps the fidelity score below what a readable and sufficient artifact would earn. Data that is missing or unreadable can never score as high as data that is present and adequate.
24. A rigor score must first identify how the claim is warranted empirically, then apply the matching rigor criteria. An observationally-warranted claim is therefore scored by observational-rigor criteria. It is not marked deficient for lacking the inferential statistics an experimental claim would require.

These gates prevent one common failure, scoring the summary of the evidence in place of the evidence itself. Each gate names the primary artifact that must exist before its score issues, meaning a retrieved neighbor set, an examined data sample, or an identified warrant. The gates bind every AI-based scoring component in this framework. That includes the SRQI and EMI step-indices, which use this full protocol, and equally the standalone AI indicators that read content against priors, meaning AAI, MGCI, GI, FDI, CFII, VPEI, and the analytical-mode floor. Section 3.15 gives the full enumeration and marks the rule-based boundary. Every one of those components scores by comparing a claim either to prior work or to a rigor standard, so all of them face the same three failure modes, scoring from summary features, presentation-gaming, and prior-poverty in young fields. Each therefore inherits three things rather than reimplementing or omitting them. It inherits the grounding-evidence gates above. It inherits the held-out-feature discipline, which bars a claim's presentation strength from raising its score. And it inherits the always-on adjacent-field prior borrowing and per-claim prior-density weighting of Section 6.9. Defining these guards once and binding them by scope follows the same inherit-once design as the seven elements. It also prevents an indicator from silently omitting a guard the others include.

Gate-contract interface, the build-phase specification every AI metric must instantiate.

Whether a guard runs correctly is settled during the build, and the builder works from this specification. A metric specified only as applying another metric's machinery therefore gets built to whatever local standard the builder infers, which under time pressure is the minimum that returns a number. To stop a gate from being built as a checkbox, every AI-based metric must instantiate a gate contract with four required fields. None may be left blank. A metric with any blank field is not build-ready and is not deployed. The four fields follow:

25. Primary grounding artifact. This names the specific evidence the score must rest on and must emit before the score issues, stated concretely for this metric rather than inherited by reference. For a novelty-bearing metric it is the retrieved prior-neighbor set. For a fidelity-bearing metric it is the examined primary-data sample. For a rigor-bearing metric it is the identified warrant with its checked criteria.
26. Retrieval scope. This names the corpus the metric retrieves against. It must include the target subfield and the adjacent fields reached by the concept-graph path of Element 2. Adjacent-field borrowing is therefore an instruction the builder wires in, not a principle the builder may quietly drop.
27. Held-out features. This lists the presentation and surface signals barred from contributing to the score, given concretely for this metric's content. The rule against presentation-gaming is therefore code the builder writes, not a value the builder is trusted to honor.
28. Per-metric acceptance test. This names the known-outcome cases the built scorer must reproduce before deployment, stated for this metric's own failure mode. A scorer whose gate runs cosmetically then fails its own test rather than passing silently.

The emitted artifact must actually constrain the score, and ablation verifies that it does. A builder can otherwise satisfy the letter of the contract by emitting an artifact the score never uses. So removing or perturbing the artifact must change the score by a stated minimum. A metric whose score does not move when its grounding artifact is withheld has a cosmetic artifact and fails the contract. The acceptance test is the essential field, because it is what detects a contract filled in form but not in function. It has no default and no waiver.

Staged deployment depends on every AI-based metric passing its own acceptance test, not on an aggregate score. An aggregate would let a few well-built metrics offset several cosmetic ones while the composite still scores as acceptable. A metric that fails or omits its acceptance test is disabled rather than shipped. The framework therefore deploys the AI metrics that are real and withholds those that are not, which matches the staged and conditional posture the preface takes toward the framework as a whole. Section 3.15 gives the filled contract for every AI-based metric. Any metric missing from that section is named there as rule-based or constitutive, with its reason. Fixing the boundary between AI-scored and rule-computed metrics in the specification, rather than leaving it to a builder, blocks one evasion, reclassifying an AI metric as rule-based to avoid the gate.

Element 3, feature-to-score function.

Each step-index computes its own feature vector, defined in its section. It then maps that vector to the 1-to-10 score by where the vector sits in the reference-population distribution of the same computed features. The anchors at 3, 7, and 10 are therefore distributional cut points, roughly the lower range, the median, and the 95th percentile of the field stratum. They are not expert-

assigned grades. The mapping needs no human quality-labels, and that is deliberate. A scale learned from expert judgments of what counts as good would reintroduce the relationship-laundering this framework avoids, this time at the calibration step. A scale anchored to the field's own computed feature distribution has no per-paper human input to capture. Some steps have two dimensions, as SObs has fidelity and novelty. Each dimension is percentile-scored separately, and the step-score combines them at a stated weight. That weight starts equal and is adjustable only through transparent governance, never by per-paper tuning. Both dimension sub-scores are reported, so a committee sees the composition. Scores above 10 arise two ways, when a paper's computed features exceed the reference range, and when the incomputability detector each relevant step defines fires. The tail is therefore produced by a stated rule rather than by unbounded model output.

Element 4, calibration across NIH-funded science.

The reference population for normalization is every publication acknowledging NIH funding in the trailing ten years, identified through the NIH acknowledgment and RePORTER linkage. Papers are stratified into fields by primary study-section assignment where that is available, and otherwise by OpenAlex top-level concept, targeting at least 2000 papers per stratum. Within each stratum, the 1-to-10 rubric is anchored directly to the computed feature distribution. A 7 is the stratum median, and a 10 is approximately the 95th percentile of the same features across the reference population. The anchors are therefore read off the distribution rather than estimated from an annotated sample. The rate of above-10 scores is monitored per stratum, and the expected rate is below roughly 2% of claims. A stratum whose rate drifts well above that is re-examined, because drift indicates either miscalibration or a real shift in the field's normal range that the reference distribution must accommodate. Recalibration runs annually against the updated reference population to track changing field norms. Because the anchors are distributional, recalibration is a recomputation rather than a re-annotation.

Element 5, feature-validation protocol.

Feature validity means that a high computed feature value really does track the quality its step names. That validity is established by retrospective outcome-controls rather than by expert annotation. The scorer must reproduce the correct signal on held-out cases whose outcomes are already known. The positive controls are the eventually-vindicated work the preface names, and the negative controls are the volume-first patterns. Features are therefore validated against what the field's later evidence showed, not against what a panel believed at scoring time. This removes the human-label capture surface entirely, and with it the need for rater-bias correction, because there are no annotator judgments to debias. Human judgment enters at one point only, in the small and auditable governance decision of which retrospective cases count as positive and negative controls. That decision is made once and openly rather than per paper, and the control set is published so the validation can be reproduced independently. The acceptance gate is that the scorer recovers the outcome-controls at a stated rate within each field stratum before deployment.

Element 6, validation and acceptance criteria.

A step scorer is accepted only when it clears five gates. First, it must recover the retrospective outcome-controls within each field stratum at a stated rate. That replaces any correlation-with-expert-consensus criterion, since this framework uses no expert consensus scores. Second, it

must pass the graceful-failure gate of Section 7, meaning its errors must not correlate with suppression of historically-vindicated foundational work. That is tested on the retrospective positive controls, Karikó, Brock, and Maynard, and on the volume-first negative controls. Third, its above-10 detector must hold a false-positive rate below 5%. That is measured by open adjudication of flagged incomputability cases against the mundane alternatives, meaning niche subfield, poor indexing, or jargon mismatch, with the procedure and cases published so the check can be reproduced. Fourth, the field-distance signal must be robust under the alternative distance measure, with the two measures agreeing on the ordinal ranking of claims above a rank correlation of 0.8. Fifth, it must pass the grounding-evidence gate stated above, meaning the scorer emitted and checked the primary evidence behind each score, the neighbor set for novelty, the data sample for fidelity, and the identified warrant for rigor, rather than scoring from summary features. A scorer failing any gate is not deployed, per the staged recommendation.

Element 7, compute and data access.

The build needs three things. It needs a local mirror of OpenAlex, on the order of hundreds of gigabytes for metadata and citation edges. It needs precomputed claim embeddings for the reference corpus, meaning billions of claim vectors at the embedding model's dimension, on the order of tens of terabytes, amortized across all step-indices because retrieval is shared. And it needs per-claim inference, whose cost is dominated by the extraction, entailment, and scoring passes. Scoring the full NIH-funded corpus is a batch job over tens of millions of papers with tens of claims each, feasible on a modest GPU cluster over weeks. A pilot on one investigator or a small cohort runs on a single workstation. Author, institution, and venue identity are excluded from every scorer's features at inference, and no lasting per-author dossier is kept, per Section 6.

3.5.1 Observation Quality Index (SObs)

Definition.

The fidelity and novelty of the empirical observations a paper reports. Fidelity combines the precision and the completeness of the reported observation. Novelty measures how far that observation departs from the prior literature and how it connects to it. The index treats observation as the foundational and most differentiating scientific step.

Motivation.

Observation is where genuine discovery most often originates, and it is the step outcome metrics reward least. A citation count cannot tell a paper that reported what it observed from one that saw selectively. This index scores whether observations are reported with the precision, artifact controls, and completeness that let others trust them and build on them.

Formulation and AI specification.

SObs scores two dimensions, both instantiating the shared protocol of Section 3.5.0. The fidelity dimension reads four features from the claim's supporting results and methods. The first is measurement precision, a binary-plus-degree feature for stated units, error bars, and instrument resolution. The second is observational completeness, the ratio of reported to methods-implied measurements, which captures whether negative and off-target observations appear alongside

the positive finding. The third is artifact control, meaning the presence of explicit confound discrimination. The fourth is primary-data plausibility.

The primary-data-plausibility feature examines a sample of the primary data behind the summary statistics, meaning the raw traces, waveforms, or images, and judges it for physical and physiological plausibility. It is a hard gate on the fidelity score, per Section 3.5.0. A neural-recording claim earns credit only when the reported waveforms show physiological action-potential morphology and refractory-period structure, rather than the non-physiological shapes that signal motion artifact. Yield, signal-to-noise, and amplitude-stability summaries can all stay high while the underlying signal is artifact rather than spikes. Sometimes a paper supplies too little primary data to substantiate its recording claim, for example no inter-spike-interval or refractory structure for a single-unit claim. That insufficiency is scored as a fidelity deficiency rather than left neutral, under the burden-on-the-paper rule of Section 3.5.0. This dimension keys on the examined primary data and on the reported measurements with their uncertainty, not on adjectives like careful or rigorous.

The novelty dimension applies the Element 2 retrieval to the observation claim and computes three features. Presence is one minus the maximum entailment confidence over the 50 same-year-or-prior near neighbors, so an observation that any prior neighbor already entails scores near zero novelty regardless of framing. Linkage is the maximum gap-entailment confidence over that same neighbor set, which credits an absent observation addressing a gap or contradiction the prior set actually contains. Distance is the normalized concept-graph path length between the fields the observation connects. Both novelty axes must clear their thresholds. An observation that is absent but unlinked is irrelevant, and an observation that is linked but already present is restatement.

Every relational feature emits the specific prior paper and sentence that produced it, and that emission is a hard gate per Section 3.5.0. No novelty is scored from presumed absence of prior work unless the retrieval ran and its neighbors were checked, and omitting that discipline is what produces false-novelty credit. The presence feature is also down-weighted by the substance score of the nearest prior neighbors. A novelty that exists because the adjacent prior work was too weak to have found the result is therefore discounted.

A dormancy exception modifies the presence feature, so that resurfacing lost prior work is credited rather than penalized. The exception fires when the nearest prior neighbor is old and no longer in the field's working memory. That is measured three ways, by its age, by a dormant citation trajectory with few or no citations in the years before the current submission, and by low retrieval accessibility. The exception also requires that the current paper cites and builds on that neighbor rather than concealing it. The observation is then scored as recovery and extension rather than restatement, because re-establishing a finding the field had lost is a contribution the citation record itself failed to preserve. The discriminating signal separates two cases. A paper that acknowledges the dormant source and builds forward is recovering it. A paper that claims fresh novelty over an actively-cited recent source is running the false-novelty gaming route addressed in Section 6.8.

Implementation.

29. Extract observation claims from the paper using the Element 1 claim-extraction model, tagging each by section of origin and identifying the primary observation from the abstract.
30. Score the fidelity features per observation claim from the results and methods, computing precision, completeness, and artifact-control features.
31. For each observation claim, run the Element 2 retrieval against the OpenAlex same-year-or-prior corpus, using SPECTER2 embeddings with k equal to 50 and a cosine threshold of 0.75. Then run the entailment pass, a DeBERTa-v3-class model with an entailment threshold of 0.85, to compute presence and linkage. Compute the concept-graph path length for distance, and retain the grounding sentences.
32. Map the fidelity and novelty feature vectors to two 1-to-10 sub-scores through the Element 3 ordinal regressions. Combine those sub-scores into the SObs claim-score at the calibrated weighting. Fire the above-10 incomputability detector where the near-neighbor set is sparse or empty and a distant linkage is verified.
33. Aggregate claim-scores to the paper-level SObs by salience weighting, with the primary observation weighted highest. Report the fidelity and novelty sub-scores separately, with confidence intervals and the grounding citations. Normalize against the Element 4 NIH-funded reference stratum for the paper's field.

Failure mode and gaming defense.

An author could pad the results with precise-looking but irrelevant measurements. The defense conditions fidelity on relevance to the stated question, so precision earns credit only for observations bearing on the claim. Completeness is verified separately, by checking whether the methods imply measurements the results omit. A second attack targets the novelty dimension by coining terminology that makes retrieval look sparse. The defense embeds the observation's meaning and judges absence by that meaning and by the cited grounds rather than by surface terms. New words alone therefore do not create apparent novelty.

Observation alone cannot separate a scientist from a fiction writer. An invented off-map observation scores high on novelty and distance as a mathematical consequence. A high SObs is therefore credited as science only when the downstream steps of Sections 3.5.3 through 3.5.11 also hold. High observation score with low downstream signal is the computable signature of overclaiming, and the separately-scored step vector is what exposes it.

Rubric anchors and scale.

On the common rubric, a 3 reports observations without stated precision, uncertainty, or artifact controls, or reports an observation already present in prior work. A 7 reports precise, uncertainty-bounded observations relevant to the claim, with basic artifact control and genuine absence from near-prior work. A 10 reports complete observations with full uncertainty quantification and explicit confound discrimination at the field's best standard, absent from prior work and linked to a real prior gap across a measurable field distance.

A score above 10 is reached two ways. One is measured excellence beyond that range. The other is principled incomputability, meaning the same-year-or-prior near-neighbor set is sparse or empty because the observation opened ground the field had not been standing on. That second route is conditioned on a verified distant linkage, which establishes that the observation

is founding rather than disconnected. Incomputability against the prior corpus is therefore the most informative novelty signal rather than a scoring failure, because founding work is inherently hard to place on a map it created. The above-10 score is a claim about novelty and foundingness only. It says nothing about correctness, which is deferred to the trajectory metrics and eventual replication.

3.5.2 Gap-Identification Index (SGap)

Definition.

The quality and originality of the knowledge gap the paper identifies and targets, scored at the reasoning level within the paper, distinct from the network-level Gap Index (Section 3.7) which tracks gaps across the literature.

Motivation.

Identifying the right gap is the reasoning act that separates consequential questions from incremental ones, and it is invisible to citation metrics. This index scores whether the paper locates a real, explicitly-stated gap and motivates why closing it matters, rather than asserting novelty generically.

Formulation and AI specification.

SGap instantiates the shared protocol of Section 3.5.0. It reads the introduction and discussion for three things. First, an explicit statement of what is unknown. Second, evidence that the gap is real, meaning prior work is cited as leaving it open rather than as having closed it. Third, a stated consequence of closing it. The scorer keys on the logical structure of a gap argument, meaning an unknown, why it matters, and why it is not yet resolved. It does not key on the word novel. This overlaps deliberately with the network-level Gap Index, and Section 3.14 reconciles the two.

Implementation.

34. Extract the gap claim, the cited prior work, and the stated consequence using the Element 1 extraction model.
35. Compute a gap-reality feature by testing, via Element 2 retrieval and NLI, whether the cited prior work is classified as leaving the gap open rather than as having closed it, retaining the grounding sentences.
36. Compute a gap-independence feature by cross-checking the claimed gap against the network-level Gap Index (Section 3.7) for corroboration that others independently treat it as open.
37. Map the features to the 1-to-10 score via the Element 3 ordinal regression and normalize against the Element 4 reference stratum.

Failure mode and gaming defense.

Generic novelty claims are the gaming vector. The defense requires the gap to be tied to specific cited prior work shown to leave it open, so an unsupported claim of novelty scores low, and cross-checks the claimed gap against the network-level Gap Index for independent corroboration.

Rubric anchors and scale.

On the common rubric, a 3 asserts novelty generically with no cited prior work leaving the gap open. A 7 states a specific gap tied to cited work and a stated consequence of closing it. A 10 identifies a narrowly-bounded gap with strong evidence it is real and unaddressed and a compelling stated stake. A score above 10 identifies a gap the field had not recognized as a gap, reframing what is unknown.

3.5.3 Question-Formulation Index (SQ)

Definition.

The falsifiability, scope, and precision of the research question the paper states.

Motivation.

A well-formed question is a precondition for interpretable results, and a vague or unfalsifiable question produces work that cannot be wrong and therefore cannot be informative. The index scores whether the question is specific, answerable, and falsifiable.

Formulation and AI specification.

SQ instantiates the shared protocol of Section 3.5.0 and reads the stated question or aims for three properties. Falsifiability asks whether some outcome would answer the question no. Scope calibration asks whether the question is matched to what the methods can address. Precision asks whether the variables and conditions are specified. The scorer keys on the presence of a falsifiable structure rather than on question phrasing.

Implementation.

38. Extract the stated question or aims using the Element 1 extraction model.
39. Compute a falsifiability feature (is there a stated outcome that would answer the question no), a scope-calibration feature (does the question match what the methods can address, tested by entailment between question and methods), and a precision feature (are variables and conditions specified).
40. Where a preregistration exists, check question-to-registration consistency to detect questions reverse-fit to the results.
41. Map the features to the 1-to-10 score via the Element 3 ordinal regression and normalize against the Element 4 reference stratum.

Failure mode and gaming defense.

Post-hoc question fitting, stating a question the results happen to answer, is the gaming vector. The defense checks consistency between the stated question, the pre-registered aims where available, and the methods, flagging questions that appear reverse-fit to the results.

Rubric anchors and scale.

On the common rubric, a 3 states a vague or unfalsifiable question. A 7 states a specific, falsifiable question matched to the methods. A 10 states a narrowly-scoped falsifiable question whose answer either way is informative. A score above 10 poses a question that opens a line of inquiry rather than closing one.

3.5.4 Hypothesis-Generation Index (SHyp)

Definition.

The clarity of predicted outcomes, the presence of a stated null, and the use of multiple working hypotheses where the domain supports coexisting mechanisms rather than a single strong-inference dichotomy.

Motivation.

Neural interface biology, and much of biomedicine, involves mechanisms that coexist rather than compete. A Chamberlin multiple-working-hypotheses structure therefore often fits better than a Platt strong-inference dichotomy. The index credits explicit, falsifiable predictions. Where appropriate it also credits a structured set of alternatives, rather than a single hypothesis defended against a strawman.

Formulation and AI specification.

SHyp instantiates the shared protocol and scores three features. Novelty applies the SObs Element 2 machinery to the hypothesis claim, testing it against the same-year-or-prior corpus of hypotheses. A hypothesis already stated in prior work therefore scores low novelty regardless of framing, and one that is absent but linked to a real prior gap scores high. An internal-logic feature tests two things, whether the hypothesis follows from the stated gap, and whether each stated alternative includes a distinct predicted observation. Undifferentiated alternatives are not genuine multiple working hypotheses.

The third feature is hypothesis-to-claim alignment, and it is the most sensitive overclaiming detector in this step. It tests whether the hypotheses the paper actually tested are the ones its conclusions are about. A common reasoning failure tests one hypothesis and then concludes about a different claim. An entailment check computes this across the stated hypotheses, the reported tests, and the abstract's conclusions, and it flags a paper whose conclusions are not entailed by the hypotheses it tested. The scorer keys on the logical relations among gap, hypothesis, test, and conclusion, not on the word hypothesis.

Implementation.

42. Extract the hypothesis claims, the stated gap, the reported tests, and the conclusion claims using the Element 1 extraction model.
43. Compute the novelty feature via SObs Element 2 retrieval and entailment against the prior-hypothesis corpus, retaining grounding sentences.
44. Compute the internal-logic feature by testing gap-to-hypothesis entailment and checking that alternatives include distinct predicted observations.
45. Compute the alignment feature by testing whether the conclusion claims are entailed by the tested hypotheses, flagging tested-H-but-concluded-C mismatches.
46. Map the three features to the 1-to-10 score via the Element 3 ordinal regression and normalize against the Element 4 reference stratum.

Failure mode and gaming defense.

Two gaming vectors apply here. Listing token alternative hypotheses that are never distinguished is the first, and the defense requires each stated hypothesis to state a distinct

predicted observation. Stating hypotheses that match the eventual claims while testing something narrower is the subtler one. The alignment feature defends against it by scoring the entailment from tested hypotheses to stated conclusions directly, so a paper cannot raise SHyp by claiming a broad hypothesis while testing a narrow one.

Rubric anchors and scale.

On the common rubric, a 3 states no explicit hypothesis or an unfalsifiable one or draws conclusions unrelated to the hypotheses tested. A 7 states an explicit falsifiable hypothesis with a null whose conclusions align with what was tested. A 10 states a structured set of distinguishable working hypotheses each with a distinct predicted observation and full hypothesis-to-conclusion alignment. A score above 10 formulates a hypothesis, novel against the prior corpus, that reconciles previously conflicting observations.

3.5.5 Prediction-Specificity Index (SPred)

Definition.

The specificity and testability of the concrete predicted observations the paper derives from its hypotheses, treated as a distinct step because a hypothesis without a stated prediction is not falsifiable.

Motivation.

Prediction is the step that converts a hypothesis into something an experiment can confront, and its absence is what lets a hypothesis be defended against any outcome after the fact. The index scores whether the paper states, before the results, what specific observations each hypothesis predicts and what observations would falsify it.

Formulation and AI specification.

SPred instantiates the shared protocol and scores two features. Specificity reads for explicit predicted observations tied to each hypothesis. Those predictions should be quantified where the domain allows, meaning a predicted direction, magnitude, or threshold rather than a vague expectation, and stated before the results rather than inferred from them. The feature scores whether the prediction names a measurable outcome together with a value or a direction.

The second feature is hypothesis linkage, paired with the SHyp alignment feature. It tests whether each prediction follows from a stated hypothesis by logic, computed as an entailment check from hypothesis to prediction. A prediction unconnected to the hypothesis it claims to derive from is not a test of that hypothesis. The scorer keys on the presence of a specific, falsifiable predicted observation logically linked to a hypothesis, not on the word predict.

Implementation.

47. Extract prediction claims and their asserted parent hypotheses using the Element 1 extraction model.
48. Compute the specificity feature by testing whether each prediction names a measurable outcome with a direction, magnitude, or threshold.
49. Compute the hypothesis-linkage feature by the hypothesis-to-prediction entailment, flagging predictions not logically derived from a stated hypothesis.

50. Where a preregistration exists, check prediction-to-registration consistency to detect predictions stated after the results (HARKing).
51. Map the features to the 1-to-10 score via the Element 3 ordinal regression and normalize against the Element 4 reference stratum.

Failure mode and gaming defense.

Stating predictions after seeing the results (HARKing, hypothesizing after results are known) is the gaming vector. The defense compares predictions against any pre-registration. It flags a prediction that matches the results with suspicious specificity when no registered protocol exists. A hypothesis-linkage feature blocks the related move, attaching a well-formed prediction to a hypothesis it does not test.

Rubric anchors and scale.

On the common rubric, a 3 states no specific predicted observation or a prediction not derived from any stated hypothesis. A 7 states a falsifiable predicted observation logically tied to the hypothesis. A 10 states quantified predictions (direction, magnitude, or threshold) distinguishing among alternatives before the results. A score above 10 makes a risky prediction that the field expected to fail and that the data confirm.

3.5.6 Experimental-Design Index (SDes)

Definition.

The adequacy of controls, sample-size justification, blinding, and randomization against the subfield standard.

Motivation.

Design quality determines whether results can support their claims, and it is the step most often asserted rather than demonstrated. The index scores the design against what the question requires.

Formulation and AI specification.

SDes instantiates the shared protocol of Section 3.5.0 and rises only when the scorer locates an actual control condition described in methods and referenced in analysis, an actual power calculation or stated effect-size assumption behind the sample size, and actual randomization or blinding procedures, not the phrases appropriate controls or adequately powered. The comparative standard against subfield norm is a learned per-subfield baseline of each design feature.

Implementation.

52. Extract the described design elements (controls, sample-size basis, blinding, randomization) using the Element 1 extraction model.
53. Score each design feature by presence as structure, so a control counts only when described as a condition and referenced in the analysis, and a power calculation counts only when the computation is present, against the per-subfield baseline of Element 4.
54. Compute the discrimination feature by testing whether the design can distinguish the stated hypotheses (entailment between design and the SHyp hypothesis set).

55. Map the features to the 1-to-10 score via the Element 3 ordinal regression and normalize against the reference stratum.

Failure mode and gaming defense.

Claiming controls without describing them is the gaming vector. The defense requires the claimed control to appear as a described condition that is actually analyzed, and a claimed power calculation to contain the computation, so claim language without structure does not score.

Rubric anchors and scale.

On the common rubric, a 3 lacks described controls or sample-size justification. A 7 has adequate controls, a stated power basis, and appropriate blinding or randomization for the subfield. A 10 has a design that discriminates cleanly among the stated hypotheses at the field's best standard. A score above 10 introduces a design or control that becomes a methodological template others adopt.

3.5.7 Execution-Fidelity Index (SExec)

Definition.

The reproducibility and technique fidelity of the experimental execution as evidenced in the methods, the step that is distributable to trainees or technicians while the work remains science, and the one least directly visible in a written paper.

Motivation.

Execution is step six of the scientific method and the only step that can be delegated without ceasing to do science, but a written paper shows execution only through the traces it leaves in the methods, so the index scores those traces rather than the bench work itself. Poor execution invisible in a paper is a reproducibility failure, and the traces that predict it are underspecified protocols and missing technique detail.

Formulation and AI specification.

SExec instantiates the shared protocol of Section 3.5.0 and scores two features. The essential one is reproducibility-gap detection. For each method described, a checklist model extracts the procedural parameters an independent laboratory would need, and compares them against a reproducibility checklist for that class of method. For a reagent, those parameters are its source, catalog identifier, and concentration. For a protocol step, they are duration, temperature, and equipment setting. For a computational method, they are version, hyperparameters, and random seed.

The reproducibility-gap feature is the fraction of required parameters present. A method that names a reagent without its concentration, or an antibody without its catalog number, therefore scores the gap explicitly. This targets the specific omissions that cause cross-laboratory non-reproducibility, where a reader is left guessing at a value the original laboratory knew but did not report. It does not penalize brevity by itself. The feature applies the same silence-counts-as-deficiency default as the analysis-rigor index of Section 3.5.8, scoring an absent required parameter as not done rather than as unknown, because assuming an unstated step was

performed correctly rewards incomplete reporting. Its required-parameter set is field-calibrated, so a field's genuine reporting convention is not mistaken for a lapse.

The second feature is methods-results consistency, an entailment check. It tests whether the reported data are of the kind and scale the described procedure could actually produce, and it flags results the stated methods could not have generated. The checklist for each method class is the point of calibration. It is populated from existing reporting standards, for example the ARRIVE guidelines for animal work and MIQE for quantitative PCR, together with equivalent community checklists, rather than invented here.

Implementation.

56. Extract each described method and classify it by method class using the Element 1 extraction model, mapping each to its reproducibility checklist.
57. For each method, extract the checklist parameters actually present in the text and compute the reproducibility-gap feature as the present-to-required ratio, retaining the list of missing parameters as the human-checkable output.
58. Run the methods-results consistency entailment (Element 2 NLI machinery) to flag results inconsistent with the described procedure.
59. Map the two features to the 1-to-10 score via the Element 3 ordinal regression, and normalize against the Element 4 reference stratum for the method's field, since reproducibility norms differ across wet-lab, computational, and clinical work.

Failure mode and gaming defense.

Padding the methods with boilerplate detail that does not enable reproduction is the gaming vector. The defense scores presence of the specific checklist parameters that matter for reproduction rather than methods-section length, so verbose but parameter-incomplete methods score low, and the methods-results consistency check catches procedures described but not actually followed. Because the missing-parameter list is emitted, a reviewer can verify each claimed gap against the manuscript rather than trusting the score.

Rubric anchors and scale.

On the common rubric, a 3 provides a protocol too underspecified to reproduce. A 7 provides a protocol reproducible by a skilled peer with the error-prone steps described. A 10 provides a fully reproducible protocol with deposited step-level detail meeting the subfield's best reproducibility standard. A score above 10 establishes a technique or protocol refinement that raises the field's reproducibility baseline.

3.5.8 Analysis-Rigor Index (SAna)

Definition.

Statistical validity is checked as logical consistency and disclosure. Four questions apply. Does the test match the data type? Does the analysis account for the dependence structure of the data? Do the conclusions match what the test measured? Are the reporting elements the field requires present? A required element that is not stated is scored as not done.

Motivation.

Analytic rigor is where many false positives enter, and current metrics reward the positive result rather than the correctness of the analysis that produced it. Any significance claim requires its p value and the correction appropriate to the test count.

Formulation and AI specification.

SAna instantiates the shared protocol of Section 3.5.0 and runs a set of logical-consistency and disclosure checks. Their ground truth is the fixed rules of statistics and the paper's own internal logic, not a human-labeled quality corpus, so the metric detects patterns computationally rather than reproducing expert taste. Four checks determine the score.

A test-to-data-type check reads two things from the methods, the data structure and the named test. The data structure may be continuous, count, categorical, ordinal, time-series, or nested. A statistical rule then verifies that the test matches the data type, and a test applied to a data type it does not fit is flagged as a mathematically-defined error rather than an opinion. A dependence-structure check catches pseudoreplication. It compares the described sampling, for example repeated measures on the same units or multiple cells from the same animals, against how the analysis treated the sample size, and it flags an analysis that treats non-independent observations as independent. A claim-alignment check, run by entailment, tests whether the conclusions are about the quantity the test actually measured, since a common error runs a test on one quantity and states results about another. A disclosure check audits whether the field-required reporting elements are present in the text. Those elements are assumption checks such as normality and variance homogeneity, multiple-comparison correction when the test count requires it, effect sizes, and exact p values.

The disclosure check applies one strict default. A required element that is not stated is scored as not done rather than as unknown. Assuming an unstated safeguard was performed rewards incomplete reporting, and the alternative would force the model to guess at hidden practice it cannot observe. Silence therefore scores as the deficiency. The required-element set is field-calibrated to what that field's rigorous papers actually disclose, so a field's genuine reporting convention is not mistaken for a lapse. Three essential validity elements are never waived for silence, because the validity of the result turns on them, and they are dependence-structure accounting, multiple-comparison correction, and the test-to-data match. Correctly stated caveats about a test's assumptions and their limits raise the score, since a paper that names its assumptions and whether they were met demonstrates the rigor this metric rewards.

Implementation.

60. Extract the data structure, sampling design, named tests, corrections, effect sizes, and p values from the methods and results using the Element 1 extraction model.
61. Run the test-to-data-type check by statistical rule, flagging any test not valid for its data type.
62. Run the dependence-structure check, comparing described sampling against the treated sample size to detect pseudoreplication and unaccounted repeated measures.
63. Run the claim-alignment check by entailment, flagging conclusions asserted about a quantity the reported test did not measure.

64. Run the disclosure audit against the field-calibrated required-element set, scoring each absent required element as a deficiency rather than as unknown, with the essential validity elements never waived for silence.
65. Map the check results to the 1-to-10 score via the Element 3 ordinal regression and normalize against the reference stratum, since reporting norms differ across fields.

Failure mode and gaming defense.

Reporting a correction in the methods but never applying it in the results is one gaming vector. The defense verifies application against the results tables rather than the methods statement, and flags a mismatch between the claimed and the applied correction. Omitting disclosure to dodge the audit is the second vector, and the silence-counts-as-deficiency default blocks it, since saying less scores as the error rather than as unknown. Full disclosure is therefore the dominant strategy.

One honest boundary remains. The checks catch errors visible in the text, meaning a wrong test for the data type, a disclosed nesting treated as independent, and conclusions that do not match the test. They cannot catch an undisclosed confound, or a nesting the methods never mention. The statistical checks are therefore strong where methods are complete and they fail where methods omit the structure. That failure is itself scored, by the disclosure audit here and by the reproducibility-gap feature of the execution index.

Rubric anchors and scale.

On the common rubric, a 3 uses a test mismatched to the data type, treats non-independent observations as independent, or omits required disclosures. A 7 uses appropriate tests with dependence correctly handled, conclusions aligned to what was tested, and the field-required elements disclosed. A 10 additionally reports assumption checks with their outcomes and full sensitivity treatment at the field's best standard. A score above 10 introduces or correctly applies an analytic approach ahead of the field's norm. At every level, unstated required elements are scored as not done.

3.5.9 Interpretation-Calibration Index (SInt)

Definition.

The proportionality of the paper's conclusions to its evidence and the presence of stated alternative interpretations.

Motivation.

Overclaiming beyond the evidence is a common and costly failure that citation counts do not penalize and can even reward. The index scores whether conclusions are calibrated to what the data support and whether alternatives are acknowledged.

Formulation and AI specification.

SInt instantiates the shared protocol of Section 3.5.0. It compares the strength of the stated conclusions against the strength of the evidence the results provide, and it reads the discussion for explicitly stated alternative explanations. The scorer keys on the calibration between claim strength and evidence strength. Honest disclosure of limitations is credited as part of that calibration. A paper that names the specific constraints on its evidence, and qualifies its

essential claims to match, therefore scores higher than one asserting the same claims without the qualification.

The credit attaches to substance rather than to a heading. The mere presence of a limitations section is a held-out surface feature. Only a disclosed limitation that corresponds to a real constraint, and that actually narrows the affected claim, earns the credit, which keeps a boilerplate limitations paragraph from collecting the reward. Calibration is scored for overclaiming and underclaiming alike, so a claim hedged below what its evidence supports is also a miscalibration, though a less harmful one than overclaiming. That keeps the credit from rewarding reflexive hedging rather than accurate self-assessment. The insufficiency debit of the fidelity gate and this calibration credit are the same principle from two sides, the burden of evidence resting on the paper. A categorical claim on thin data is debited by the gate and uncredited here. A modest claim on the same data with honest limitations is spared the debit and earns the credit.

Implementation.

66. Extract the conclusion claims and the evidence each rests on using the Element 1 extraction model.
67. Compute a calibration feature as the entailment gap between conclusion strength and the strength the results actually support, flagging conclusions stronger than their evidence.
68. Compute an alternatives feature crediting explicitly stated alternative explanations tied to distinguishing evidence, not boilerplate hedging.
69. Map the features to the 1-to-10 score via the Element 3 ordinal regression and normalize against the reference stratum.

Failure mode and gaming defense.

Ritual limitations paragraphs that acknowledge alternatives without engaging them are the gaming vector. The defense requires stated alternatives to be tied to specific evidence that would distinguish them, so boilerplate hedging does not score.

Rubric anchors and scale.

On the common rubric, a 3 draws conclusions beyond what the evidence supports. A 7 draws conclusions proportional to the evidence and states alternatives. A 10 calibrates every claim to its evidence and engages alternatives with distinguishing evidence. A score above 10 correctly identifies the broader significance of a result that the narrow data alone would not imply.

3.5.10 Synthesis-and-Integration Index (SSyn)

Definition.

The density of genuine cross-scale and cross-field connection in the paper's reasoning, with verified methodological dependency, scored at the reasoning level and overlapping deliberately with the Cross-Field Integration Index (Section 3.9) and Mechanism-Graph Centrality Index (Section 3.2).

Motivation.

Cross-domain synthesis density is the signature of high scientific reasoning, integrating materials, glial and vascular biology, electrophysiology, neurocomputation, and clinical translation within a single framework, and it is the operation the flat prior version of this index underweighted. This step-index restores it to full status. It scores how many distant domains the paper connects and how densely, not how many it name-checks.

Formulation and AI specification.

SSyn instantiates the shared protocol of Section 3.5.0 and measures the number and distance of domains connected in the paper's own argument and requires methodological dependency (a connected domain's method or concept is actually used in the analysis), reusing the CFII field-distance machinery and the MGCI mechanism graph. The scorer keys on structural dependency between domains, not on citations spanning fields.

Implementation.

70. Extract the domains the paper connects and the methods or concepts it borrows using the Element 1 extraction model.
71. Apply the SObs Element 2 field-distance machinery to measure the distance of each connected domain, and require methodological dependency by a semantic match above 0.6 between the borrowed method and the paper analysis, so listed-but-unused domains do not count.
72. Compute connection density as the count of distance-weighted genuine dependencies, retaining the grounding sentences.
73. Map the feature to the 1-to-10 score via the Element 3 ordinal regression and normalize against the reference stratum, applying the incomputability above-10 rule where a connection has no prior precedent.

Failure mode and gaming defense.

Tokenistic cross-field citation is the gaming vector. The defense requires each connected domain to appear in the paper's analysis with methodological dependency above a 0.6 semantic-match threshold, so listed-but-unused domains do not raise the score. Overlap with CFII and MGCI is reconciled in Section 3.14.

Rubric anchors and scale.

On the common rubric, a 3 connects no domains beyond its own or name-checks them without use. A 7 integrates one adjacent domain's method or concept into the analysis. A 10 integrates multiple distant domains with verified methodological dependency at high connection density. A score above 10 forges a cross-domain connection that opens a new integrative direction, the signature of the highest synthetic reasoning.

3.5.11 Reporting-Transparency Index (SRep)

Definition.

The explicitness and traceability of the causal chain from evidence to conclusion, including data, code, and method availability.

Motivation.

Transparency is what makes a result reusable and checkable, and it is rewarded by no current metric. The index scores whether a reader can trace each conclusion to the evidence and reproduce the path.

Formulation and AI specification.

SRep instantiates the shared protocol of Section 3.5.0 and reads for an explicit traceable chain from evidence to each conclusion, and for data, code, and protocol availability statements that resolve to actual deposited resources. The scorer keys on the presence of a followable chain and on availability statements that verify against real repositories.

Implementation.

74. Extract the evidence-to-conclusion chain and the data, code, and protocol availability statements using the Element 1 extraction model.
75. Compute a traceability feature testing whether each conclusion links to specific reported evidence, and a resource-resolution feature testing whether availability statements resolve to actual accessible deposits (a live check against the named repository).
76. Flag availability statements that do not resolve to a real deposit.
77. Map the features to the 1-to-10 score via the Element 3 ordinal regression and normalize against the reference stratum.

Failure mode and gaming defense.

Data-availability statements that point to nothing are the gaming vector. The defense verifies that availability statements resolve to actual accessible resources, so a statement without a real deposit does not score.

Rubric anchors and scale.

On the common rubric, a 3 leaves conclusions untraceable to evidence and provides no working data or code availability. A 7 provides a traceable evidence-to-conclusion chain and availability statements that resolve to real resources. A 10 provides fully transparent reasoning with complete deposited data, code, and protocols at the field's best standard. A score above 10 sets a transparency or open-resource practice that others adopt.

3.5E Engineering-Method Index (EMI), a meta-index over engineering-method steps

Definition.

A meta-index parallel to SRQI that composes six named engineering-method step-indices into a profile of the engineering reasoning a paper demonstrates. EMI applies to design-and-build work, where the governing process is not observe-hypothesize-test but define, design, prototype, characterize, validate, and iterate, and it is reported as the vector of its six step-scores.

Motivation.

A large fraction of NIH-funded work, including most of neural engineering, is engineering rather than discovery. Scoring an engineering paper on scientific-method steps misjudges it. A device

paper has no hypothesis in the Popperian sense, but it does have a requirement specification, a design-space exploration, and a validation against that specification. SRQI and EMI are separate meta-indices because the scientific and engineering methods are distinct processes with distinct step structures, and conflating them reintroduces the field-mismatch error this framework warns against. Many neural-engineering papers are scored on both, because they do both, characterizing a biological mechanism, which is science, while building and validating a device, which is engineering.

Formulation.

$$EMI(p) = (EReq, EDes, EProto, EChar, EVal, EIter)$$

reported as the vector of the six step-indices defined in Sections 3.5E.1 through 3.5E.6, each on the same common anchored 1-to-10 rubric (uncapped above 10) as SRQI, with a confidence interval, no canonical weighting, and committee-selected role-appropriate weights, so the EMI composite is a weighted average commensurable across its steps.

AI specification and mode selection.

A mode classifier first determines whether a paper is discovery-mode, engineering-mode, analytical-mode, or a combination, reading its aims and methods. Three structural markers drive that choice. The first is generation of new empirical data, whether by experiment or by systematic observation. The second is the presence of a requirement and a validation. The third is the absence of new data in favor of an argument built by integrating prior literature.

Discovery-mode covers two kinds of work. Experimentally-warranted work tests a hypothesis by manipulation and inferential statistics. Observationally-warranted work establishes claims by systematic observation and inference to the best explanation. These are coequal modes of empirical warrant rather than a norm and a lesser exception, so the rigor steps are polymorphic by warrant. SExec, SAna, and SHyp apply experimental-rigor criteria to experimentally-warranted claims, meaning statistical validity, control conditions, and hypothesis-test structure. They apply observational-rigor criteria to observationally-warranted claims, meaning sampling adequacy, observer and instrument bias controls, marker or measurement specificity, reproducibility of the observation, and whether the inference actually ruled out the alternatives.

An observational paper is therefore scored by the standard its own warrant sets, and it is not marked deficient for lacking inferential statistics. Brock 1969, one of this framework's positive controls, is observational natural history with no controlled experiment and no statistics. A discovery mode presuming the hypothesis-test template would mishandle the framework's own founding case. Analytical-mode covers theory, review, and perspective papers, whose contribution is identifying a gap, a contradiction, or a wrong shared assumption by linking literature rather than generating new data. Section 3.5A specifies it, and it is distinct from observational discovery because it generates no new data at all. Each paper is scored on SRQI, EMI, the analytical-mode step subset, or a combination as appropriate.

Each EMI step-index instantiates the shared protocol of Section 3.5.0 and scores two axes. An internal-rigor axis specific to the engineering step asks three questions. Was the requirement quantified? Was the design space actually explored? Did validation run against every requirement? A corpus-novelty axis then applies the SObs Element 2 machinery to the prior engineering literature, so a requirement, design, or validation approach is credited as more

innovative when it is absent from and distant to prior engineering work. The incomputability above-10 rule applies where an approach has no prior precedent.

Each EMI step reads structural engineering evidence rather than claim language. Its score is anchored to how the same computed features are distributed across the reference population, with no expert quality-labels, matching the SRQI protocol. The same held-out surface features apply, so naming an operation does not substitute for performing it. Papers scored on multiple modes report each vector separately, so a bidirectional-translation paper is credited for its science and its engineering separately rather than averaged into one misfitting number.

Failure mode and mitigation (meta-index level).

The dominant risk is mode-misclassification, scoring an engineering paper as science, an analytical paper as discovery, or any other mismatch, mitigated by multiple scoring where the mode classifier is uncertain and by reporting the mode decision with its confidence. A paper mis-routed to discovery-mode when it is analytical would be scored on execution and analysis steps it has no basis to satisfy, which the analytical-mode branch of Section 3.5A prevents by not instantiating those steps. Gaming is addressed at the step level.

RFI category alignment.

Entrepreneurship and Translation and Foundational Scientific Exploration where the engineering is foundational infrastructure, cross-cutting content calibrator for design-and-build work.

3.5E.1 Requirement-Definition Index (EReq)

Definition.

The clarity, completeness, and justification of the specification the engineering work targets, the engineering analogue of question formulation.

Motivation and specification.

A design is only as good as the requirements it is judged against, and unstated or post-hoc requirements make a device impossible to evaluate. EReq reads for explicit, quantified performance requirements stated before the design (target values with units and tolerances), justification tying each requirement to the application need, and constraints (power, size, biocompatibility, cost). The scorer keys on the presence of quantified, justified specifications, not on the word requirement.

Implementation.

78. Extract the stated performance requirements, constraints, and their justifications using the Element 1 extraction model.
79. Score the rigor axis by whether requirements are quantified (target values with units and tolerances) and justified against the application need, checking for reverse-fit by comparing requirements to any preregistration or prior protocol.
80. Score the novelty axis by applying SObs Element 2 retrieval to the requirement against the prior engineering corpus.

81. Map both axes to the 1-to-10 score via the Element 3 ordinal regression and normalize against the Element 4 engineering reference stratum.

Failure mode and gaming defense.

Reverse-fitting requirements to the achieved performance is the gaming vector. The defense checks consistency between stated requirements and any pre-registration or prior protocol, and flags requirements that match achieved results as suspect.

Rubric anchors and scale.

On the common rubric, a 3 states no quantified requirements or reverse-fits them to results. A 7 states quantified, justified performance requirements with constraints before the design. A 10 states a complete, well-justified specification tied rigorously to the application need. A score above 10 defines a requirement set that reframes what the device class should achieve.

3.5E.2 Design-Space-Exploration Index (EDes)

Definition.

The breadth and rigor of the design alternatives considered and the justification for the chosen design, the engineering analogue of multiple working hypotheses.

Motivation and specification.

A design chosen without considering alternatives is an assertion, not an engineering decision. EDes reads for stated design alternatives, explicit trade-off analysis among them, and a justified selection tied to the requirements. The scorer keys on the presence of a real trade-off analysis, not on a single design presented as inevitable.

Implementation.

82. Extract the stated design alternatives and the trade-off analysis using the Element 1 extraction model.
83. Score the rigor axis by whether real alternatives are considered with genuine trade-offs on stated axes and a justified selection, rejecting strawman alternatives that present no real trade-off.
84. Score the novelty axis by SObs Element 2 retrieval of the chosen design approach against the prior engineering corpus.
85. Map both axes to the 1-to-10 score and normalize against the engineering reference stratum.

Failure mode and gaming defense.

Strawman alternatives introduced only to be dismissed are the gaming vector. The defense requires each alternative to present a real trade-off against the chosen design on a stated axis, so token alternatives do not score.

Rubric anchors and scale.

On the common rubric, a 3 presents one design with no alternatives considered. A 7 considers real alternatives with a trade-off analysis and justified selection. A 10 explores the design space

rigorously with quantified trade-offs across the relevant axes. A score above 10 identifies a design approach the field had not considered.

3.5E.3 Prototype-Realization Index (EProto)

Definition.

The completeness and reproducibility of the build, the engineering analogue of experimental execution.

Motivation and specification.

A described design that was not actually built and characterized is a proposal, not a result. EProto reads for evidence the artifact was realized (fabrication methods, materials, and process parameters sufficient to reproduce it) and for the fidelity of the realized artifact to the design. The scorer keys on the presence of reproducible build detail.

Implementation.

86. Extract the fabrication methods, materials, and process parameters using the Element 1 extraction model.
87. Score the rigor axis by whether the build is specified in enough detail for independent reproduction (the engineering analogue of the SExec reproducibility-gap feature) and whether realized-to-design fidelity is demonstrated.
88. Score the novelty axis by retrieval of the fabrication approach against the prior engineering corpus.
89. Map both axes to the 1-to-10 score and normalize against the engineering reference stratum.

Failure mode and gaming defense.

Claiming a build without reproducible detail is the gaming vector. The defense requires fabrication and process parameters sufficient for independent reproduction, so an underspecified build does not score.

Rubric anchors and scale.

On the common rubric, a 3 describes a build too underspecified to reproduce. A 7 provides fabrication and process detail sufficient for independent reproduction. A 10 provides complete reproducible realization with verified design fidelity at the field's best standard. A score above 10 achieves a fabrication result the field considered infeasible.

3.5E.4 Characterization-and-Measurement Index (EChar)

Definition.

The rigor and completeness of the measurements characterizing the realized artifact's performance, the engineering analogue of analysis rigor.

Motivation and specification.

Characterization is where a device's real performance is established, and selective or under-powered characterization overstates it. EChar checks that performance is measured across the

operating range, with appropriate sample sizes across fabricated units, statistical treatment of unit-to-unit variability (any significance claim requires its p value), and reporting of failure cases and off-nominal behavior. The scorer keys on the completeness and statistical treatment of the measurements.

Implementation.

90. Extract the performance measurements and their sampling using the Element 1 extraction model.
91. Score the rigor axis by coverage across the operating range, adequate unit-to-unit sampling with variability statistics (any significance claim requires its p value), and failure-case reporting, flagging best-unit-only reporting.
92. Score the novelty axis by retrieval of the characterization method against the prior engineering corpus.
93. Map both axes to the 1-to-10 score and normalize against the engineering reference stratum.

Failure mode and gaming defense.

Best-unit reporting, characterizing only the device that worked, is the gaming vector. The defense requires reporting across fabricated units with unit-to-unit variability, so single-best-unit results are flagged.

Rubric anchors and scale.

On the common rubric, a 3 reports only best-unit or partial-range performance. A 7 characterizes across the operating range with adequate unit-to-unit sampling and failure reporting. A 10 characterizes comprehensively with full statistical treatment of variability at the field's best standard. A score above 10 establishes a characterization method others adopt.

3.5E.5 Validation-Against-Specification Index (EVal)

Definition.

Whether the characterized performance is tested against the stated requirements, the engineering analogue of interpretation calibration and the step with no scientific-method equivalent.

Motivation and specification.

Validation closes the engineering loop by testing the built artifact against the requirements defined at the start, and its absence lets a paper claim success without a standard. EVal reads for an explicit comparison of characterized performance against each stated requirement, an honest account of which requirements were met and which were not, and validation under application-relevant conditions rather than only benchtop-ideal ones. The scorer keys on the presence of a requirement-by-requirement comparison.

Implementation.

94. Extract the stated requirements from EReq and the validation results using the Element 1 extraction model.

95. Score the rigor axis by requirement-by-requirement comparison of characterized performance against every stated requirement under application-relevant conditions, flagging silently dropped unmet requirements as a mismatch between the requirement set and the validation set.
96. Score the novelty axis by retrieval of the validation approach against the prior engineering corpus.
97. Map both axes to the 1-to-10 score and normalize against the engineering reference stratum.

Failure mode and gaming defense.

Validating only against the requirements that were met is the gaming vector. The defense requires validation against every stated requirement from EReq, so silently dropping an unmet requirement is flagged as a mismatch between the requirement set and the validation set.

Rubric anchors and scale.

On the common rubric, a 3 validates against no stated requirement or only the met ones. A 7 compares performance against every stated requirement under realistic conditions with honest met-and-unmet accounting. A 10 validates comprehensively under application-relevant conditions at the field's best standard. A score above 10 validates against a more demanding standard than the field currently requires.

3.5E.6 Iteration-and-Optimization Index (EIter)

Definition.

Evidence of design iteration informed by characterization and validation, the engineering analogue of the self-correcting cycle of science.

Motivation and specification.

Engineering advances through iteration, and a paper that reports a single design pass without learning from measured shortfalls demonstrates weaker engineering reasoning than one that closes the loop. EIter reads for evidence that characterization or validation results drove a subsequent design change, with the change justified by the measured shortfall. The scorer keys on the traceable link from a measured result to a design revision.

Implementation.

98. Extract claimed design iterations and their driving measurements using the Element 1 extraction model.
99. Score the rigor axis by whether each claimed iteration links a specific measured shortfall to a specific design change with before-and-after data, rejecting unsupported iteration narratives.
100. Score the novelty axis by retrieval of the iteration or optimization approach against the prior engineering corpus.
101. Map both axes to the 1-to-10 score and normalize against the engineering reference stratum.

Failure mode and gaming defense.

Narrating iteration that did not occur is the gaming vector. The defense requires each claimed iteration to link a specific measured shortfall to a specific design change with before-and-after data, so an unsupported iteration narrative does not score.

Rubric anchors and scale.

On the common rubric, a 3 reports a single design pass with no learning from shortfalls. A 7 links a measured shortfall to a justified design change with before-and-after data. A 10 demonstrates a rigorous closed iteration loop driving measured performance gains. A score above 10 achieves through iteration a performance level the field considered a hard limit.

3.5A Analytical-Mode Assessment for Theory, Review, and Perspective Papers

Why a third mode.

Theory, review, and perspective papers make no primary observations, run no experiments, and build no devices. The execution and statistical-rigor steps of SRQI, and the realization and validation steps of EMI, therefore have nothing to read on them. Their contribution is identifying a gap, a contradiction, or a wrong shared assumption, by linking literature that had not been linked. That contribution is among the hardest to count and among the most consequential when it redirects a field. Routing such a paper to discovery-mode would score it on experimental steps it has no basis to satisfy. The silence-counts-as-deficiency default would then convert the structural absence of an experiment into a cascade of false deficiencies, penalizing the paper for not being an experiment. Analytical-mode exists so that a synthesis contribution is scored on what it does rather than on what it cannot do.

What is scored, and what is inert.

Analytical-mode scores only the reasoning and integration steps of the scientific method. Those are the observation step in its corpus-relational sense (SObs), gap identification (SGap), hypothesis or thesis generation (SHyp), interpretation (SInt), and synthesis (SSyn). It also scores the standalone indicators that already read integration and origination rather than experiment, meaning the assumption-addressing indicator (AAI), mechanism-graph centrality (MGCI), cross-field integration (CFII), the field-define index (FDI), and the corpus-relational novelty machinery. Three components are not instantiated at all in analytical-mode, rather than scored as deficient. Those are the execution-fidelity step (SExec), the analysis-rigor step (SAna), and the primary-data-ratio component of the paper-substance score (PSS). A paper with no experimental execution has no execution to check, no experiment-derived statistics to validate, and no primary data whose absence is a fault. Making these steps inert rather than gating them to a lenient setting is the essential decision. A gated but active experimental checklist would still record every experimental element as absent, and the silence-counts-as-deficiency default would still fire.

The deficiency floor, stated with its uncertainty.

A mode that rewarded only positive signals would credit the appearance of synthesis. It would have no way to score down a fluent repackaging that links nothing new and argues nothing sound, which would make analytical-mode a gaming surface and an unusable signal for an evaluator. Analytical-mode therefore has its own deficiency floor, the analogue of the experimental required-element checklist, built from three corpus-relational checks.

The linkage-novelty check tests whether the connections the paper claims to draw are actually absent from the prior literature, using the same retrieval machinery as SObs novelty detection. A synthesis that restates known connections therefore scores low on the contribution it claims. The dormancy exception applies here too. A synthesis that resurfaces connections lost in old, uncited, hard-to-retrieve work and builds on them is credited as recovery rather than penalized as restatement, which follows the framework's founding concern for neglected work, since reviving a forgotten linkage is the synthesis analogue of producing a neglected finding. A source-characterization accuracy check tests whether the cited sources are characterized consistently with what they actually report. It applies the entailment machinery of the SAna claim-alignment check to the citing sentences rather than to a statistical claim, so a paper that mischaracterizes what it cites is flagged. An assumption-exposure check tests whether the paper states the assumptions its argument depends on rather than smuggling them in. That is detectable as the presence or absence of explicit conditional and scope statements in the argument structure.

These three checks sit in the corpus-relational tier of Section 2 rather than the rule-based tier, and this is stated rather than hidden. Whether a linkage is new, and whether a source is faithfully characterized, are questions about the structure and content of the existing literature, which retrieval and entailment can address. They rest on softer ground than a statistical-validity check whose ground truth is mathematics. Analytical-mode substance is therefore assessed with more uncertainty than experimental rigor. The checks return a finding with an explicit confidence rather than a determinate pass or fail, and that confidence is reported alongside the score. A program officer can then weight the analytical assessment for what it is, a corpus-relational judgment of a contribution that resists exact measurement rather than a hard adjudication of whether an argument is correct. The framework does not computationally decide whether an idea is good. It detects whether a synthesis introduces a new and faithfully argued linkage, and it reports the confidence of that detection.

Relation to the framework's general treatment of hard-to-count contribution.

Analytical-mode is one instance of a general principle rather than a special case. A synthesis paper and a patent share a property. Their value lies not in a countable artifact but in what they introduce and what the field or the market subsequently takes up. Both are therefore assessed by the novelty and the uptake of what they introduce rather than by artifact count. That is the same move the field-define index makes for originated concepts, and the same move the incentive arm makes when it credits constitutive behaviors rather than proxies.

Where a contribution is hard to count, the framework's answer stays consistent. Measure the novelty of what was introduced against the prior corpus and the independent uptake that followed, and report the measurement with its uncertainty, rather than defaulting to the artifact tally that undercounts the work this framework credits.

RFI category alignment.

Foundational Scientific Exploration, since a field-redirecting synthesis is a foundational contribution, with a secondary tie to any category where review and perspective work shapes subsequent research direction.

3.6 Verifiable Public-Engagement Index (VPEI)

Definition.

A score quantifying an author's substantive public-communication output through verified audience reach, content-quality scoring, and downstream policy or educational citation.

Motivation.

Current metrics ignore public-engagement contributions entirely, and many institutional cultures actively penalize them. Carl Sagan published approximately 500 peer-reviewed papers across 39 years while also producing the most influential public-science communication of the late 20th century. The National Academy of Sciences blocked his 1992 nomination explicitly because of the public work. Later bibliometric analyses have shown that scientifically active science communicators outperform non-communicators on traditional research metrics, so the Sagan Effect, the perception that scientific popularity is inversely related to scientific quality, is empirically false. This indicator treats substantive public communication as an output class, with verified reach, content-quality scoring, and downstream policy or educational impact.

This indicator applies beyond a single impact category. A foundational-science funder in a democracy has a structural vulnerability. Its payoff horizon is longer than its funding horizon, so the work is perpetually exposed to appropriations cycles that resolve faster than the science does. The only durable protection is a public that understands why slow, risky, non-appropriable work deserves patience.

Public communication of foundational science is therefore the meta-incentive that protects the survival of every other category, since it determines whether the appropriations funding all the evaluation decisions endure across political cycles. The indicator must be scoped tightly to communication that builds durable public understanding of why foundational science matters. It is weighted by the quality and durability of understanding produced rather than by volume of engagement or self-promotion, or it degrades into the volume-first failure mode. A researcher who makes taxpayers understand why slow foundational work deserves support is protecting the entire enterprise, and that contribution should receive credit.

Formulation.

$$VPEI(a) = \Sigma \text{ over } e \in E(a) \text{ of } reach(e) \cdot quality(e) \cdot downstream_impact(e)$$

where *E(a)* is the set of engagement events for author *a* (books, op-eds, broadcasts, lectures, podcasts, verified science journalism), *reach(e)* is the verified audience size from publisher data, broadcast Nielsen ratings, or attendance records (not platform-reported only), *quality(e)* is the LLM-classified science content quality benchmarked against established science-communication exemplars, and *downstream_impact(e)* is the count of citations of *e* in policy documents, regulatory filings, educational curricula, and textbook adoption.

AI specification.

A multi-source aggregation system combining NLP classification of engagement content quality, external reach databases for audience verification, and cross-reference matching against policy-document and curriculum corpora for downstream impact tracking. Quality benchmarks calibrated against historical exemplars (Sagan's Cosmos, Hawking's A Brief History of Time,

Carson's Silent Spring) at the upper range and against demonstrated misinformation at the lower range.

Parameters and thresholds.

Each engagement event has three scored factors on a common 0 to 1 scale. Reach is the log of verified audience size, meaning log base 10 of publisher print runs, broadcast Nielsen figures, or verified attendance, normalized against the field distribution. Platform-reported figures are excluded, and only independently-verified reach is admitted. Quality is a classifier score benchmarked so the named exemplars anchor near 1.0 and demonstrated misinformation anchors near 0, with a hard gate zeroing the event if adversarial-content detection flags it, so reach cannot compensate for false content.

Downstream impact counts verified citations of the event in policy documents, regulatory filings, curricula, and textbooks, entered as the log of one plus the citation count. It is weighted most heavily, at a suggested 0.5 of the event score, because it is the least gameable and tracks durable understanding most closely. The event score is the product of the three factors. Per the failure-mode analysis, this indicator's total weight in any evaluation is capped below the constitutive indicators, since it remains a proxy rather than a constitutive metric.

Implementation.

102. Build engagement-event corpus through ORCID extension supporting author self-report of verified outputs.
103. Verify reach against publisher and broadcast data sources, with platform-reported metrics treated as unverified.
104. Score the verifiable-count dimensions computationally (independent reach verification, policy-document and curriculum citation of the content), and treat the content-substance dimension as the disclosed exception below, since substance is the one dimension the framework does not claim to compute objectively.
105. Track downstream policy and educational citation through automated matching against policy and curriculum corpora.
106. Aggregate per-author with field-normalized weighting.

Failure mode and mitigation.

This is the least Goodhart-resistant indicator in the framework, and that is stated so evaluators can weight it appropriately. Unlike the constitutive incentive-arm metrics, it is a proxy. Reach and engagement stand in for the thing actually wanted, meaning durable public understanding of foundational science, rather than being that thing directly. Reach can be gamed through paid distribution, bot amplification, or strategic platform selection, and high-reach low-substance content is the influencer failure mode. Three partial mitigations apply, independent reach verification rather than platform-reported figures, a downstream-impact term that weights policy and educational citation over raw audience, and open methodology. These reduce the gaming risk without eliminating it.

The recommendation is therefore to cap this indicator's evaluative weight below the constitutive indicators and to treat it as advisory rather than determinative. It still promotes a wanted behavior, since the cheapest path to a durable-impact score runs through producing

communication that policy documents and curricula actually cite, which is the public-understanding contribution the enterprise depends on. This is also the one place the framework does not claim objective computation of a quality dimension. Content substance resists the corpus-relational and rule-based methods the other indicators use. Rather than smuggle in the expert quality-labels the reasoning indices deliberately avoid, the framework specifies that substance judgment here is human, advisory, and the specific reason the indicator is capped.

RFI category alignment.

Public Impact.

3.7 Gap Index (GI)

Definition.

Credit accumulated by papers that fill knowledge gaps documented in the prior literature, weighted by independent identification of those gaps across distinct author groups.

Motivation.

Current metrics reward citation accumulation without distinguishing incremental work from gap-filling work that addresses documented unresolved questions. That creates a structural preference for safe incremental research. Incremental work cites established work that cites established work in self-reinforcing loops, while genuine gap-filling work that diverges from established narratives receives less initial citation.

This index tracks documented field-wide gaps, extracted from the future-directions, limitations, and open-questions sections of the literature, and it credits papers that address them with mechanism-level engagement.

Formulation.

$$GI(p) = \Sigma \text{ over } g \in G_corpus \text{ of } sim(p, g) \cdot ind(g, t_p) \cdot addr(p, g)$$

where *G_corpus* is the corpus of identified gaps extracted from "future directions," "limitations," and "open questions" sections across the literature, *sim(p, g)* is the semantic similarity between paper *p* and gap statement *g*, *ind(g, t_p)* is the independent-identification count of *g* across distinct sources prior to publication date *t_p*, and *addr(p, g)* is whether *p* actually addresses *g* mechanistically rather than asserting it.

AI specification.

A three-stage pipeline. First, a gap-extraction LLM identifies unresolved-question statements across large volumes of review articles, position papers, and limitations sections. Second, gap-clustering identifies independent restatements as the same underlying gap using semantic clustering with independence verification across author groups. Third, a semantic-match LLM scores the filling-extent for new papers, requiring mechanism-level engagement with the gap rather than rhetorical claim.

Parameters and thresholds.

Gap extraction reads sentences in the Future Directions, Limitations, Discussion, and Conclusion sections to locate stated gaps. It favors precision over recall, since a missed gap

costs less than a spurious one, and the corpus-relational logic below determines the score rather than any judgment of gap quality. Gap-clustering uses embedding cosine similarity with a merge threshold near 0.85, set per field because gap resolution varies, so same-gap statements merge and distinct-gap statements do not.

A gap qualifies for the corpus only if at least three distinct author groups stated it independently before the candidate paper's submission date, with no shared authors and no shared institution. That sets the independent-identification floor and defeats self-defined gaps. Filling-extent is a semantic-match score from 0 to 1, thresholded at 0.6 for partial credit and 0.8 for full credit, with a mechanism-engagement gate requiring the paper's Results or Methods to reference the gap, and not its Introduction alone. The independent-identification count enters as a log-weighted multiplier, the log of one plus the number of independent groups, so a gap noted by 50 groups scores higher than one noted by three, with diminishing returns.

Implementation.

107. Extract gap corpus from review articles, position papers, and Discussion sections across the literature.
108. Cluster gaps semantically with independence checks (distinct authors, distinct institutions, distinct time periods).
109. Timestamp gaps with earliest published identification.
110. Apply to new papers as filling-extent calculation with substance scoring.
111. Weight by independent-identification count and substance score.

Failure mode and mitigation.

Authors can frame work to claim gap-filling regardless of substantive contribution. Mitigation requires that the gap be documented before paper submission date (verifiable timestamp) and that the paper actually address the mechanism, scored by substance index. Independence of gap identification across distinct author groups prevents self-citation cliques from defining the gap distribution.

RFI category alignment.

Foundational Scientific Exploration and Rigor and Reproducibility.

3.8 Field-Define Index (FDI)

Definition.

Credit accumulated by papers that originate concepts, terminology, methods, or frameworks that subsequent work adopts as foundational, distinguishing originators from elaborators and co-opters.

Motivation.

Current metrics credit citation accumulation but not concept origination. A paper that introduces a foundational concept receives one citation per downstream paper using that concept, the same as a paper that uses the concept later, so originators are not distinguished from adopters. Richard Normann's Utah intracortical microelectrode array, developed at the University of Utah

through the late 1980s, defined the standard architecture for cortical recording that BrainGate and most subsequent clinical brain-computer interface work has used. The existing metrics give no extra weight to the originating papers. The Field-Define Index tracks concept genealogies through the literature, identifies originators, and weights their credit by the breadth, longevity, and fidelity of downstream adoption.

Formulation.

$$FDI(p) = \Sigma \text{ over } c \in Concepts(p) \text{ of } origin(p, c) \cdot adopt(c) \cdot stab(c) \cdot fid(c)$$

where *Concepts(p)* is the set of concepts contributed by paper *p*, *origin(p, c)* is 1 if *p* is the first substantive treatment of concept *c* and 0 otherwise, *adopt(c)* is the count of downstream papers using *c*, weighted toward adopters with no co-authorship relationship to the originator so reciprocal within-clique adoption does not inflate it, *stab(c)* is whether *c* persists in the literature 10 or more years later, and *fid(c)* is the fraction of downstream uses consistent with the originator's definition (semantic fidelity).

AI specification.

A concept-genealogy system using LLM-based concept extraction, citation-network tracking, and semantic-consistency checking to identify originators and downstream users. The system distinguishes passing mention from substantive treatment using paragraph-level context analysis.

Parameters and thresholds.

Concept extraction runs against field-stratified dictionaries seeded from UMLS, MeSH, and Gene Ontology, plus emergent-term detection for concepts not yet in ontologies. Substantive treatment, which sets the origination term, requires the concept to appear in at least two distinct sections of the paper with a definitional or empirical passage of at least three sentences. That structural rule distinguishes origination from a one-line mention, rather than matching an annotated set.

Adoption counts downstream papers using the concept, weighted by independence. Adopters sharing no co-authorship with the originator count at full weight, and within-network adopters are down-weighted by a factor near 0.3, which defeats reciprocal-citation cartels without zeroing legitimate collaborator use. Stability is a binary gate, set to 1 only if the concept still appears in the literature 10 or more years after origination, and applied only to concepts old enough to test. Semantic fidelity is the fraction of downstream uses whose local context matches the originator's definition above a 0.7 embedding-similarity threshold, which penalizes term co-option. The four factors combine multiplicatively, so a coined term with high adoption but low fidelity or no stability scores low.

Implementation.

112. Build concept-extraction pipeline over full-text corpus with field-stratified concept dictionaries.
113. For each concept, identify earliest substantive treatment using paragraph-level context (not passing mention).

114. Track downstream papers using the concept with attribution and semantic-fidelity scoring.

115. Verify persistence at 10-year horizon for concepts old enough to test stability.

116. Aggregate to paper-level scores with confidence intervals.

117. Calibrate originator and adoption thresholds against the NIH-funded reference population per Section 3.5.0 Element 4, using the Element 2 corpus and concept graph for genealogy tracking.

Failure mode and mitigation.

Two gaming modes require mitigation. First, the index can reward coining over substance, where papers introduce flashy terminology without real conceptual work. Joint conditions with mechanism-graph centrality and the substance score mitigate that, since the new concept must connect to broader knowledge structure. Second, a coordinated group can manufacture adoption by reciprocally using each other's coined terms, inflating the adoption count without genuine field uptake.

An independence check on adoption mitigates the second mode, analogous to the gap index, crediting adoption weighted toward downstream users with no co-authorship relationship to the originator, so reciprocal within-clique adoption does not drive the score. Semantic-fidelity scoring further requires downstream adoption to use the concept the originator's way rather than co-opting the term differently. The independence-weighted adoption count is the primary defense against organized citation cartels, and where residual coordinated behavior evades it, expert review of claimed originations at the career-terminal horizon provides a backstop.

RFI category alignment.

Foundational Scientific Exploration.

3.9 Cross-Field Integration Index (CFII)

Definition.

Score measuring whether a paper synthesizes methods, findings, or concepts from separate fields through genuine methodological dependency rather than tokenistic cross-field citation.

Motivation.

Current metrics fail to distinguish genuine cross-field integration from tokenistic cross-field citation. A paper can cite work from multiple fields without using those fields' methods or concepts in its own analysis, accumulating apparent breadth without genuine integration.

Wuchty, Jones, and Uzzi in Science 2007 established that team-produced cross-field work has higher disruption scores than within-field work. Current metrics still provide no way to tell which papers actually integrate fields from which papers cite them without integration. This index combines reference-list field span with semantic verification of methodological dependency on the cited work.

Formulation.

$$CFII(p) = fs(refs(p)) \cdot md(p) \cdot ds(p)$$

where *fs(refs(p))* is the average pairwise field-distance among citations in *p*'s reference list (computed from the field-distance matrix), *md(p)* is the LLM-verified methodological dependency (cited methods are used in the analysis, not just listed), and *ds(p)* is the downstream field-span of papers citing *p* (genuine integration produces downstream integration).

AI specification.

A field-distance matrix computed from topic modeling and citation networks across the corpus, plus LLM verification of methodological usage in text. The field-distance matrix is the foundational object and must be field-stratified and updated quarterly as fields evolve.

Methodological dependency is the decision that separates genuine integration from tokenistic breadth. It is scored by locating each cross-field cited method in the paper's own analysis, requiring a semantic match above 0.6 between the citation and the surrounding methods or results text. A reference cited in the introduction but never used in the analysis contributes to apparent breadth and is excluded from this term, so the score rises only when a foreign-field method is actually executed.

The field-distance component is normalized against the field-specific distribution of reference breadth, so fields with naturally broad literatures are not scored as integrative by default. Downstream field-span is computed only for papers at least five years old, and it confirms that genuine integration produced integration in the work that cited it. The 0.6 methodological-dependency threshold is calibrated against the field-specific distribution rather than against a hand-labeled exemplar set, so the separation of integrative from tokenistic breadth rests on measured method-execution in the text rather than on annotated judgments.

Implementation.

118. Build field-distance matrix from topic models on full corpus with confidence intervals.
119. Compute reference-list field-span per paper using pairwise distances.
120. LLM-verify methodological dependency by checking that cited methods appear in analysis sections.
121. Track downstream citation field-span for papers older than 5 years.
122. Aggregate as multiplicative score with field-normalized output.
123. Draw the field-distance matrix from the Section 3.5.0 Element 2 concept graph and calibrate integration thresholds against the field-stratified reference population per Element 4.

Failure mode and mitigation.

Tokenistic cross-field citation without methodological dependency can inflate the index. Mitigation requires that cited methods appear in the paper's analysis sections (semantic match between citation and surrounding methodological text), not just in the reference list. Downstream span verification at 5-year horizon further filters tokenistic claims.

RFI category alignment.

Collaboration, with secondary alignment to Foundational Scientific Exploration.

3.10 Co-Author Composition Index (CACI)

Definition.

A team-configuration score along innovation-correlated structural axes including team size (number of authors), geographic heterogeneity (international and inter-regional collaboration), institutional heterogeneity (R1, R2, government laboratory, industry, non-US institution), career-stage range, and disciplinary breadth, with optional demographic variables included only where consented through ORCID self-report.

Motivation.

Current metrics treat all author lists equally. They ignore the team-configuration variables that bibliometric research has associated with innovation outcomes across more than two decades of empirical work. Wuchty, Jones, and Uzzi (Science 2007) established that team-produced work has dominated knowledge production for over 50 years, and that team-produced papers receive substantially higher citation rates than solo-authored work. Team size also shows a positive relationship to disruption scores, up to a field-specific optimum. Later bibliometric work documented three further axes that each independently predict disruption outcomes, geographic heterogeneity (Adams 2013 Nature), institutional heterogeneity (Jones, Wuchty, and Uzzi 2008 Science), and disciplinary breadth. The Co-Author Composition Index scores team configuration along these empirically validated axes. It supplies decision-relevant signal about likely innovation output at the moment of evaluation, rather than waiting for impact to accumulate.

Formulation.

$$CACI(authors) = \Sigma \text{ over } d \in D \text{ of } w_d \cdot het_d(authors)$$

Here D is the set of structural axes, meaning team size, geography, institution, career stage, and discipline, with optional opt-in demographic variables for gender, ethnicity, and age. The term het_d(authors) is the team-configuration score along axis d, computed as a raw count for team size and as Shannon entropy or a normalized Gini coefficient for categorical axes. The weight w_d is tuned to the empirical correlation with disruption outcomes for that axis. Field-stratified weighting is required, because optimal team configurations differ across disciplines, as they do between theoretical physics and clinical translational research.

Empirical justification.

Several bibliometric studies report that varied team configurations predict innovation. They include Wuchty Jones and Uzzi 2007 Science (team size and disruption), Jones Wuchty and Uzzi 2008 Science (institutional heterogeneity and impact), Adams 2013 Nature (geographic heterogeneity), AlShebli Rahwan and Woon 2018 Nature Communications (ethnic heterogeneity and citation impact), and Yang et al. 2022 PNAS (gender heterogeneity and novelty). The empirical case rests on innovation outcomes (citation impact, disruption scores, novel-idea generation), not on normative claims about representation. CACI is justified on these empirical grounds.

AI specification.

A multi-source aggregation system extracting team-configuration from ORCID, institutional records, and (where consented) demographic self-report. Algorithmic inference of demographic

variables from names or photographs is prohibited as both privacy-violating and known to be biased. Structural variables (team size, geography, institution type, career stage, disciplinary background) are inferable from public records without requiring consent.

Each structural axis is computed by a defined rule. Career stage is binned field-relative rather than by fixed year cutoffs. Years since first publication are normalized to the field's time-to-independence distribution, meaning the field's median interval from first publication to first independent grant or last-author paper. Early, mid, and senior are therefore defined against how careers in a given field actually progress, rather than by a uniform boundary that would misjudge fields with slower or faster paths to independence. That follows the field-stratified calibration of Section 3.5.0 Element 4. Institution type is classified from affiliation against Carnegie-style categories, meaning R1, R2, government laboratory, industry, and foreign. Disciplinary background is assigned from each author's prior-publication topic distribution. Heterogeneity per axis is Shannon entropy normalized to its maximum. Team size enters as a raw count weighted against the field-specific optimum rather than on a more-is-better scale.

The gaming-relevant decision is that each co-author's axis contribution is gated by verified participation. An author counts toward heterogeneity only when CRediT contribution roles are recorded and the author has a prior-publication track record in the declared specialty. A name added purely to widen a heterogeneity axis, without a contribution role or a track record, does not raise the score. CRediT roles postdate many older papers, so retrospective application to pre-CRediT work runs the participation gate on weaker evidence. It falls back to author position and prior-topic track record without the role declaration. Retrospective CACI scores therefore have more attribution uncertainty than contemporary ones and should be reported as weaker evidence.

Implementation.

124. Extract author count and affiliation from ORCID and Web of Science author records.
125. Identify career stage from publication history (years since first publication, total publications, position type when available).
126. Identify institutional type (R1, R2, government laboratory, industry, foreign institution) and geographic location from affiliations.
127. Identify disciplinary background from prior publication topic modeling.
128. Apply demographic variables only via consented ORCID self-report (opt-in only, with explicit downstream use disclosure).
129. Compute heterogeneity scores per axis using entropy or Gini normalization, with team size as a raw count weighted against field-specific optimum.
130. Combine into composite score with empirically tuned per-axis weights, field-stratified.

Failure mode and mitigation.

Two gaming modes require naming. First, tokenistic co-authorship can inflate the index without substantive contribution from the added authors. Weighting by CRediT contribution roles partly mitigates this, as does verifying that co-authors have downstream citation linkage to prior work

in their declared field. CRediT roles are self-reported and themselves gameable, so this mitigation is partial.

Second, and harder, a well-resourced laboratory can assemble credentialed collaborators across varied geographies and institutions to raise the heterogeneity score more easily than an independent investigator can. That inverts the intent, rewarding resource access rather than the collaborative behavior itself. Measurement cannot fully close this mode, since the added collaborators are real and contributing. The framework names it for two reasons. Evaluators should weight CACI as a team-context signal rather than an individual-merit score, and CACI should never be used to disadvantage independent or single-institution investigators. Even in its gameable form the indicator promotes a wanted behavior, since assembling heterogeneous teams that collaborate is the behavior the bibliometric evidence associates with higher innovation output. CACI should be reported descriptively alongside team size rather than as a rank.

RFI category alignment.

Collaboration.

3.11 Citing Breadth Index (CBI)

Definition.

Score quantifying the breadth, balance, and timing of a paper's reference list, inverting the citation asymmetry that drives Matthew Effect concentration in current metrics. Every existing metric rewards being cited, while CBI rewards how widely and well a paper cites and characterizes the literature.

Motivation.

Current citation metrics suffer from the Matthew Effect described by Merton in 1968, where established work accumulates citations automatically while comparably valuable work outside dominant citation cliques is overlooked. Every existing metric measures who cites you. None measures whom you cite. The metric system therefore rewards being read by established networks and gives no incentive for reading widely outside them. The Citing Breadth Index inverts that asymmetry. It scores whether a paper engages original sources or only reviews, whether it spans field boundaries, whether it balances cited authors across career stages, and whether it covers geographic breadth. It also addresses an operational limitation of citation-based metrics, that they lag, by producing a signal at publication when the reference list is immediately available.

Formulation.

$$CBI(p) = \alpha \cdot OSR(p) + \beta \cdot FSpan(p) + \gamma \cdot CSB(p) + \delta \cdot GBr(p)$$

where *OSR(p)* is the original-source ratio (citations to primary work versus review papers), *FSpan(p)* is the field span of references across the field-distance matrix, *CSB(p)* is the career-stage balance of cited authors (entropy across career-stage bins), *GBr(p)* is the geographic and institutional breadth of cited authors, and weights *α, β, γ, δ* are tuned empirically against downstream impact correlation.

AI specification.

A reference-list analyzer that classifies each citation by source type (primary versus review), field, cited-author career stage, and institution, then computes balance measures across each axis. Citation context analysis ensures cited works are used in analysis (semantic match between citation and surrounding text), rather than listed.

Parameters and thresholds.

Each of the four components is normalized to a 0-to-1 range. The original-source ratio is the fraction of references that are primary sources rather than reviews, classified against journal and article-type metadata. Field span is the mean pairwise field distance across references, using the field-distance matrix of Section 3.9, normalized against the field-specific reference-breadth distribution. Career-stage balance is the Shannon entropy of cited-author career stages, binned into early, mid, and senior, normalized to its maximum. Geographic breadth is the Shannon entropy of cited-author countries and institution types, normalized the same way.

The four weights are tuned by regression against downstream impact on a held-out corpus rather than set by assertion, starting from an equal-weight prior of 0.25 each. A padding gate requires each counted citation to have a semantic match above 0.6 between the citation context and the cited abstract, so padding a reference list with unused citations does not inflate breadth. The index is computable at submission, which supplies the immediate signal the motivation names.

Implementation.

131. Parse reference lists with structured citation extraction tools.
132. Classify each citation by source type, field, cited-author career stage, and geography.
133. Compute balance measures along each axis using entropy or Gini normalization.
134. Aggregate as weighted sum with empirically tuned weights.
135. Validate weights against downstream impact correlation in retrospective data.

Failure mode and mitigation.

Reference-list padding with tangentially relevant work can inflate breadth scores without substance. Mitigation requires substance scoring on citations themselves, the cited work must be used in the paper's analysis (semantic match between citation and surrounding text), not just listed.

RFI category alignment.

Cross-cutting calibrator with primary alignment to Foundational Scientific Exploration and Collaboration.

3.12 Data-Driven Innovation Composite (DDIC)

Definition.

A learned meta-indicator that weights the preceding twelve indicators against historical disruption labels, providing a single calibrated probability that a paper will produce disruptive contribution while preserving per-component sub-scores for inspection.

Motivation.

Current metrics provide no calibrated probability of future scientific impact, reporting aggregate counts and rankings without any explicit model of what predicts innovation outcomes. Reviewers must infer likely impact from h-index numbers and citation counts using intuition that varies across panels and institutions, producing inconsistent evaluation across comparable applications. The Data-Driven Innovation Composite fills this gap by training a supervised ensemble on historical disruption labels and the twelve upstream indicators, providing a single probability output that summarizes content-level scoring across the framework while preserving per-component inspection for cases where the composite and peer judgment diverge.

Formulation.

$$DDIC(p) = f_ML(\ SBTI,\ MGCI,\ AAI,\ PSS,\ SRQI,\ EMI,\ VPEI,\ GI,\ FDI,\ CFII,\ CACI,\ CBI\ )$$

where *f_ML* is a supervised ensemble model (gradient boosting plus neural ensemble) trained on retrospective disruption scores from the Funk and Owen-Smith CD index, Wu et al. disruption score, and verifiable long-term impact labels (Nobel Prize awards, NAS membership elections, and foundational-paper recognition in field histories).

AI specification.

A supervised ensemble model with explicit bias-correction terms in the loss function, for known demographic and institutional biases in citation networks. The model is required to be inspectable, with feature importance reported per inference and per-component sub-scores always available.

The upstream indicators are not statistically independent. SBTI already incorporates mechanism-graph centrality and gap-filling status among its features, and several indicators share the substance-score calibrator. The ensemble handles that correlation directly, since tree and neural ensembles do not assume feature independence. Feature-importance reporting must still attribute shared signal transparently rather than obscuring that correlated inputs contribute jointly, so evaluators are not misled into treating correlated components as independent evidence.

Scope.

This composite is computed at two explicit scopes, to keep its inputs coherent. The paper-level composite uses the twelve inputs in the formulation above. Ten of those are paper-level, meaning SBTI, MGCI, AAI, PSS, SRQI, EMI, GI, FDI, CFII, and CBI. Two are author-level or team-level, meaning VPEI and CACI, and they enter only through their paper-attributable components rather than as raw author or team scores. SRQI and EMI enter as their composite meta-index scores rather than as their individual step-indices.

An author-level composite additionally incorporates the full author-level and team-level indicators, including the Independent Recognition Indicator of Section 3.13. That indicator is

excluded from the paper-level composite because it is an author-level measure. Stating the two scopes explicitly prevents a category error, feeding an author-level score into a per-paper prediction. It is also why the paper-level formulation lists twelve inputs while the author-level composite additionally draws on IRI, and why neither draws on the SRQI and EMI step-level sub-indices directly, since those enter only through their meta-index composite scores.

Implementation.

136. Compute per-indicator scores for the training corpus across the past 30 years of literature.
137. Label with disruption scores at 20-year horizon plus categorical labels for Nobel-recognized work and historical foundational papers.
138. Train ensemble with bias correction for gender, ethnicity, institutional tier, and geographic-region biases verified in citation networks.
139. Validate against held-out historical disruption cases including Karikó, Brock, Normann, and Sagan papers.
140. Publish model weights, feature importance, and training data composition openly.

Failure mode and mitigation.

The composite concentrates evaluation authority in a single model that can become opaque if governance is weak. Mitigation requires open-source model with public audit trail, use as advisory input to peer review rather than autonomous decision-maker, mandatory per-component sub-score inspection in any application, and external audit every 18 months by an independent bibliometric panel.

RFI category alignment.

Meta-indicator applicable across all RFI categories.

Consequence and calibration are separate reported axes, and calibration cannot raise the consequence read.

Two axes are reported separately and are never netted into one number, a consequence axis and a calibration axis. The consequence axis estimates how much a contribution changes what a field asks, does, or believes, and it aggregates the forward-looking signals, the disruption probability of this composite, the Field-Define Index of Section 3.8, the Sleeping-Beauty Trajectory Index of Section 3.1, and the mechanism-graph centrality shift of Section 3.2. A calibration axis estimates the honesty and rigor with which a paper supports its stated claims, and it aggregates the SRQI and EMI reasoning scores, the claim-alignment check, and the honest-limitations credit. Each paper receives an independent score on each axis, and both scores appear side by side rather than combined, so an evaluator reads a consequence estimate and a calibration estimate rather than one value that obscures which estimate produced it.

The separation enforces one rule. Calibration cannot raise the consequence read. A rigorous, well-calibrated paper reporting a small but correct increment receives a high calibration score with a low or uncertain consequence score rather than a strong-contribution score, because honest reporting of a minor result does not make that result major. Substitution of calibration for

magnitude is the most likely failure. Calibration components number eleven reasoning steps, six engineering steps, and the claim-alignment and limitations checks, against four indicators on the consequence side, so an evaluator reading the full vector can treat the larger volume of calibration signal as evidence of magnitude. Separate axes and a prohibition on netting remove that substitution, so an honest minor paper and a field-redirecting paper separate on the axis that discriminates them rather than combining on the axis that does not.

The consequence axis has the widest uncertainty in the framework, because magnitude at publication time is a forward prediction rather than a measurement, so it is reported with an explicit confidence interval rather than a point estimate. Low predicted consequence is not scored as a deficiency, because the rule that incomputability scores high of the founding-novelty case applies here. A contribution too far ahead of its field for measurable downstream signal is flagged as high-uncertainty and possibly dormant rather than as minor, which preserves the protection the Karikó case in the preface establishes. Three states are therefore distinguished rather than two, high consequence, low consequence from a small increment, and unresolved consequence for a contribution a field has not yet incorporated. Downstream signal accrues over time, so an early high-uncertainty score is revisited rather than fixed, and the retrospective validation of Section 7.5 tests whether the axis separates a small increment from a dormant one.

3.13 Independent Recognition Indicator (IRI)

Definition.

A distribution-robust measure of how much of a researcher's recognition comes from authors with no co-authorship relationship to them. It is computed per paper across the entire publication portfolio, then aggregated by a median, which prevents one or two high-citation papers from dominating the result. It therefore distinguishes recognition earned from independent groups from recognition inherited through collaboration networks or borrowed from senior co-authors.

Motivation.

Current citation counts conflate independent recognition with network-internal citation. A researcher heavily cited by their own collaborators, trainees, and co-authors therefore appears identical to one cited by strangers who found the work on its merits. That favors researchers embedded in large collaboration networks and disadvantages independent investigators whose work is recognized outside any citation clique, which reproduces the Matthew Effect at the author level. This indicator uses citation author-position analysis to separate two kinds of citation, those from non-collaborators who have never co-authored with the researcher, and those from inside the collaboration network. It therefore measures recognition that network membership cannot explain. This is the one salvageable mechanism from perception-based reputation scores, extracted as an objective network measurement rather than a subjective impression.

Formulation.

Computing independence over pooled citations across a researcher's whole portfolio lets one or two high-citation papers dominate the statistic. Citation distributions run from lognormal to

power-law, so a small number of papers typically hold most citations. A researcher with one widely-cited method paper would then have their independence score determined almost entirely by that paper rather than by their body of work.

The indicator avoids this by computing independence within each paper first, then aggregating with a distribution-robust central tendency that treats each paper as one observation rather than weighting by citation count.

$$r(p) = |\{\ q \in Cit(p) : coauth(a,\ author(q)) = 0\ \}| \ /\ |Cit(p)|$$

computes the per-paper independence ratio, where *Cit(p)* is the set of papers citing paper *p* and *coauth(a, author(q)) = 0* holds when no author of citing paper *q* has ever co-authored with researcher *a*. Each ratio is then field-normalized against same-field, same-era papers, and the researcher-level indicator is the median across the portfolio:

$$IRI(a) = median\ over\ p \in Papers(a),\ |Cit(p)| \geq c_min\ \ of\ \ znorm(\ r(p)\ )$$

where *znorm(...)* field-normalizes the per-paper ratio to a z-score against the distribution of independence ratios for same-field, same-era papers (correcting for smaller fields having fewer possible non-collaborators), and *c_min* is a minimum citation floor excluding near-zero-citation papers that would add noise. The median across papers is robust to the one or two outlier papers distortion as a mathematical consequence, since a single dominant paper is one observation among many rather than the bulk of a pooled sum, which prevents the skewed-portfolio artifact that a citation-weighted pooled fraction produces.

AI specification.

A citation-network analysis over a co-authorship graph, computed per paper and then aggregated. The co-authorship graph is built from the full publication corpus. For each citation to each paper, the system checks whether any author of the citing paper has ever co-authored with the researcher. Per-paper independence ratios are field-normalized against same-field same-era distributions before the median aggregation. This requires accurate author disambiguation, which ORCID and modern name-disambiguation models provide with high but imperfect accuracy.

Parameters and thresholds.

Co-authorship is defined over all prior years with no decay, so any shared authorship at any time marks a citing author as network-internal. The citation floor excludes papers below the field-median citation count for papers of the same age, which removes low-signal papers without discarding recent or early-career work disproportionately, since the floor is relative to field and age rather than an absolute count. Hyperauthorship papers above 50 authors are excluded from the co-authorship-relationship computation, since consortium membership does not indicate a genuine collaboration tie.

Aggregation uses the median across qualifying papers as the primary statistic. The interquartile range is reported alongside it, which exposes a bimodal portfolio where some papers are highly independent and others network-internal. The full per-paper distribution is shown rather than collapsed, so a researcher is characterized rather than ranked. Where disambiguation

confidence falls below a per-author threshold, the researcher is flagged for manual review rather than given a possibly-erroneous automated score.

Implementation.

141. Construct co-authorship graph from full corpus with ORCID-based author disambiguation.
142. For each paper by the researcher, compute the per-paper independence ratio (non-collaborator citations over total citations to that paper).
143. Field-normalize each per-paper ratio against same-field, same-era papers to a z-score or percentile.
144. Aggregate across the researcher's papers using the median (or trimmed mean) over papers above the citation floor, so no single high-citation paper dominates.
145. Report alongside raw citation count and the per-paper distribution so evaluators see recognition quality across the portfolio, not just a pooled fraction driven by outliers.

Failure mode and mitigation.

Three failure modes require mitigation. Skewed-portfolio distortion, where one or two high-citation papers would dominate a pooled fraction, is addressed by the per paper, then median aggregation above. Author disambiguation errors misclassify co-authorship relationships, mitigated by ORCID-verified disambiguation. Large collaborations (consortium papers with hundreds of authors) distort the co-authorship graph, mitigated by excluding hyperauthorship papers above a co-author threshold from the relationship computation. The indicator is reported as a descriptive pattern with its per-paper distribution rather than a single rank, so network-embedded researchers are characterized, not penalized.

RFI category alignment.

Collaboration, as a measure of recognition independent of collaboration-network membership.

3.14 Reconciliation of Overlapping Indices

Note on deliberate overlap.

Building the SRQI step-indices fresh produced intended overlaps with three existing indicators, and the framework resolves each by scope rather than by deletion.

Gap identification appears twice. The reasoning-level Gap-Identification Index of Section 3.5.2 scores how well a single paper identifies and argues its gap from its own text. The network-level Gap Index of Section 3.7 tracks gaps across the literature and credits filling a gap that others independently identified. The first is a within-paper reasoning measure and the second is a cross-literature contribution measure. Synthesis also appears twice. The reasoning-level Synthesis-and-Integration Index of Section 3.5.10 scores connection density in the paper's own argument, while the Cross-Field Integration Index of Section 3.9 scores reference-list field span together with downstream integration, so the first reads the reasoning and the second reads the citation structure. Mechanism density appears as the mechanism dependency inside SSyn and as the Mechanism-Graph Centrality Index of Section 3.2, which scores a paper's concepts against the field-wide mechanism graph, so the first is internal and the second is network-level.

The pattern is the same in all three cases. The step-index is the within-paper reasoning signal, and the standalone indicator is the network or literature signal. They are reported separately, and the Data-Driven Innovation Composite treats them as correlated inputs per its scope note rather than as independent evidence.

RFI category alignment.

Cross-cutting, clarifying the relationship among Rigor, Foundational Exploration, and Collaboration indicators.

3.15 Gate-Contract Instantiation for Every AI-Based Component

The table fills the gate contract of Section 3.5.0 for each AI-based metric, so the building phase inherits a populated specification rather than a principle it must remember to apply. Each row is a required deliverable, a blank cell blocks the metric from build-readiness, and the acceptance-test column is the field that detects a build populated in form but not in function. Metrics with no content gate are named after the table as rule-based or constitutive, with the reason each is exempt, so the boundary is fixed here rather than left for a builder to draw.

Metric	Grounding artifact (emitted, ablation-verified)	Retrieval or evidence scope	Held-out features	Acceptance test (known-outcome)
SObs (3.5.1)	Retrieved k=50 prior-neighbor set with entailing sentences (novelty), plus an examined primary-data sample, waveform, trace, or image (fidelity)	Target subfield plus adjacent fields by geodesic	Categorical-language strength, venue prestige, abstract salience, narrative framing	Credits a corroborated novel observation, flags a re-presented known finding, and flags physiologically implausible primary data on held-out cases
SGap, SHyp, SSyn (3.5.2, 3.5.4, 3.5.10)	Retrieved prior claims that leave the gap open, that the hypothesis departs from, or that the synthesized link connects, each with source sentences	Target plus adjacent and connected fields by geodesic	The paper's own claim of a gap, of originality, or of interdisciplinarity	Credits a gap or link absent from the prior set, flags one the prior set already contains
SExec (3.5.7)	Extracted procedural parameters checked against the per-method-class reproducibility checklist (ARRIVE, MIQE, or a community equivalent)	Method-class checklist, not a corpus	Method-section length and the words rigorous or validated	Flags a named reagent without concentration or an antibody without catalog number, and flags results the stated method could not produce
SAna (3.5.8)	The paper's reported statistics and extracted data structure, checked against fixed statistical rules	Fixed rules of statistics and the paper's internal logic, not a corpus	The word significant without a p value, and conclusion-strength language	Flags test-to-data-type mismatch, pseudoreplication, and a conclusion about a quantity the test did not measure
MGCI (3.2)	The extracted mechanism-graph edges with the source sentence asserting each edge, emitted for human check	Biomedical relation-extraction corpus plus adjacent fields by geodesic	Claim language asserting a concept is central or important	Extracted edges match human-adjudicated edges above a stated F1, and centrality reproduces known hub concepts on

				held-out graphs
AAI (3.3)	Retrieved prior papers that state or rely on the assumption the paper claims to overturn, correct, or build past, with the entailing sentences	Target plus adjacent fields, so an assumption settled next door is caught	The paper's framing that it is the first to, and venue	Credits a genuine correction, does not credit a paper overturning an assumption no prior neighbor held, and recognizes a correction already made in an adjacent field
GI (3.7)	Retrieved prior papers documenting the gap across distinct author groups, with the documenting sentences	Target plus adjacent fields	The paper's self-declaration that a gap exists	Credits a gap independently documented by at least a stated number of distinct groups, does not credit a self-declared gap no prior work states
FDI (3.8)	Retrieved later adopting papers plus the first-use origin evidence, with citation-context sentences separating originator from elaborator and co-opter	Target plus adjacent fields plus downstream adopters	The paper's self-claim of origination, and venue prestige	Attributes origination to the true originator on held-out concept-lineage cases, does not credit a popularizer over the originator, and catches prior origination in an adjacent field
CFII (3.9)	Retrieved prior work in each connected field plus the sentences showing the borrowed method or concept is used in the analysis, rather than cited	Each connected field plus adjacents by geodesic	Cross-field citations that are tokenistic, and interdisciplinarity framing	Credits genuine methodological dependency and flags tokenistic cross-citation on held-out cases
VPEI (3.6)	The examined communication artifacts, verified reach records, and downstream policy or educational citation records	Content-quality scoring against a domain-accurate reference	Reach inflated by virality or controversy, and follower counts	Credits substantive accurate communication, does not credit high-reach low-substance output, verified against known policy-citation outcomes
CBI (3.11), content part	The reference set with its field, recency, and group distribution (structural), plus the entailment that each	The paper's reference list and the cited works	Raw reference count and self-citation padding	Rewards broad and apt referencing, does not reward a padded or off-target reference list

	sampled citation supports its citing sentence (content)			
SBTI (3.1), content part	Early-trajectory features (structural), plus the prior-neighbor set showing the paper is ahead of its contemporaries (content)	Target plus adjacent fields for the content part	Early citation count and venue	Content score is high at publication on known sleeping-beauty cases, does not fire on mere obscurity or low quality
DDIC (3.12), meta-learned	The per-component sub-scores it weights, each already gated and inspectable	The twelve upstream indicators, no direct corpus retrieval of its own	Raw citation counts, so it cannot learn to proxy citation	Predicts held-out disruption above a citation-only baseline, and preserves per-component transparency
EMI steps (3.5E)	The quantified requirement, the explored design points, and the validation results against each requirement, plus the prior-engineering neighbor set for the novelty axis	Prior engineering literature plus adjacent fields	Naming an operation in place of performing it, and device-marketing language	Credits a quantified and validated design, flags an unquantified requirement or a validation that skips a requirement, on held-out engineering papers
Analytical -mode floor (3.5A)	The retrieved prior set for the linkage-novelty check, and the citing sentences for the source-characterization check	Target plus adjacent fields	Fluent synthesis language and the number of citations spanned	Flags a synthesis that re-states known links, one that mischaracterizes a cited source, and one that smuggles an unstated assumption

Four metrics ground their scores in a retrieved set of prior claims rather than in primary data, meaning AAI, GI, FDI, and CFII. Their contract is met only when that retrieved set is the object the score is computed from, rather than a set displayed beside a score computed some other way. The ablation applies with full force here, since a relational metric is the easiest place to emit a nominal artifact. A builder who retrieves the neighbor set but scores from the paper's own framing has produced the presentation-gamed score the contract forbids. Each of these acceptance tests therefore includes a claim whose framing asserts a contribution the retrieved set does not support, and the metric passes only if it scores that claim on the set rather than on the framing.

The Data-Driven Innovation Composite is a learned meta-weighting rather than a content scorer, so its grounding artifacts are the per-component sub-scores it combines, each with its own gate, and its distinctive risk is learning to reproduce citation rank because citation is the easiest signal correlated with its disruption labels. Its held-out feature is therefore the raw citation count, excluded from its inputs so it cannot proxy citation, and its acceptance test requires out-of-sample disruption prediction that beats a citation-only baseline. A composite that

reproduces the citation ordering has added nothing and has reintroduced the incumbent it would replace.

Three metrics are part structural and part AI, and the contract binds only their AI part. SBTI computes early-trajectory features by rule and scores content novelty by the SObs machinery, so it inherits the SObs row for its content half. PSS computes data novelty and the primary-data ratio by provenance matching, and it reuses the SAna checks for statistical rigor, so its AI exposure is the SAna row rather than a separate contract. CBI computes breadth, balance, and timing from structure and scores citation aptness by entailment, so only the aptness component includes the content gate. Naming which half is AI keeps the structural half from being treated as gated, and the AI half from being treated as rule-based.

Two indicators have no content gate, because they compute from structure rather than from reading claims against priors. The Co-Author Composition Index derives team configuration from authorship and consented ORCID fields. The Independent Recognition Indicator computes over the co-authorship graph. Both are therefore rule-based, and their correctness requires correct counting rather than correct judgment. The constitutive metrics of the incentive arm are also rule-based. Stating this boundary explicitly matters, because the failure this whole section guards against is a builder assigning an AI metric to the rule-based side to escape the gate. The ablation is the enforcement. A metric that claims to be rule-based, but whose score moves when a retrieved neighbor set is withheld, is an AI metric operating without its contract.

Each row's acceptance test joins the Element 6 acceptance gates and the thin-prior stress test of Section 7.4 as a per-metric deployment condition, so a metric ships only when it passes the test written for its own failure mode. The framework that reaches deployment is therefore the subset of AI metrics that are real, rather than the full set with some built cosmetically and offset by an aggregate.

4. Diagnostic Arm: Indicator-to-RFI Category Mapping

The following table summarizes which of the fourteen top-level diagnostic-arm indicators address each of the seven RFI categories, where the Scientific-Reasoning Quality Index and Engineering-Method Index are meta-indices each composing named step-level sub-indices (Sections 3.5 and 3.5E). Indicators with primary alignment are noted as primary, and indicators with secondary alignment are noted as secondary. The incentive arm (Section 5) maps separately.

RFI Category	Indicators (primary and secondary)
Rigor and Reproducibility	AAI (primary), GI (primary), SRQI (primary), PSS (secondary)
Data, Software, and Model Sharing	Addressed by RGI (Reuse Generation Indicator) in the incentive arm, Section 5.3.1
Training and Mentorship	Addressed by TTI (Trainee Trajectory Indicator) in the incentive arm, Section 5.3.3
Collaboration	CFII (primary), CACI (primary), IRI (primary), CBI (secondary)
Entrepreneurship and	EMI (primary, for design-and-build work). Existing metrics

Translation	overweight translation as an outcome, so the framework adds no outcome-based translation indicator, but the Engineering-Method Index scores the quality of the engineering reasoning itself, which existing metrics ignore
Foundational Scientific Exploration	SBTI (primary), MGCI (primary), FDI (primary), GI (secondary), SRQI (secondary), CBI (secondary)
Public Impact	VPEI (primary)
Cross-cutting	PSS (substance calibrator), SRQI (reasoning-quality calibrator), CBI (real-time signal), DDIC (meta-composite)

Foundational Scientific Exploration is intentionally over-represented in the framework, with three primary indicators plus two secondary, because the existing metrics most damage this category. Entrepreneurship and Translation is intentionally not addressed with new diagnostic indicators because existing metrics already overweight translation, and the structural argument of this submission is that translation as the primary metric is itself the problem driving the false-positive failure mode.

5. Incentive Arm: Metrics Whose Construction Rewards Wanted Behaviors

This arm is the primary contribution of the submission. Most of its indicators require no artificial intelligence and can be enacted through human judgment and verified counts, which makes them deployable now and independent of whether any diagnostic-arm scorer is ever built. Where an incentive indicator does use AI components, it reuses the diagnostic-arm infrastructure and inherits the same gating preconditions. The arm leads with foundational and exploration incentives because those behaviors have the longest payoff horizon and the weakest existing constituency.

5.1 Design Principle: Constitutive Rather Than Proxy Metrics

The diagnostic indicators in Sections 3 and 4 detect quality the existing metrics miss, and they share the vulnerability of all proxy metrics. Goodhart's Law holds that when a measure becomes a target it stops being a good measure, because people optimize the proxy rather than the quality it stands for. That applies to any metric that stands in for something else.

It applies far less to a constitutive metric, where the measured behavior is itself the thing wanted. Consider a system that credits verified independent reuse of a shared dataset. The only way to score high is to produce a dataset other groups actually reuse, so gaming the metric is the wanted behavior. The incentive arm is built entirely from constitutive metrics. Each one is designed so that the dominant strategy for a researcher optimizing it is to perform more of the intended behavior.

The incentive arm rewards behaviors at their cost point, meaning the place where a researcher currently pays a career penalty for doing the wanted thing. Exploration costs failure risk, so the arm credits the failed high-risk attempt rather than only the success. Replication costs novelty, so it credits the replication. Data and tool sharing costs competitive advantage, so it credits verified downstream reuse. Corrective work costs the appearance of productivity, so it credits the dead end retired. Each indicator neutralizes the specific disincentive that currently suppresses a behavior the public-funding mission depends on.

The incentive-arm indicators vary in how fully constitutive they are, and the framework specifies this rather than claiming uniform gaming-resistance. The reuse, replication, corrective, and trainee indicators are fully constitutive. The only way to score high on them is to produce reusable artifacts, run replications, publish genuine corrections, or train independent scientists, so optimizing the metric is the wanted behavior.

Two indicators are only partly constitutive. The research risk portfolio is gameable by cheap-risk accumulation until its initiation-assessment mechanism exists, and the foundational investment indicator is gameable by relabeling incremental work. Even these tend to promote productive behavior, because the cheapest path to a high score still runs through attempting more ambitious work, or through foregrounding mechanism over translational packaging, and both are intended behaviors even in their gamed form. Where a residual gaming mode cannot be closed, the framework names it, so evaluators can weight the indicator appropriately and later work can address it, rather than presenting the metric as fully robust.

The incentive arm should receive heavier evaluative weight than the diagnostic arm, and the foundational and career-terminal metrics within it should receive the most. That weighting is structural rather than technical. Study sections reward near-term clinical translation because it is fundable within a grant cycle. Public and congressional sentiment reward the same, because visible cures arrive during the appropriations window.

Both forces already push toward the short horizon. An evaluation system that weights all work equally therefore under-invests in the long-horizon foundational research that has the greatest cumulative payoff and the weakest existing constituency. Heavier weight on long-horizon incentives corrects that standing imbalance, and only a public funder with a multi-decade mission has the mandate to make the correction. The incentive metrics are largely Goodhart-resistant, which is what makes the heavier weight safe to apply. The two partly-constitutive indicators are weighted more cautiously until their residual gaming modes are closed.

5.2 Foundational and Exploration Incentives

5.2.1 Research Risk Portfolio Indicator (RRPI)

Definition.

A career-spanning score of the high-variance, high-potential-value work a researcher has attempted, crediting the attempt itself including failed attempts, conditioned on the potential value of each attempt if successful.

Motivation.

Current metrics reward outcomes. A researcher who attempts ten high-risk projects and succeeds at one therefore scores worse than one who completes ten safe incremental projects, even though the first produced the more valuable result and advanced the field's state of knowledge. That penalizes the exploratory behavior foundational science requires, and only public funding tolerates it, because private capital cannot absorb a portfolio with a high failure rate. The Research Risk Portfolio Indicator credits the attempt at high-value risk rather than only the success. A researcher optimizing this indicator therefore attempts more ambitious work, which counters the chilling effect that suppresses exploratory volume.

Formulation.

$$RRPI(a) = \Sigma \text{ over } j \in Projects(a) \text{ of } risk(j) \cdot value_if_success(j)$$

where *risk(j)* is the prior probability of failure at project initiation (higher risk scores higher, and the score does not depend on whether the project succeeded), and *value_if_success(j)* is the potential value of the project conditional on success, assessed at initiation. Conditioning credit on potential value prevents the cheap-risk-accumulation failure mode, in which a researcher accumulates risk credit through many low-value attempts unlikely to succeed and unlikely to matter. Only high-stakes risk earns credit, not mere failure.

Implementation.

Robust specification requires a registered-report-style initiation mechanism. At project start, before outcomes are known, peer assessment records two things, the project's risk, meaning its probability of failure, and its potential value if it succeeds. This front-loaded assessment is

reliable because it does not require estimating the counterfactual payoff of already-failed work, which post-hoc scoring cannot do accurately.

A lighter interim specification uses AI scoring at publication or preprint time, measuring novelty distance from the researcher's prior work and departure from field consensus. That version is buildable immediately, and it is weaker, because it cannot assess potential value as dependably and is more exploitable by cheap-risk accumulation. The registered-report mechanism requires NIH to build initiation-time assessment infrastructure. That is a program-design investment beyond pure measurement, and it sits squarely within the incentives the RFI solicits.

Failure mode and mitigation.

Cheap-risk accumulation, meaning credit gathered through low-value long-shot attempts, is the dominant failure mode. Conditioning all risk credit on potential value assessed at initiation mitigates it. That mitigation depends on the registered-report initiation mechanism, which does not yet exist. The lighter interim AI-only specification therefore has no working defense against cheap-risk accumulation, and it should receive zero evaluative weight in funding or promotion decisions until the initiation-assessment infrastructure is built. The interim version is useful descriptively, for surfacing exploratory-work patterns, not for ranking.

Even in its unguarded interim form the indicator promotes a wanted behavior. The cheapest path to a high score still runs through more ambitious departures from consensus, which raises exploratory volume even without the potential-value conditioning. Peer-assessment capture at initiation is a secondary risk in the full version. Blinded multi-reviewer assessment mitigates it, together with periodic audit of initiation scores against realized trajectories.

RFI category alignment.

Foundational Scientific Exploration (primary).

5.2.2 Foundational Investment Indicator (FII)

Definition.

A score crediting sustained investment in basic, mechanism-level, and pre-competitive research that has no near-term translational application at the time of the work, measured by the depth and continuity of foundational contribution rather than by translational output.

Motivation.

Current metrics and study-section incentives reward translational framing. Researchers doing foundational mechanism work must therefore dress it in translational language to stay funded, which distorts the work and defunds the pure foundational inquiry with the longest eventual payoff. Basic science that industry will not touch, because its returns are decades away and no single actor can capture them, is the public-funding mission, yet no metric rewards it. The Foundational Investment Indicator credits sustained foundational contribution directly. Doing basic science is then rewarded rather than penalized, and researchers need not disguise mechanism work as near-term translation.

Formulation.

$$FII(a) = \Sigma \text{ over } p \in Papers(a) \text{ of } found(p) \cdot depth(p) \cdot (1 + delayed_realization(p))$$

where *found(p)* measures how far paper *p* is foundational rather than translational (scored from content, high for mechanism and theory work with no near-term application claim), *depth(p)* reuses the mechanism-graph centrality and paper-substance scores, and *delayed_realization(p)* is a bonus that accrues if the foundational work later enables translation, rewarding the researcher retroactively for foundational bets that matured.

Implementation.

Foundational-versus-translational scoring reuses the diagnostic-arm content classifiers, inverting the translation-hook detection so that absence of a near-term application claim combined with high mechanism centrality scores high. The delayed-realization bonus links foundational papers to later translational work that cites them as enabling, computed at long horizons (10 or more years), which requires the same longitudinal citation infrastructure as the sleeping-beauty indicator.

Failure mode and mitigation.

Researchers could relabel incremental work as foundational to capture the credit, mitigated by joint conditioning on mechanism-graph centrality and substance scores, so that foundational credit requires demonstrated mechanistic depth rather than a mere absence of translational claims. Field-stratified calibration is required because the foundational-translational balance differs across disciplines.

RFI category alignment.

Foundational Scientific Exploration (primary).

5.3 Behavior Incentives

5.3.1 Reuse Generation Indicator (RGI)

Definition.

Credit for verified independent reuse of datasets, code, reagents, protocols, and other research artifacts a researcher has shared, weighted by the independence and productivity of the reusing work.

This indicator addresses the Data, Software, and Model Sharing category the RFI names and the diagnostic arm defers. It is constitutive, since scoring high requires producing artifacts that other groups reuse, so gaming it is the wanted behavior. Verified reuse is tracked three ways, through data and code citation, through repository fork and download provenance, and through reagent-request records. Each is weighted by whether the reusing group is independent of the originator. Sharing costs competitive advantage, and this indicator credits at that cost point. Foundational and infrastructure artifacts are the highest-value case, meaning shared datasets, reference methods, and model organisms, because they are pure public goods the private sector will not create. RFI category alignment: Data, Software, and Model Sharing (primary), and infrastructure commons.

Formulation and data availability.

RGI(r) sums, over the artifacts a researcher has shared, the independence-weighted count of downstream reuses, where each reuse is weighted by whether the reusing group shares no co-

authorship tie (the IRI independence machinery) and by the reusing work's own substance, so a dataset reused by many independent productive groups scores far above one reused only by the originating lab. Reuse is detected from data-and-code citation (DataCite and software-citation records), repository fork and download telemetry where available, and formal reagent-and-materials citation.

Data requirement, partially available. Citation of data and code through DataCite and Software Heritage, together with repository telemetry, is queryable today, so the dataset-and-code portion is buildable now. Systematic reagent-and-materials reuse tracking is not. No queryable resource records which cell line, plasmid, antibody, or mouse line a downstream paper obtained from whom.

Capturing the reagent-and-materials contribution the definition names as highest-value therefore requires a materials-and-data-reuse registry that does not currently exist. NIH is uniquely positioned to build it, maintain it, and drive its adoption, since such a registry is itself non-appropriable public-good infrastructure the private sector will not create, and building it is a program-design investment squarely within the incentives the RFI solicits. Adoption would plausibly run through linkage to existing repositories such as Addgene, ATCC, and model-organism stock centers, and through a data-management-and-sharing-plan reporting requirement. Until that registry exists and reuse reporting is normalized, this indicator measures data-and-code reuse well and reagent reuse poorly, and the reagent gap should be stated wherever it is reported.

5.3.2 Corrective work (folded into the Assumption-Addressing Indicator)

Corrective and negative work earns near-zero annual reward but has large cumulative value. A field spared decades of chasing a wrong model is an enormous saved cost, and only non-commercial science performs this work, because there is no product in proving something does not work.

Earlier versions scored this with a separate corrective-contribution indicator. What that indicator measured at publication time, meaning how well a paper engages and overturns a wrong assumption, is the same act the Assumption-Addressing Indicator of Section 3.3 now scores. Its lagging question, meaning whether the correction was right and whether the field came to agree, is now the career-terminal Assumption-Correctness Indicator of Section 5.4.2. The two-metric split is deliberate. The quality of a corrective engagement is observable at publication, while its correctness is observable only over years, and binding them into one score would force the correctness question to be answered prematurely. Corrective work is therefore credited by AAI at the paper level and by the career-terminal correctness metric across a career, rather than by a separate incentive-arm indicator here.

5.3.3 Trainee Trajectory Indicator (TTI)

Definition.

Credit for the positive career outcomes of a researcher's trainees, broadly construed to include both independent scientific success and successful careers outside research, weighted toward outcomes that reflect the trainee's own trajectory rather than the mentor's. A trainee who launched an independent research direction distinct from the mentor's and a trainee guided into a well-fitting non-research career both count as successes, and not the former alone.

A career's largest long-term multiplier is often the people it launched, and current metrics credit none of this terminally. This indicator credits a trainee's independent scientific success, meaning their own funding, their own foundational contributions, and their own trainees. It credits verified successful non-research careers equally. Both are weighted toward divergence from the mentor's exact topic, so the metric rewards training for independence rather than cloning.

One design principle is essential here. The metric must not reward retention for its own sake, meaning the pattern of keeping a poorly-suited trainee in the laboratory for years of low-productivity work before an eventual washout. Recognizing early that a trainee is not suited to research, and guiding them into a career where they will thrive, is a good mentorship act that saves the trainee years of lost productivity. This indicator therefore counts that redirected trainee as a success rather than a zero, and it never scores a departure as a negative. It is constitutive, since scoring high requires producing people who succeeded, in or out of research, rather than retaining bodies. This addresses the Training and Mentorship category the RFI names and the diagnostic arm defers. RFI category alignment: Training and Mentorship (primary).

Formulation and data availability.

This indicator sums each verified trainee's positive outcome score across a researcher's trainees. A research-track trainee contributes their independent scientific success, meaning independent funding, last-author output, and their own trainee production, weighted toward topical distance from the mentor by the SObs field-distance machinery. A non-research-track trainee contributes a verified successful career outcome, meaning a stable position in a science-adjacent field, industry, policy, education, or another profession. Departures are never scored negatively, so a mentor is not penalized for a trainee who left. A trainee redirected early into a well-fitting career counts as a positive outcome, which removes any incentive to retain a poorly-suited trainee for the mentor's short-term labor. The sum is normalized by trainee count and career stage, so large laboratories do not dominate by volume and recent mentors are scored on their trainees' trajectories so far with appropriate uncertainty.

Data requirement, partially available and partly manual, with one component difficult. Mentor-trainee links are recoverable from co-authorship followed by independence patterns, and from dissertation and ORCID records for some trainees. A per-laboratory research-track score is therefore assemblable by hand today. Population-scale automated scoring requires the training-lineage registry listed in Section 6.6, which NIH would build and which does not currently exist. The non-research career outcome component is harder still. No systematic source tracks where trainees went after leaving academia, so that component would depend on the same registry incorporating voluntary career-outcome reporting, plausibly through institutional alumni tracking or a trainee-outcome reporting requirement tied to training grants.

One limitation is intrinsic and stated here. Honest early redirection of a poorly-suited trainee, and neglectful churn of a mismentored trainee, can produce similar external traces, since both show a trainee leaving. Distinguishing them requires knowing whether the departure served the trainee, which the records do not hold. The rule against scoring departures negatively avoids penalizing honest redirection, and it also means the metric cannot by itself reward good redirection over bad churn. Fully separating the two would require a trainee-side signal, meaning an alumni assessment of whether the training served their eventual career, which no

current mechanism collects and which would raise its own gaming and privacy considerations. Until such a signal exists, this indicator credits verified positive outcomes and stays silent on departures, rather than pretending to judge the quality of a departure it cannot observe.

5.3.4 Replication Contribution Indicator (RCI)

Definition.

Credit both for performing replication studies and for producing original work that independent groups successfully replicate, where the replication relationship between two papers is detected by comparing their experimental structure across the corpus rather than requiring either paper to declare itself a replication.

Replication scores near zero on current career metrics despite being foundational to a reliable evidence base. This indicator credits two things, performing replications, which cost novelty, and producing replicable work, verified when an independent group re-runs the design and confirms the result. Detection compares experimental structure across the corpus, so a replication need not declare itself. The same comparison distinguishes three relationships a later paper can bear to an earlier one, and only replication is credited here. It is constitutive on both sides, since scoring high requires either running real replications or writing methods rigorous enough that independent replication succeeds. RFI category alignment: Rigor and Reproducibility (primary).

Formulation and data availability.

This indicator detects the relationship between a later paper and an earlier one by comparing experimental structure together with the temporal and citation pattern between them. The compared structure is the experimental groups, control groups, model system, and measured endpoints, extracted by Element 1 of Section 3.5.0 and matched by Element 2. The relationship is then classified into one of three, and only replication earns credit.

Pure replication is a large publication-time gap, plus a back-reference to the earlier paper, plus a re-run of substantially the same design. It earns credit for the replicator and, on the other side, for the original paper whose work proved replicable when the results concord. Independent convergence is a small time gap, within the field-calibrated concurrent-submission window, with no back-reference, which indicates two groups had the same idea at once. That is corroboration rather than replication, so it is labeled but not scored here. Extension is a shared experimental base with added analysis, characterization, or data the original lacked. That is a distinct valuable act, scored by the Extension and Deepening Indicator of Section 5.3.5 rather than credited here.

Both replication directions are weighted by the independence of the replicating or replicated group, through the IRI co-authorship machinery. Concordance, meaning whether the replication confirmed or contradicted the original, is detected by comparing the reported results through the Element 2 entailment machinery.

Data availability, computable now with qualifications. The three-way detection reads the existing corpus through the Element 1 and Element 2 machinery, so this indicator no longer depends on a replication-linkage registry as a precondition and is buildable now. The registry listed in Section 6.6 would improve precision and record outcomes the corpus does not state explicitly.

Separating independent convergence from replication turns on a concurrent-submission window, field-calibrated from each field's publication-lag distribution rather than fixed. That window also accounts for preprint priority dates, since a preprint posted a year before journal publication moves the priority date and can turn an apparent replication into independent-but-earlier work, or the reverse. Three limitations remain. Design extraction and cross-paper matching have a nontrivial error rate that varies by field reporting convention. Concordance detection, meaning whether the replication confirmed the original, is a further entailment step with its own error rate. And the convergence window is noisy at its boundary, where publication lags overlap.

5.3.5 Extension and Deepening Indicator (EDI)

Definition.

Credit for taking a prior experimental base and adding the analysis, characterization, or data collection the original lacked, the research goes deeper act that matures a field and that current metrics undervalue because it is neither a celebrated novel breakthrough nor a pure replication.

Motivation.

Most work that reuses a prior experimental design does not replicate it. It extends it, running substantially the same conditions while collecting data the original missed, characterizing a mechanism the original left unexamined, or pushing the analysis deeper. This is how fields actually mature, yet it falls in the gap between novelty and replication that citation counts and venue prestige both undervalue. This indicator credits the deepening act directly. It credits only the extender, since the original base is credited by its own metrics, and it is constitutive because scoring high requires actually going deeper on a real prior base rather than repackaging it. RFI category alignment: Rigor and Reproducibility, and Foundational Scientific Exploration.

Formulation and data availability.

This indicator shares the replication indicator's corpus-comparison detection. It identifies an extension relationship as a shared experimental base, meaning high design overlap by the Element 1 and Element 2 machinery, combined with added analysis, characterization, or data absent from the original. Credit requires clearing two guards that together block trivial add-ons.

A depth guard scores the substance of what was added relative to the original, using the SObs and SAna machinery on the added material. A single confirmatory figure or a cosmetic reanalysis therefore does not qualify, and only a substantive deepening does. A gap-filling guard then requires the addition to answer a question the original raised or left open, tested by entailment between the original's stated limitations or open questions and the extension's contribution. Adding arbitrary data unrelated to what the original needed therefore does not score. Only work clearing both guards is credited, and only to the extender. This is computable now from the corpus through the shared detection machinery, with the same design-extraction error-rate qualification as the replication indicator, and the registry of Section 6.6 would improve precision without being a precondition.

Failure mode and gaming defense.

Salami extension is the dominant gaming vector here, meaning credit gathered through many minor me-too papers with one added figure. The depth guard blocks it by scoring the substance

of an addition rather than its existence, and the gap-filling guard blocks it by requiring the addition to address a question the original actually left open. A second vector is claiming a shared base the paper did not truly build on, blocked because design overlap is measured from the extracted experimental structure rather than from the paper's framing. Both guards emit their grounding, meaning the original's stated open question and the specific added analysis, so a reviewer can verify each extension credit against the two papers rather than trusting the score.

5.4 Career-Terminal Incentives

5.4.1 Lifetime Foundational Impact Indicator (LFII)

Definition.

A metric computed once, late in or after a career, scoring the whole arc of a researcher's foundational contribution across dimensions no annual metric can observe, ordered by what most advances science over the longest horizon.

Motivation.

The Nobel Prize and National Academy membership are the field's existing career-terminal metrics. They are sparse, slow, politically mediated, and they recognize a few researchers per generation. Every other metric in the evaluation system operates on annual or grant-cycle horizons that cannot register origination, delayed payoff, or generativity, because those resolve over decades.

The absence of a computable career-terminal metric means the vast majority of researchers have nothing to strive for that rewards the long-horizon foundational bets the annual metrics actively punish. This indicator scores, once and late, the accumulated foundational contribution of a career. It gives researchers a long-term target that rewards the risks, discoveries, and field-building the near-term system suppresses. It is almost inherently Goodhart-resistant, since a metric computed once over decades of work cannot be gamed by writing to a scorer within any tractable optimization horizon.

Formulation.

$$LFII(a) = w_1 \cdot Orig(a) + w_2 \cdot Delayed(a) + w_3 \cdot Risk(a) + w_4 \cdot Gen(a) + w_5 \cdot Corr(a) + w_6 \cdot Infra(a)$$

The six components are ordered by how much each advances science over the longest horizon, and equivalently by how strongly each represents work only public funding will support, since the two orderings coincide (the most generative and longest-maturing acts are also the least appropriable by private capital):

146. Origination (Orig): fields, methods, concepts, or tools that did not exist and now do, and that others built on. First because origination is the rarest and most generative scientific act, enabling thousands of downstream careers.

147. Delayed impact realized (Delayed): work that scored low for years or decades and then became foundational, the sleeping-beauty payoff. Second because it is the direct empirical case for patient public funding, visible only to a metric that waited.

148. Risk portfolio (Risk): the lifetime record of high-variance, high-value attempts, crediting the failed bets alongside the successes. Third because it rewards the exploratory behavior itself.

149. Generativity (Gen): the independent scientific lineage launched, trainees who became independent scientists and diverged from the mentor's topic. Fourth because a career's largest long-term multiplier is often the people it produced.

150. Corrective contribution (Corr): work that overturned an error, retired a dead end, or resolved a controversy, sparing the field wasted decades. Fifth because corrective value is large cumulatively and rarely rewarded elsewhere.

151. Infrastructure and commons (Infra): datasets, reagents, tools, cohorts, and methods that became shared infrastructure the whole field depends on. Sixth, and the most direct public-goods case, since shared infrastructure is non-appropriable by its nature.

Implementation.

Each component reuses infrastructure from the diagnostic and incentive arms computed at career-terminal horizons. Origination reuses the field-define indicator. Delayed impact reuses the sleeping-beauty trajectory realized at long horizon. Risk reuses the research risk portfolio. Generativity reuses the trainee trajectory indicator. Correction reuses the assumption-addressing indicator at the paper level and the assumption-correctness indicator (Section 5.4.2) at career horizon. Infrastructure reuses the reuse generation indicator aggregated over a career. The weights are set by the evaluating body (an academy, an award committee, a lifetime-achievement mechanism) rather than canonically, preserving the anti-homogenization principle.

Failure mode and mitigation.

The dominant risk is not gaming but measurement lag and attribution, since career-terminal scoring depends on decades of downstream data and on correctly attributing origination and delayed impact across long citation chains. Mitigation requires the long-horizon citation and provenance infrastructure specified for the sleeping-beauty and field-define indicators, and explicit uncertainty reporting on each component given the attribution difficulty over long time spans.

RFI category alignment.

Foundational Scientific Exploration (primary), spanning Public Impact, Training and Mentorship, and Rigor through its component structure.

5.4.2 Assumption-Correctness Indicator (ACI)

Definition.

A career-terminal measure of whether a researcher's assumption-challenges turned out to be right. It is scored once and late, and it states the time lag openly. It supplies the correctness layer that the Assumption-Addressing Indicator of Section 3.3 deliberately leaves out at publication time.

Motivation.

The Assumption-Addressing Indicator scores how well a paper engages a wrong assumption at publication. It cannot know whether the challenge was correct, since correctness is revealed only by what the field's later evidence shows. Separating the two questions along the horizon axis is the point. The quality of an assumption-challenge is observable now, while its correctness is observable only over years, so one metric measures the act at publication and a second measures the outcome across a career. Placing the second among the career-terminal incentives matches how an academy, an award committee, or a retrospective assessment already reasons, asking not what a researcher published but what of it held up.

Formulation and data availability.

ACI sums, over the assumption-challenges a researcher mounted (identified by their AAI-scored papers), whether each was subsequently vindicated by the field's accumulated evidence, measured as eventual field-concordance, how far later independent work came to agree with the challenge, read from the downstream corpus at long horizons. It is inherently a lagging measure and is scored only at career or post-career timescales, with explicit per-challenge uncertainty given the attribution and timing difficulty. The measure is buildable from the downstream corpus without new infrastructure, though it accrues over the decades its horizon requires.

Failure mode and mitigation.

The honest limit is that this indicator measures eventual field-concordance as the best available proxy for correctness, rather than correctness directly. A field can be slow, can be wrong for a long time, or can vindicate a challenge only partially, and these usually converge with truth but not always and not quickly. The indicator states that proxy relationship rather than claiming to measure correctness itself, and it reports each challenge's outcome with its horizon and uncertainty rather than as a settled verdict. Attribution across long citation chains is the secondary difficulty, mitigated by the same long-horizon provenance infrastructure the sleeping-beauty and field-define indicators require.

RFI category alignment.

Rigor and Reproducibility and Foundational Scientific Exploration, at career-terminal horizon.

6. Implementation Principles

6.1 Auditability and the Open-Reproducibility Precondition

Every model in the framework must be inspectable, and open reproducibility is a hard precondition for deployment rather than an aspiration. No scorer should be deployed whose training data, calibration, and computation cannot be independently reproduced and audited by parties outside the body that built it. This is the specific defense against training-capture, meaning the risk that incumbents calibrate the scorer to ratify the existing hierarchy while appearing objective. Black-box outputs are not acceptable for funding decisions or career evaluation. Implementation requires four things, open-source code, published training-data composition, feature-importance transparency at the per-inference level, and external audit by independent bibliometric experts every 18 months with results published openly. A scorer that cannot meet the reproducibility precondition should not be used, and the incentive-structure reforms, which require no scorer, should be pursued independently.

6.2 Network-Blindness

The content scorers deliberately exclude the social graph that current committee judgment is captured by. They score what is in the paper and, for citation-based indicators, the pattern of who cites whom. They do not take institutional prestige, training lineage, or collaboration-network membership as inputs to quality scoring. That exclusion is how this framework escapes relationship-laundered evaluation, replacing errors structured by who you know with errors that are random with respect to social position. The Independent Recognition Indicator applies the same principle to citation analysis, separating recognition from non-collaborators from network-internal citation. Network-blindness is a design requirement rather than an incidental property, and any modification that reintroduces prestige or lineage as a scoring input would reintroduce the bias this framework corrects.

6.3 Bias Testing

Every indicator must be tested for bias across demographic and structural subgroups including gender, race, ethnicity, institutional tier, geographic region, and career stage. Bias-correction terms in loss functions are required during training. Continuous monitoring after deployment is required with quarterly bias reports published openly. The DDIC meta-composite has the highest bias risk because it aggregates across all components and can amplify component-level biases.

6.4 Temporal Stability and Adversarial Retraining

Adversarial retraining cycles every 12 to 18 months are required, to prevent gaming of the diagnostic-arm indicators. Researchers will learn the indicators' features over time, so those indicators must evolve to keep their validity. The PSS, AAI, SRQI, and VPEI components are most vulnerable, because they score content-level features authors can engineer. Incentive-arm indicators need far less adversarial retraining, because they are constitutive rather than proxy, so gaming them produces the wanted behavior. The career-terminal metric is ungameable within any tractable optimization horizon.

6.5 Complementarity with Peer Review and Weighting Guidance

Diagnostic-arm indicators are advisory inputs to peer review and not autonomous replacements for expert judgment. The incentive-arm indicators, being largely Goodhart-resistant, can receive heavier evaluative weight, and the foundational and career-terminal metrics in particular receive the heaviest weight for the reason given in Section 5.1. Cases where indicator scores and peer judgment diverge are the most informative for both indicator refinement and review-process improvement, and any deployment must preserve peer-review primacy for the diagnostic arm.

Because indicators differ in gaming-resistance, the framework recommends tiered weighting rather than uniform application. The fully constitutive incentive indicators can bear the heaviest weight, meaning reuse generation, replication, corrective contribution, and trainee trajectory, together with the career-terminal metric. Gaming those produces the wanted behavior, and the terminal metric is ungameable within any tractable horizon. Partly constitutive incentive indicators bear moderate weight, meaning the research risk portfolio and foundational investment, with the interim risk-portfolio version receiving zero weight until its initiation mechanism exists. Diagnostic indicators bear advisory weight. VPEI, the one proxy metric near the incentive arm, is capped below the constitutive indicators.

Three residual gaming modes have been named and cannot be closed by measurement. They are the resource-access advantage in co-author composition, reach-gaming in public engagement, and cheap-risk accumulation in the interim risk portfolio. Naming them is deliberate, for three reasons. Evaluators can then discount appropriately, each indicator is used descriptively rather than as a rank, and later methodological work can target the open problem. Even these partly-gameable indicators are retained, because their gamed forms still route through intended behaviors.

6.6 Governance

Indicator development, audit, and update must occur through transparent multi-stakeholder governance including NIH Office of Science Policy, university research offices, scientific societies, bibliometric experts, and patient and public advocacy representatives. Single-contractor opaque development is unacceptable. Funding for indicator development should follow open-science principles with code and training data available to the research community. The registered-report initiation infrastructure required by the Research Risk Portfolio Indicator is a program-design investment that NIH would build and govern directly.

Several indicators depend on data infrastructure that does not yet exist, and NIH is uniquely positioned to build it, maintain it, and drive its adoption. Each piece is non-appropriable public-good infrastructure the private sector will not create, and each raises the measurability of behaviors the RFI identifies for reward.

152. A materials-and-data-reuse registry linking downstream work to the datasets, code, and physical reagents it reused, required by the Reuse Generation Indicator and plausibly built on existing repositories and on data-management-and-sharing-plan reporting.

153. A citation-intent layer, classifying whether a citation corrects, supersedes, or builds on the cited work. This would improve the precision of the Assumption-

Correctness Indicator and related citation-derived signals. Those signals are computable by citing-sentence entailment without the layer, at a higher noise level.

154. A replication-linkage registry, connecting each replication attempt to its target study and recording the outcome. This would improve the precision of the Replication Contribution Indicator. That indicator is now computable from corpus comparison without the registry.

155. A training-lineage registry recording verified mentor-trainee relationships and, ideally, trainee career outcomes in and out of research, required by the Trainee Trajectory Indicator.

156. The registered-report initiation-assessment mechanism required by the Research Risk Portfolio Indicator.

Building these is a program-design investment. The metrics that depend on them reward sharing, correction, replication, mentorship, and risk, which are the specific behaviors currently under-rewarded. The infrastructure investment and the incentive it enables are therefore the same act.

6.7 Anti-Homogenization

Content-scoring indicators create a convergence risk that citation counts do not have. If a scorer rewards a particular reasoning structure, methodological template, or synthesis style, the field will converge on that structure and penalize different cognitive approaches, which is the opposite of what foundational exploration requires. The framework addresses this risk with three provisions.

First, multi-component indicators must report their components separately rather than as a collapsed score, meaning SRQI, PSS, CBI, and LFII, so no single composite ranking forces convergence. Second, evaluating committees select role-appropriate component weights rather than applying a canonical weighting, so different roles reward different profiles. Third, scorers that assess reasoning or synthesis quality, meaning SRQI component eight, MGCI, and CFII, must be calibrated to reward variety in reasoning structure across a field rather than proximity to any single high-scoring exemplar. That calibration is measured by monitoring the diversity of high-scoring reasoning structures over time, and convergence is flagged as an indicator-failure signal requiring recalibration. An indicator that produces increasing homogeneity of high-scoring work across successive cohorts is malfunctioning regardless of its predictive accuracy on historical cases.

6.8 Gaming Defenses and Their Coverage

Gaming defenses here are judged against the metric they would replace, not against perfection. The applicable baseline for the automated layer is h-index and high-impact-venue counting. A defense that reduces a gaming route the incumbent leaves open, or actively rewards, is an improvement even when it does not close that route completely.

The defenses follow an escalation principle. Exhaust the corpus-anchored checks first, then the ecosystem-level checks, and invoke human review last. That ordering follows from this document's own premise. The founding argument is that human judgment is laundered through relationships and biased by prestige, which makes human review the most biased tier rather

than a clean backstop above the automation. Human review is never eliminated, because it remains the honesty and transparency check no automated tier can fully replace. It is pushed as late as possible and bounded when invoked, applied to the residue the corpus and ecosystem checks cannot reach rather than treated as the court of first appeal. The tiers below appear in escalation order, corpus checks, then ecosystem checks, then the bounded human check. Each tier's own bias is named, so the ordering reduces total bias rather than exchanging a visible bias for a hidden one.

The principal defense is the temporal-corpus false-novelty check, which anchors gaming detection outside the paper's own text. Each novelty or gap claim is tested against the corpus published before the submission or preprint date, using the same-year-or-prior retrieval of the SObs novelty dimension and the SGap gap-reality feature. The test asks one question. Was the connection the paper claims as novel already present at threshold density in the prior literature? A claim of novelty for a connection the field was already making is flagged as false novelty. The prior corpus is fixed at submission time, so an author cannot manipulate it. That moves the defense from a property of the paper, which a writer controls, to a fact about the corpus, which a writer does not. The check credits recovery of dormant work through the dormancy exception of the SObs novelty dimension, so resurfacing lost prior art is rewarded rather than penalized. The h-index has no concept of novelty at all and cannot tell a new finding from a restatement of common knowledge, so this check adds a discrimination the incumbent entirely lacks.

Two limits belong here. First, the check verifies that a claimed-novel connection was absent, but it cannot judge whether an absent connection is worth drawing. Novelty that is real but trivial therefore passes at submission, and only the lagging uptake metrics catch it later. Second, the check inherits the coverage of its retrieval substrate. A novelty claim against a thinly-indexed, non-English, or adjacent-field literature the retrieval does not reach can pass falsely, and an informed gamer could aim at that. Multiple retrieval methods and cross-lingual embeddings reduce this without closing it. The check also reports its corpus-coverage confidence for each claim, so novelty confirmed only against a thin corpus is flagged as lower-confidence rather than passed as clean.

Cross-metric consistency is the second defense, and it catches a broad class of gaming, because an isolated gamed signal produces a profile its neighbors contradict. A paper that games novelty but has thin execution shows high claimed novelty against low SExec and SAna. That is a recognizable adversarial signature, and the ensemble scores it as a mismatch. A citation clique that inflates one signal also finds no corroboration from the independence-weighted others. This defense is real, and it closes most single-route gaming. Its limit is structural. It catches only gaming that produces inconsistency. A sophisticated actor who builds coherent mediocrity, where every signal is individually plausible and all of them agree at a modestly inflated level, is not caught, because nothing contradicts. Summing consistent but inflated signals conceals the gaming instead of revealing it, which repeats the false confidence in one aggregate that this framework opposes elsewhere. The claim here is therefore narrow. The ensemble closes gaming that produces inconsistency, not gaming in general.

Two routes survive the per-paper defenses. Both are addressed by widening the scope from the single paper to the temporal ecosystem around it, which is an AI computation over a body of work and its distribution rather than a human judgment call.

The first route is salami-slicing, meaning one study divided into several papers, each individually honest and each novel against the prior corpus. It is invisible at the per-paper level, and invisible to any sum of per-paper scores, because the gaming lives in the division rather than in any one paper. AI author-ecosystem analysis can detect it. That analysis reads the cluster of papers one group published in a time window and looks for the signature of an artificially divided study, meaning shared methods and cohorts, overlapping data, and telling citation timing. This is a corpus computation over an author's output rather than a per-paper score. It is also less biased than a human auditor, who might wave salami through from a prestigious laboratory and flag it from an unknown one. The ecosystem check belongs to the governance and audit function of Section 6.6, because it operates on a person's output, but it runs before any human audit. The h-index actively rewards salami-slicing, since more papers accruing citations raise the index. Even before the ecosystem check, then, per-paper contribution scoring is less vulnerable to salami-slicing than the incumbent that encourages the division.

The second surviving route is coherent multi-metric inflation, the coordinated-mediocrity attack described above, and it is the harder one. Adversarial retraining in Section 6.4 addresses part of it, and ecosystem-covariance detection addresses another part. Real quality co-varies across metrics in specific, spiky ways. Engineered coherence instead sits at a too-uniform level of modest inflation, which is anomalous against the way genuine papers' signals actually co-vary. Building coherent inflation across many independent dimensions costs far more than the volume-and-prestige gaming the h-index rewards. The framework therefore raises the cost of gaming even where it does not eliminate gaming, which is the achievable win against an incumbent that is cheaper to game.

Some fabrication produces a plausible artifact. Invented but internally consistent data, a real but cherry-picked finding, or an experiment repeated until a clean result appears all yield a paper whose signals look honest, because the dishonesty sits in the process that generated the data rather than in the artifact.

A large fraction of this is still reachable by AI ecosystem analysis that no single reader can match. That analysis includes statistical fingerprinting across a paper's reported values, meaning digit-distribution and variance-structure anomalies, cross-paper image-reuse detection, impossible-consistency detection, and comparison of the paper's reported effect sizes against the distribution of real effect sizes in the field. These checks catch more fabrication than citation counting, which never examines the artifact, and more than a human reading one paper alone. They are therefore exhausted before human review rather than after.

Two things remain. One is fabrication that survives ecosystem fingerprinting because the invented data were built to match the field's real distributions. The other is the consequence question the corpus cannot answer, whether a technically novel connection is worth anything. For that residue, and only that residue, the framework invokes human review as an honesty and transparency check. That review is bounded by the same controls applied elsewhere, meaning blinding where feasible, diverse panels, and published reasoning, so the human tier's own relationship and prestige bias is constrained rather than trusted. Human review is never eliminated, because transparency and honesty require a human accountable for the judgment. It is invoked last and on the smallest possible residue, which inverts the usual arrangement, where biased human judgment is the court of first appeal.

The escalation reduces total bias but does not eliminate it. The ecosystem tier has its own bias, and naming it matters, or the reordering exchanges a visible bias for a hidden one.

Widening from the single paper to the ecosystem does not make the judgment objective. The ecosystem itself, meaning the citation network, the retrieval corpus, and the distribution of real effect sizes, is a product of the same prestige and access dynamics this framework criticizes. If the ecosystem skews toward well-funded and well-indexed work, then anomalous against the ecosystem can quietly come to mean unlike what advantaged laboratories produce. That would penalize the neglected and unconventional work this framework credits. It is also the recursive form of the problem of metrics becoming targets, applied to the ecosystem itself.

The ecosystem tier is therefore less relationship-biased than human review, but it has coverage and representation bias along field, language, and resource lines. Two provisions bound it. First, ecosystem anomaly flags are confidence-discounted for under-represented fields and thin-coverage literatures, so a paper flagged as anomalous only against a sparse ecosystem is treated as low-confidence rather than low-quality. Second, an anomaly against the ecosystem is never a quality penalty on its own, because founding and neglected work is inherently anomalous against the distribution it departs from. An ecosystem flag therefore routes to review rather than to a score reduction. That preserves the framework's core commitment, that departure from the field's normal range is a novelty signal and not a deficiency.

6.9 Always-On Grounding Guards, Adjacent-Field Borrowing, and Per-Claim Prior Weighting

Every AI-based scorer in this framework inherits the novelty, fidelity, and rigor gates of Section 3.5.0, and each gate judges a claim against priors. Three failure modes attend that judgment, and they occur in every field rather than only in young ones. Presentation-gaming scores a claim at the strength its framing asserts, meaning bold categorical language, a high-visibility venue, and a clean narrative, whenever the priors needed to check it are not brought to bear. False novelty credits a finding as new whenever retrieval does not reach the prior work that already holds it. Summary-scoring credits a measurement whenever its statistics are accepted without examining the primary data beneath them. These are pathologies of the scoring act rather than of a field's age. They surface wherever the prior for a specific claim is thin, and that happens at a mature field's newest questions and interdisciplinary boundaries as readily as across a young field's whole corpus. Two documented patterns fit this. A categorical tissue-response claim was credited on recording summaries whose underlying waveforms were physiologically implausible. An observation was credited as novel that an adjacent older literature had already established. Both occurred in a field with every surface marker of maturity, and each passed the field's citations and an initial trace for the same reason.

The guards below therefore run unconditionally, on every claim in every field. A gate that fired only when a field-level maturity detector flagged the field would skip the mature-looking fields where those two patterns occurred. What varies is not whether a guard runs, but how much confidence attaches to its output, and that variation is measured per claim rather than per field. A local-prior-density signal estimates how well-settled the relevant priors are for the specific claim. It draws on three things, the replication and citation-linkage density around the claim's own topic, the distance to the nearest prior work retrieval surfaced, and the terminological stability of the claim's central terms. This per-claim measure replaces the field's aggregate

maturity, which averages over the local prior-poverty that lets a specific claim slip through. A claim with thin local priors, or one scored against distant borrowed priors, has its guard outputs confidence-discounted and reaches human scrutiny earlier. Demoting the maturity signal from an activation gate to a per-claim confidence weight removes a single point of failure. A miscalibrated weight degrades a score's confidence gradually, whereas a gate that fails to fire skips the check entirely and silently. The local-prior-density estimate is imperfect and partly gameable, as the field-level version was, but its failure now costs a confidence miscalibration rather than a skipped guard.

Adjacent-field prior borrowing is the first guard, and it is correct retrieval, run always rather than as a rescue for young fields. Each gate draws its priors from the target subfield together with the adjacent fields identified by the Element 2 concept-graph path, never from the target subfield's citation graph alone. A finding is prior art, and a plausibility standard is binding, whether it sits in the subfield or one field over. Three instantiations follow:

157. The novelty gate always retrieves against the adjacent fields as well as the target subfield. A finding already present in an older or adjacent literature is therefore recognized as prior art, even when the subfield's own citation graph never linked to it. This is the check that catches a re-presented observation the subfield believes is new.

158. The fidelity gate always checks a claim's primary data against the nearest settled model of what physiological or physical data of that kind looks like, wherever that model resides. A subfield's failure to consolidate a prior therefore does not let implausible data through. This is the check that flags a non-physiological waveform against mature electrophysiology's settled action-potential morphology.

159. The rigor gate always evaluates a claim against the settled reporting and analysis standards of its parent discipline as well as the subfield. An emerging area is therefore held to the established standard of the discipline it grew from, rather than to its own norms that have not yet settled.

Adjacency is chosen by concept-graph path, and the borrowed-from fields are named in the output, so a human can reject an adjacency that does not apply. An area departing from its parent field may make the parent's priors wrong for a given claim. Borrowed priors are therefore applied as flags that route to scrutiny, never as automatic score reductions. The scorer also reports how much of each score rests on borrowed priors rather than native ones. A score resting heavily on distant borrowed priors receives lower confidence under the per-claim weighting, and it is read as a prompt for human judgment rather than a settled result. This preserves the framework's commitment that genuine novelty, including a real departure from a parent field, is a signal and not a deficiency. It still catches the false novelty and the implausible primary data that a within-subfield check would miss.

The anti-presentation-gaming rule is the second guard, and it is unconditional as a property of the rule, because it is a held-out-feature discipline rather than an escalation. A claim's presentation features are held out and cannot contribute to any score. Those features are the strength and boldness of its categorical language, its abstract salience, its venue prestige, and its narrative framing. This matches the held-out surface features already required for the reasoning steps, so that naming an operation does not substitute for performing it. Each score is set only by the grounding evidence Section 3.5.0 requires, meaning the retrieved neighbor set,

the examined primary-data sample, and the warrant-appropriate rigor criteria. A claim asserted more strongly than its grounding supports is flagged by the claim-alignment check rather than credited for the force of its assertion. This is the computational form of a discipline that a reader with mature priors applies without effort, judging a claim by its evidence and not its framing. Installing it as a hard held-out-feature rule is what keeps the scorer from being gamed the way a credulous citation record is gamed.

Escalation is modulated per claim rather than switched by a field-level flag. When a claim's local priors are thin, or when its score leans on distant borrowed priors, the automated output is confidence-discounted and the human-reviewer check moves earlier. In the mature-field ordering of Section 6.8 that check is the last-resort backstop. It is least trustworthy where the prior for a claim is thinnest, wherever in a field's maturity that claim sits. The honest ceiling where priors are thin is narrower than where they are settled. The framework's advantage over the incumbent citation count narrows to two things. It brings adjacent-field priors the local corpus has not consolidated, and it makes its grounding inspectable, so a human with better priors can see and overrule what the scorer accepted. That is narrower than a claim to independently correct a judgment the field itself has not settled. A thin-prior score is therefore an advisory flag for human scrutiny rather than a signal to act on, and the framework specifies this rather than implying a correction it cannot deliver where priors are not yet formed.

7. Validation Approach

7.1 Retrospective Validation

Retrospective validation against historical cases is the primary acceptance test, and it must demonstrate discrimination for positive and negative controls alike. Three positive controls apply. The framework must score Katalin Karikó's 2005 paper, Karikó and Weissman in Immunity 23:165-175, above the median of contemporaneous papers in immunology and molecular biology. It must score Brock and Freeze 1969, in J Bacteriol 98:289-297, above the median of contemporaneous microbiology papers. And it must score Maynard and colleagues 1997, in Electroencephalogr Clin Neurophysiol 102:228-239, above the median of contemporaneous neural-engineering papers.

As negative controls, the framework must score volume-first archetypes below field median on the paper-substance and scientific-reasoning-quality indicators. Those archetypes are papers running single-test analyses on reused public datasets with no primary data collection, which accumulate citation counts through publication volume rather than substantive contribution. A framework that scores foundational work high but fails to score volume-first work low is not discriminating. It is tracking eventual citation, and it fails the acceptance test.

The graceful-failure gate is a hard deployment condition rather than an aspiration. An indicator does not deploy unless its errors are demonstrably uncorrelated with systematic suppression of foundational, slow, corrective, or exploratory work, which is the specific failure mode of the incumbent metrics it would replace.

The bar is comparative. The indicator must predict genuine contribution better than the h-index does, and its residual errors must be closer to random with respect to research type than the incumbent's structured errors are. An indicator that is more accurate on average, but that concentrates its errors on the same foundational work the h-index penalizes, has not cleared the gate, because it reproduces the harm under a new name. Deployment is conditional on passing both the discrimination test above and this graceful-failure test, evaluated during the forward-validation pilot before any use in funding or promotion decisions.

One limitation is intrinsic to retrospective validation and applies to every historical control. The positive controls all predate CRediT and much of the machine-readable metadata that contemporary application relies on. Any co-author-composition score computed on them therefore runs on the weaker pre-CRediT participation evidence described in Section 3.10, and the older cases have more attribution uncertainty than a present-day paper would. This does not defeat the retrospective test, since the content-scoring and trajectory indicators read the paper text and citation structure that do exist for historical work. The retrospective controls exercise the team-composition indicator less dependably than the reasoning and impact indicators, so retrospective validation results should be read with that unevenness stated rather than treating every indicator as equally testable on decades-old papers.

7.2 Forward Validation

Forward validation requires a pilot study at three to five institutions across diverse fields, scoring in parallel against traditional metrics for 24 months before any use in funding decisions. Pilot sites should include at least one institution outside the United States, to test geographic

generalization. The incentive-arm indicators need a longer validation horizon than the diagnostic arm, because their behavioral effects appear only over multiple grant cycles, meaning whether researchers actually attempt more exploratory work.

7.3 External Audit

External audit by independent bibliometric experts is required every 18 months, with results published openly. The audit panel should include representatives from DORA, the San Francisco Declaration on Research Assessment, and from the Center for Open Science. It should also include at least two non-US institutions, to test international generalizability.

7.4 Thin-Prior Stress Test

The guards of Section 6.9 require their own validation, because the regime where the framework degrades is thin local priors, and those arise at a mature field's newest questions and interdisciplinary boundaries as well as across a young field. The controls of Section 7.1 are drawn from mature or historically-settled cases that do not probe that regime. This stress test therefore assembles, for several fields spanning a maturity gradient, a set that includes each field's most-cited early paper whose central claim was later qualified or overturned. It then measures whether the framework, with adjacent-field borrowing, flags at publication time the overclaim that the field's citation record missed.

Two design conditions are essential. The trace must run unprimed, meaning the evaluator is not told which papers are the suspected negative controls, since a primed evaluator who knows where to look overstates the framework's real detection, and that specific overstatement has already been observed. And success is measured against time-to-correction, meaning whether the framework reports the flag years before the field's own slower self-correction did, rather than against a single right-or-wrong score. The framework's honest value in a young field is shortening the correction lag and making the grounding inspectable, not independently settling a judgment the field itself had not yet settled.

7.5 Consequence-Calibration Separation Test

The consequence and calibration axes of Section 3.12 require their own validation, because the failure they address is substitution of calibration for magnitude, and the retrospective controls of Section 7.1 do not isolate it. This test assembles two sets matched on calibration, one of rigorous, well-calibrated papers reporting small increments and one of rigorous, well-calibrated papers that redirected their field, both drawn from settled history where magnitude is known. Acceptance requires similar scores on the calibration axis across the two sets and separated scores on the consequence axis, since equal calibration with divergent consequence is the discrimination the two-axis split is specified to produce. This test must run unprimed, for the same reason the thin-prior test must, because a calibration-weighted evaluator who knows which papers are minor conflates the axes and overstates the separation, a conflation observed during this framework's own development when honest minor papers were scored as strong contributions.

8. Discussion and Closing

The framework proposes two arms, answering the two jobs the RFI names. The diagnostic arm has fourteen top-level indicators that detect quality the existing metrics miss. They score content rather than metadata. They identify the shape of a trajectory rather than an aggregate count. They score scientific and engineering reasoning directly from paper text, through the SRQI and EMI meta-indices and their step-level sub-indices, rather than inferring quality from venue prestige. And they invert the citation asymmetry by rewarding reading breadth as well as being read. The incentive arm rewards wanted behaviors constitutively, so that gaming a metric produces the intended behavior. It leads with foundational and exploration incentives, because those behaviors have the longest payoff horizon and the weakest existing constituency.

The central argument is that evaluation should push back against the forces already acting on the research enterprise, rather than adding to them. Study sections and public sentiment both reward near-term translation. Weighting all work equally therefore under-invests in the long-horizon foundational research that only public funding will support, and so the incentive arm is weighted toward foundational and career-terminal metrics. The career-terminal Lifetime Foundational Impact Indicator gives researchers a long-horizon target. It rewards origination, delayed payoff, risk-taking, generativity, correction, and infrastructure, the acts that advance science most and that no annual metric measures. Public understanding of why foundational work matters is what protects its funding across political cycles. The public-engagement indicator therefore works as a meta-incentive, protecting the survival of everything else.

Each indicator has documented failure modes and required mitigations. The diagnostic arm will be valid only if adversarial retraining, bias testing, auditability, and anti-homogenization provisions are implemented. Without them it will fail as the h-index failed, by becoming a proxy that displaces the thing it was built to measure. The incentive arm is more robust, because its metrics are constitutive rather than proxy. It still has its own risks, meaning cheap-risk accumulation and attribution difficulty at long horizons, and its specifications address both directly. This submission does not argue that AI-enabled indicators solve the metric problem. It argues that they can be specified to do two things, to detect the failure modes existing metrics produce, and to reward constitutively the long-horizon foundational work that the public-funding mission supports.

What this framework does not yet establish should be stated as fully as what it does, and measured against the same baseline the framework competes with. Three limits are real. First, the gaming defenses of Section 6.8 close false novelty and inconsistency-producing gaming, but they leave salami-slicing to author-level audit and coherent multi-metric inflation to adversarial retraining and cost, and they defer fabrication of a plausible artifact to replication and human review. Second, validation to date shows that the procedures resolve and discriminate on rigorous work across contribution types, including negative results. The discrimination claim against low-quality and gamed work is a different matter. The retrospective negative controls of Section 7.1 test that claim rather than settle it, and the deficiency floors and the aggregate's neutrality toward rigorous nulls still need negative-control calibration in the validation plan. Third, the corpus-relational machinery inherits the coverage of its retrieval substrate. Fields and literatures that are thinly indexed, non-English, or pre-digital are therefore scored with lower confidence, and the framework reports that rather than hiding it.

A fourth limit is the most consequential. The novelty, fidelity, and rigor gates judge a claim against field priors. A scorer calibrated on a forming field's thin corpus therefore inherits what that field cannot yet see, and it can reproduce the field's credulity. That is the failure that lets a presentation-gamed claim pass the gates just as it passed the citation record. Section 6.9 addresses this three ways, with always-on adjacent-field prior borrowing, a held-out-feature rule against presentation-gaming, and a per-claim prior-density weighting that discounts and escalates scores where the local prior for a specific claim is thin. Those guards run always, rather than switching on at a field-level maturity flag. The honest ceiling in a forming field is narrow. The framework can borrow priors the field has not formed, and it can make its grounding inspectable. It cannot independently correct the field's judgment. Young-field scores are therefore advisory flags for human scrutiny rather than signals to act on.

Measured against the applicable baseline, each of these limits is a reduction of a problem the incumbent handles worse. The h-index has no concept of novelty, so it cannot detect false novelty at all. It actively rewards salami-slicing through paper counts. It rises identically for fabricated and for genuine citations. And it inherits the coverage biases of the citation graph, which are more severe than those of the retrieval corpora. The honest claim is not that this framework is ungameable or complete. On each named limit it moves the failure in the right direction relative to the metric it would replace, exhausting the corpus and ecosystem checks first and reserving human review for the irreducible residue. Human review is never eliminated, because honesty and transparency require an accountable human judgment. It is invoked last and bounded, which follows from this framework's own premise that human judgment is the most relationship-biased tier rather than the clean backstop above the automation.

A fifth limit is the one a domain expert raises first, and it runs against the applicable baseline more directly than the others. Novelty is measured as the presence of an increment against field priors. Calibration and rigor are measured densely. Contribution magnitude, meaning whether an increment changes what a field asks, does, or believes, is measured through only four forward-looking indicators, and only as a prediction with wide uncertainty. A paper can therefore pass every novelty check and score high on calibration while reporting a small increment. Without the consequence-axis separation of Section 3.12, the dense calibration signal is then treated as magnitude, and honest minor work receives a strong-contribution score.

One comparison is unfavorable and belongs in the record. The h-index is itself a lagging magnitude proxy, since citations accrue to consequential work over time. This framework therefore exchanges a lagging but real magnitude signal for calibration and honesty, plus a forward magnitude prediction that no validation at publication time can confirm. That exchange depends on the use case rather than being uniformly favorable. It is most favorable for forward-looking decisions on early-career or new-direction work, where the lagging proxy has not resolved and honest reporting supplies more information. It is least favorable for retrospective assessment of a long senior record, where accrued citations are a competitive magnitude signal. Measured against the baseline, this framework does not outperform citation counts at ranking realized magnitude. Its advantage lies in separating magnitude from honesty and in withholding credit for network position. The consequence axis is therefore where that advantage is narrowest and its uncertainty is widest, and the two-axis reporting with the Section 7.5 test makes that visible rather than hiding it.

Author disclosure. The author is an established, well-cited, network-embedded senior investigator. That is the profile relationship-biased evaluation advantages, and it is the profile this framework would constrain. The recommendation therefore runs against the author's own positional interest, since network-blind content scoring and independent-recognition weighting reduce the advantages a well-connected senior investigator currently holds. This critique is offered from inside a position that benefits from the current system, and it proposes to dismantle the arrangements that produce that benefit, which is the opposite of a self-interested recommendation.

1. Rigor and Reproducibility: Core recommendation: Recognize rigor and reproducibility not only through the quality of study design and analysis, but also through the conditions that allow others to understand, evaluate, reproduce, validate, and extend research findings. Our review of barriers to data sharing and reuse highlighted a broader lesson about scientific impact: rigorous science does not end when a study is completed or a manuscript is published. Reusing data requires understanding the explicit documentation supplied with a dataset and the implicit assumptions embedded in the original study design, which are rarely transferred with data. Long-term scientific value increasingly depends on whether findings can be independently interpreted and tested by others.

Potential indicators: Potential indicators should focus on whether the research itself was designed, conducted, analyzed, and reported in ways that support credible interpretation and independent verification of findings. Indicators could include use of appropriate study design, clearly specified research questions or hypotheses, transparent sampling and recruitment methods, valid and reliable measures, prespecified analytic plans where appropriate, robust statistical methods, sensitivity or validation analyses, clear reporting of limitations, and sufficient methodological transparency to allow others to assess whether the conclusions are supported by the evidence. Where data or code are relevant to reproducing findings, NIH could consider whether the analytic workflow, assumptions, and key methodological decisions are documented well enough to support independent evaluation or replication.

Implementation approaches and incentives: NIH could incentivize reproducibility-enabling work by recognizing documentation, curation, harmonization, stewardship, and preservation of contextual knowledge as legitimate scientific contributions. These activities could be reflected in progress reporting, biosketch contributions, funding opportunity language, review criteria, supplements for replication or validation work, and recognition of research products beyond traditional publications.

Risks and feasibility considerations: A dataset, protocol, or analytic workflow may be technically available but still insufficiently documented to support meaningful assessment or reproduction. Metrics should account for variation across career stages, disciplines, data types, and institutional resources, and should

avoid penalizing investigators working with sensitive data, emerging methods, smaller teams, or resource-constrained institutions.

2. Data, Software, and Model Sharing: Core recommendation: Distinguish among availability, accessibility, usability, and demonstrated reuse when assessing the impact of shared data, software, models, and related research products. Impact is determined not simply by whether research products are shared, but by whether they can be found, understood, governed appropriately, and used by others to advance new questions.

Potential indicators: Potential indicators should focus on the quality, accessibility, governance, and sustainability of shared research products after they are made available. For data, software, and models, indicators could include use of persistent identifiers, appropriate repository placement, clear access conditions, licensing or use terms, versioning, machine-readable metadata, data dictionaries or codebooks, governance information, common data elements or interoperable formats, and documentation that enables a user to find, understand, request, run, or apply the product appropriately. For software and models, indicators could also include version control, example workflows, test data, model cards or equivalent documentation, clarity about limitations and intended uses, and concrete maintenance and sustainability plans that describe how dependencies, documentation, updates, preservation, and user support will be managed over time. NIH could also consider evidence of uptake or reuse by investigators outside the original team, including citations, secondary analyses, integration into new studies, or use in policy, clinical, public health, or methodological work.

Implementation approaches and incentives: NIH could incentivize high-quality sharing by rewarding reusable research products as scientific outputs in applications, progress reports, and review processes. NIH could also support shared infrastructure, repository coordination, metadata standards, common data elements, governance templates, and resources for curation and long-term stewardship. Incentives should emphasize the quality and utility of shared products rather than volume alone.

Risks and feasibility considerations: NIH should avoid incentives that reward posting large numbers of products without assessing whether they are usable, interpretable, or responsibly governed. Care should be taken so that metrics do not encourage premature or inappropriate sharing, especially where privacy, consent, tribal sovereignty, community expectations, intellectual property, or legal restrictions require tailored governance. It is important to consider infrastructure disparities across institutions and how data stewardship expectations might disproportionately burden early-career investigators, smaller teams, or less-resourced organizations.

3. Training and Mentorship: Core recommendation: Recognize training and mentorship that prepare researchers to contribute to rigorous, collaborative, data-intensive, and reusable science. Future scientific impact will depend not only on disciplinary expertise, but also on researchers' ability to operate within complex research ecosystems that require documentation, stewardship, governance, interdisciplinary communication, and responsible knowledge sharing. Literature on data reuse barriers identify training gaps across disciplines around data reuse, including uncertainty about which expertise should be represented on reuse teams and how mentors should prepare trainees for rapidly changing tools such as AI-enabled analysis.

Potential indicators: Potential indicators include mentorship and training activities that build capacity in FAIR data practices, reproducible workflows, transparent documentation, interdisciplinary collaboration, research governance, ethical secondary use of data, and community-engaged stewardship. NIH could also recognize trainee contributions to shared data resources, software, standards, documentation, governance processes, or other research infrastructure that supports cumulative science.

Implementation approaches and incentives: Mentorship plans and training programs to include explicit competencies related to reproducibility, data stewardship, collaborative science, and responsible sharing should be encouraged. These competencies could be incorporated into training grant expectations, career development awards, mentorship plans, progress reports, or recognition of trainee products beyond first-author publications.

Risks and feasibility considerations: Mentorship metrics that privilege large, well-resourced laboratories or rely only on easily counted outcomes such as publication counts, grant awards, or placement in traditional academic roles should be avoided. Measures should account for diverse career paths, institutional contexts, team-based contributions, and the time required to mentor trainees in high-quality stewardship and collaborative research practices.

4. Collaboration: Core recommendation: Recognize collaboration-enabling work as a form of scientific impact when it creates durable infrastructure, standards, governance pathways, shared vocabularies, or trusted networks that allow research findings to extend beyond a single project. Our literature review of data reuse barriers suggests that scientific impact is increasingly generated through networks, not only through individual studies.

Potential indicators: Potential indicators include development or adoption of shared standards, harmonization across studies or datasets, cross-institutional governance models, community coordination activities, shared repositories, common vocabularies, consensus processes, and interdisciplinary tools or documentation resources. NIH could also consider evidence that collaborative infrastructure enabled future studies, cross-study analyses, broader participation, or more generalizable findings.

Implementation approaches and incentives: NIH could encourage applicants and awardees to describe or document specific collaboration-enabling contributions, including standards development, governance alignment, stakeholder coordination, knowledge translation across disciplines, and maintenance of shared resources. These contributions could be recognized in biosketches, progress reports, team science review criteria, center or consortium evaluations, and supplemental funding opportunities.

Risks and feasibility considerations: Measures equating collaboration with the number of co-authors, participating institutions, or number of events/meetings may not reflect the quality, durability, or scientific utility of collaborative contributions. Metrics should account for invisible coordination labor, community-building, governance work, and the contributions of investigators and staff whose roles may not be captured by traditional authorship or leadership indicators.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: Core recommendation: Assess public impact through evidence that research knowledge remains available, understandable, trustworthy, and useful over time. Public value is not determined solely by publication of new findings. Value also depends on whether scientific outputs can inform future research, clinical guidance, public health practice, policy, community decision-making, and responsible innovation.

Potential indicators: Potential indicators include evidence that research outputs informed clinical guidance, public health practice, policy development, future research priorities, methodological standards, community decision-making, or subsequent funded research. NIH could also recognize reuse of research products to address high-burden health conditions, engagement with patients, communities, practitioners, or other end users, and governance practices that improve trust and responsible use.

Implementation approaches and incentives: NIH could encourage applicants and awardees to describe plausible pathways from research outputs to public benefit, including how data, tools, models, standards, or findings may be used by researchers, clinicians, public health practitioners, policymakers, communities, or other stakeholders. NIH could also recognize public-impact contributions that occur over longer time horizons, including foundational infrastructure, replication, stewardship, and community-engaged work that builds trust and enables future advances.

Risks and feasibility considerations: Public impact should not be interpreted only as near-term commercialization, immediate clinical translation, or highly visible media attention. Foundational research, infrastructure-building, replication, data stewardship, and responsible governance may create substantial public value over longer periods. Metrics should also avoid encouraging overstatement of public benefit or disadvantaging fields where impact emerges gradually, through cumulative evidence, or through improved trust and responsible use of sensitive research resources.

1. Rigor and Reproducibility: Reproducible and replicable biomedical approaches are foundational to rigorous research. New strategies are needed to identify areas ripe for replication and reproducibility efforts, as well as incentives and infrastructure to support the reproduction and replication of existing findings.

NIH should reinforce principles that reward methodological rigor, transparency, and high-quality reporting. Evaluation systems should place greater emphasis on the robustness of study design, analytical methods, and adherence to rigorous scientific standards, rather than only rewarding positive or novel results. This might use standard metrics like invention disclosures, patents filed/issued, licenses executed (more critical than invention disclosures or patents issued), startups launched, startup survival rates, startup fund raising activity, products on market, etc. Evaluation systems need to include recognition and metrics for open scholarship, such as open access repositories, open access publications, and open-source code.

Replication and reproducibility studies should likewise be incentivized and rewarded, as they play a critical role in validating important findings and strengthening confidence in biomedical research, yet are often undervalued relative to studies that emphasize novelty alone. NIH could have calls for proposals that are specific to replication and reproducibility in specific areas of interest as a means to confirm and certify innovative and promising findings faster in order to get them into the public with strong reliability and confidence for the general public. This will support additional commercialization and translation from bench to market.

Additionally, NIH may offer more expedited ways for advancing clinical trials that may demonstrate promise, efficiency, or safety without the large scale generally required of traditional clinical trials. Further, leveraging existing infrastructure like the NCI's National Clinical Trials Network could expand replication.

2. Data, Software, and Model Sharing: Sharing scientific data and tools accelerates biomedical research discovery, in part, by enabling validation of research results, providing accessibility to high-value datasets, and promoting data reuse for future research studies. NIH seeks to incentivize and reward these activities to maximize the value of research investments, catalyze collaborations, and accelerate scientific impact.

The sharing of research protocols, analytical workflows, open-source code, open access data, and open access publications should be required to facilitate verification, replication, and data reuse. In addition, the publication of well-executed studies with null/negative findings should be recognized as an essential contribution to the scientific record, helping to reduce publication bias and improve the accuracy of the evidence base. The systematic integration of open and community-engaged scholarship expectations will prompt faculty to accurately represent the work that they are already doing. It will enhance the perception that faculty receive "credit" for all the ways in which they share their work within and beyond the university.

Moreover, we anticipate that faculty will be more likely to participate in open and community-engaged scholarship when they perceive that it is valued and recognized in evaluation by NIH in grant reviews in explicit and tangible ways, such as including a section on open access scholarship to document not only ways that previous research has been openly shared through open source code, open access data, and open access publications, but to also indicate plans to openly share outcomes from the proposed research project in all areas of research protocols, analytical workflows, open source code, open access databases, and open access publications.

NIH needs to provide training to peer reviewers to increase awareness and knowledge of the importance of open access scholarship broadly, and recommendations about how to evaluate submissions that include open access research protocols, analytical workflows, open source code, open access data and open access publications. In addition, NIH should educate peer reviewers on the importance and evaluation of public impact metrics to demonstrate the value to the public in terms of licenses (including patents) and policy briefs. Patents, licenses, and policy briefs are now trackable through reliable databases, and metrics include repeated use of them through a "citation" type of tracking and have peer evaluation aspects. These include tracking of patents in Google Scholar and tracking policy briefs by Sage at Sage Policy Profiles. These can and should be considered as seriously as peer reviewed publications when it comes to evaluating the impact of previous scientific research and the quality of the P.I. and their team of Senior Key Personnel.

While it is essential that faculty members retain the freedom to choose how and in what venues they will disseminate their research, they will also attain greater awareness of the benefits of open scholarship for not only public access to their work, but also the potential for higher citation rates and visibility in their field. Research published between 2011 and 2021 suggests open scholarship finds more readers and generates more citations, as described below:

- 2.6x-4.4x: Increase in page views when articles are open. (Wang, et al., 2015)
- 115%: Increase in downloads when articles are open. (Davis, 2011)
- 8%, 18%, 1.24x: Increases in citations to open articles. (McCabe, Snyder, 2014), (Piwowar, et al., 2018), (Archambault, et al., 2013)
- 10x: Increase in online mentions when books are open. (Lucraft, 2017)
- 50%: Increase in citations to open books. (Lucraft, 2017)
- 2.7x: Increase in downloads when books are open. (Neylon, et al., 2021)

Such awareness of the impact of open scholarship can help address the challenge of traditional mindsets that link the quality and impact of one's work solely to the historical prestige of a journal title and/or publisher. This would also help reassure junior scholars that the senior scholars who are reviewing their work have been familiarized with and support this commitment to open scholarship.

NIH could include subsections in proposals that require the description of institutional resources that explicitly call out resources for open access repositories on campus and open databases. This may also request information about policy and faculty review processes that explicitly value open scholarship and resources to support innovation and entrepreneurship.

To assist in data generation, NIH should prioritize investment in large data collaborative initiatives, creation of databases for research methodologies and protocols and open-source code. By investing in scientific leaders to create and develop these open scholarship sources who are well-prepared in areas of biomedical research, there will be enhanced credibility and utilization. They can develop new forms of open scholarship with tracking ability to indicate metrics of use and evaluation. This type of approach will reward institutional and investigator contribution by reinvesting back on its contributors to promote data utilization, offer computing resources, technical support, for rigor and reproducibility.

3. Training and Mentorship: NIH recognizes that advancing its mission requires promoting the growth and stability of the biomedical research workforce. While NIH supports training and protects time through existing policies and programs, additional indicators are needed to assess and quantify the impact of these efforts.

Training on the value of open/community-engaged scholarship for the researcher/scholar, for the scientific community and for the public good needs to be a priority for preparing our graduate students, post docs, early career professionals, faculty mentors, and review committees. Integration and alignment of these systems through NIH training grants, and expectations for proposals will increase faculty capacity to assess and adopt various open and community-engaged scholarship practices.

In order for NIH to advance team science, there will need to be an accompanying shift acknowledging that mentoring in team science requires unique skills, and best practices than the traditional 'one-one' mentoring in a hierarchical structure. Translational and team science requires collaborators not only with disciplinary expertise but also a leadership team that represents the diversity of necessary experience, skills, access and experience, coupled with the skill at leading team science and conducting convergence research. Given that not all faculty receive training best practices in mentoring, NIH could require training in team science mentoring for best practices among all funded proposals that work with junior scholars, post-docs and graduate students. The agency must consider how a proposed project will address team and bi-directional mentoring approaches and consider how researchers at all stages of their careers develop new team leadership and mentoring skills that will be required for successful project outcomes and outputs.

Outstanding examples of collaboration among Universities and NIH to support workforce development are the NHLBI PRIME program which focuses on promoting researcher training for early career researchers. Programs such as these may be replicated across institutes and centers supporting a broader pool of talent. Given the limited funding available under F, T, K mechanisms for physician

scientists, it has become increasingly difficult to provide time protection for training, institutions with limited resources are unable to invest in this essential phenotype of researcher. Similarly, salary caps for mentors, and lack of funding for mentors also limits the availability of physician scientists to truly dedicate time, emotional and technical effort towards training the upcoming generations.

In their 2015 report, Enhancing the Effectiveness of Team Science , the National Research Council noted a number of strategies that have been shown to be effective in supporting team science. Researchers submitting proposals to NIH could be asked to provide a narrative section in the proposal and evidence that they use these strategies when managing their research team. Alternatively, NIH could require a narrative paragraph incorporated into their biographical sketch to demonstrate they have experience leading large collaborative teams to successful outcomes. NIH could require evidence of training in best practices with team science mentoring in order for the proposal to be competitive because it demonstrates the likelihood that the team will be successful in achieving outcomes without becoming worn down with internal conflicts or lack of effective team based strategies to move the science forward more quickly with better outcomes for all involved, as well as preparing a broader base of future scientists who are prepared to work in large teams.

The key strategies noted in the report include:
· ensuring that the team has task-relevant diversity
· using task-analytic methods
· getting training in team science approaches
· taking time to developed shared knowledge (particularly important for geographically diverse teams)
· the leader should delegate responsibility to smaller groups
· have a collaboration plan

These are simple and straightforward tangible metrics that can be required or at least evaluated in the evaluations of proposals.

4. Collaboration: As biomedical research becomes increasingly interdisciplinary and convergent, collaboration is growing in both scale and complexity. NIH seeks new approaches for assessing and recognizing contributions to team-based science.

To incentivize team and translational science, NIH must examine to what extent the calls for proposals are written in ways that require and incentivize collaboration, both from an inter- and trans-disciplinary (e.g. including non-academic partners) aspect but also looking at institutional types that would generate even more convergence. This can be considered by movement away from the one P.I. model to more models that support and encourage multiple P.I.s and team led-science. This recommendation is consistent with the team science work that has emerged from the NCI, in that grand challenges require multiple disciplines to solve. This can be motivated through proposal requirements, revised budget categories and allocations, and recognition of different types of team leaders. Teams would no longer be led by one or two disciplinary experts but rather would be composed of co-investigators/co-leaders from the various entities, including community-based organizations, industry partners, and bioinformatics partners that are required to move basic research to translation. Team science has been shown to enhance leadership, collaboration structures, and cross-disciplinary research productivity. This also means to address any other existing barriers to collaboration and sharing of funds and data across

institutions.

NIH could incentivize and recognize the value of co-produced research, driven by identified community needs. This would require projects that authentically and deeply engage interest holders across a diverse spectrum. NIH creation of funding opportunities specifically to create training programs to lead and participate in team based collaborative approaches would advance work in this area of high quality collaboration for scientific success. Such capacity building programs could provide toolkits, promote community-based practices, and provide training frameworks for faculty and researchers. Another way of promoting the use of team science, efforts like University of Texas Medical Branch Team Science training microcredentials and/or badges offer introduction to essential principles that are valued across some but not all institutions.

NIH could start taking into account inter and transdisciplinary features of research as they evaluate proposals. Similar to discussions of multiple PI and their roles, a discussion of specific contributions across disciplines will highlight and emphasize the value of different disciplines working together to solve some of our greatest biomedical challenges. These could be linked across the NIH community to stimulate more team-science and translational project proposals and to ensure investigators are equipped with all relevant skills to lead significant research projects. Concurrently, review functions would have to shift away from strictly biomedical disciplinary experts but also include those with expertise in non-biomedical specific areas required for collaboration (e.g. bioinformatics, social science, evaluation, community engagement.)

To stimulate more translational research projects, NIH could offer phased funding approaches where successful ‘phase 1’ funding comes with opportunities for follow on funding. Not every team with an innovative idea is immediately networked or capable of forming the cross-disciplinary, cross-community, and cross industry team needed to be fully successful in community engaged, translational, and public impact research. It takes time to find the right collaborators and co-develop research questions and methods in true collaboration. A successful phase 1 project could lead to a non-competitive ‘phase 2’ award to fund the implementation of the project, develop outputs that and are suitable for all partner’s needs, and assess outcomes.

5. Entrepreneurship and Translation: To advance the translation of discoveries into products for people, NIH fosters the maturation of discoveries from bench to bedside and promotes innovation across sectors. More can be done to incentivize, assess, and integrate the impact of innovation and entrepreneurial efforts as critical to the NIH mission.

NIH can strengthen its impact on innovation and entrepreneurship by integrating translational and commercialization outcomes into funding mechanisms, metrics, and institutional incentives. Some specific ideas might include:
• Create explicit budget lines within major research funding opportunities for Technology Transfer Offices (TTO) operations and staffing. Provide a small budget allocation of 2-5% of institutional overhead costs to support TTO personnel. A strong TTO infrastructure directly correlates with successful technology transfer.
• Establish pilot project funding mechanisms specifically for feasibility and proof-of-concept studies. Again, providing a small budget allocation of 5-10% for competitive pilot projects focused on early-stage

commercialization validation.
• Allow researchers to request some percentage (maybe up to 10%) for startup-related expenses, including things like business plan development and market research; initial intellectual property filing and prosecution; regulatory pathway assessment and FDA pre-submission meetings; early-stage clinical trial planning and preparation; etc.
• NIH could explicitly require funded institutions recognize excellence in commercialization in their P&T processes. Not something so simple as “patents” but there are several other ideas including products on market, “impact score” for patents, etc.

However, NIH should avoid creating competition between NIH and institutions. Intellectual property protection is essential for entrepreneurship. An important balance may be reached between facilitating replication, expansion, and leveraging of findings while prioritizing gains by the original thinkers and developers. NIH mandates for data sharing may be balanced with support for product development, etc. NIH may have partnership with private industry to facilitate this collaboration which should remain inclusive and protective of researchers and their institutional interest.

6. Foundational Scientific Exploration: Basic research and high-risk, high-reward initiatives represent foundational scientific exploration with an inherent risk of failure but the potential for paradigm-shifting breakthroughs. Further embedding these approaches within the academic enterprise is essential to ensuring continued support for bold and innovative research directions.
NIH's effort to develop metrics that better reflect the rigor, collaboration, and long-term value of modern biomedical research is well-timed and necessary. This means that we need to consider how science outcomes have moved beyond peer reviewed publications and include open scholarship, innovation and entrepreneurship as well as community-oriented reporting and sharing of research projects and outcomes. However, as the agency develops new indicators, it should guard against placing disproportionate emphasis on only translational outcomes.

Translation is an essential part of the biomedical enterprise, but many of the most transformative advances originated from curiosity-driven basic research with no obvious clinical application at the time. For example, CRISPR emerged from studies of bacterial immune systems. GLP-1 therapeutics grew from fundamental investigations of hormone biology. Taq polymerase, the foundation of PCR, arose from research on microorganisms living in extreme environments. In each instance, the breakthrough was not initially a therapy or product, but a new understanding of biology that later enabled major innovations.

Metrics that heavily reward near-term translational impact, commercialization, or clinical implementation may unintentionally favor incremental advances over fundamental discoveries. This creates a risk that researchers, particularly early-career investigators building their portfolios, will pursue projects with predictable outcomes rather than tackle the deeper biological questions that often generate the greatest long-term benefits. This dynamic may be especially acute at institutions without robust industry partnerships or translational infrastructure.

A central challenge in evaluating scientific contributions is that their future value is not always predictable at the time of discovery. Many foundational discoveries reveal their significance only years or decades later. Basic research therefore creates not only knowledge, but opportunity; the possibility of future discoveries, technologies, and therapies that cannot yet be imagined. For this reason, NIH should

explicitly recognize and reward contributions that expand the scientific foundation upon which future advances depend. Measurable indicators could include:
• Tool and method creation: Novel methods, data visualizations, tools, datasets, and model systems adopted by the broader community, as measured by protocol citations, plasmid deposits, software downloads, or reagent requests.
• Resource generation: Open scholarship for shared resources that enable research across multiple groups, as measured by data reuse metrics, secondary publications arising from deposited datasets, and cross-institutional collaborations enabled.
• Field-opening discovery: Discovery-driven research that opens new lines of investigation, as measured by time-lagged citation impact and the initiation of new funding programs or research areas.

These measures should complement, not replace, assessments of translational success. Alternatively, NIH may further differentiate funding types, e.g., the R01 versus the SBIR/STTR funding (and perhaps a version of SBIR/STTR for academic institutions). A healthy biomedical research ecosystem requires both discovery and application. Translation converts knowledge into benefit, but basic science generates the knowledge that makes translation possible. Ultimately, scientific impact should be measured not only by what research immediately accomplishes, but also by what future discoveries it makes possible. Translation is the harvest, but basic science is the seed corn. If the research enterprise rewards only the harvest, it risks undermining the source of future innovation. NIH's assessment framework should ensure that foundational discovery science remains a visible and valued component of scientific success across all career stages, disciplines, and institution types.

7. Public Impact: NIH seeks approaches for assessing and recognizing the broader public impact of biomedical research, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit.

In addition to traditional metrics of scientific dissemination, such as conference presentations and peer-reviewed publications, NIH must clearly recognize and reward contributions that demonstrably include community in meaningful ways and that directly benefit society, scientific community, and public health. These contributions may include informing clinical practice guidelines and public health practice/policies; improving patient outcomes; enhancing public understanding of science, health, and medicine; fostering meaningful public engagement in science; developing widely adopted tools, software, databases, and research standards; and advancing the translation of discoveries through licensing, commercialization, and implementation. Recognizing these forms of impact would better align scientific incentives with NIH's mission to improve health, extend life, and generate value for the American public.

Scientific communication has become an increasingly important component of the biomedical research enterprise, yet it remains inadequately recognized and rewarded within current evaluation systems. Public trust in science depends not only on the rigor of the research itself, but also on scientists' willingness and ability to communicate evidence, uncertainty, limitations, and evolving knowledge in ways that are accessible and meaningful to a broad range of audiences. However, many researchers devote limited time to public engagement because such activities are rarely valued and may expose scientists to ideological criticism.

NIH can be a leader by recognizing, incentivizing, as well as facilitating the sharing of activities that

explicitly recognize and incentivize activities that strengthen public understanding and trust in science, including public lectures and outreach, engagement with patient and community groups, science communication training, expert participation in public forums, contributions to evidence-based public discourse, and the development of educational resources and content. Potential indicators of impact could include participation in NIH-supported science communication initiatives, contributions to public educational materials, evidence-based expert engagement in public discussions, public media (e.g., podcasts and social media influence) development of community-engaged research partnerships, and demonstrated reach and effectiveness of outreach efforts. Importantly, these activities should be evaluated based on their quality, accuracy, educational value, and societal benefit rather than on popularity metrics such as social media engagement alone.

NIH could document the ways that NIH-funded research has been taken up and used in practice and by practitioners. Citation of research in policy documents, such as through the Overton Index is one approach. Incorporating narrative descriptions of impact, such as used by the REF, is appropriate in many cases because it allows researchers to explain the context and significance of the use of their work. The UK's Research Excellent Framework (REF) includes a well-established method for documenting the societal impacts of research from across all disciplines.

8. Other Areas: Scientific inquiry can be shaped by changing policy and administrative priorities. These shifts may discourage work in areas with significant potential impact and may reduce attention to factors that influence health, access, outcomes, and broader societal effects. Establishing processes that protect rigorous, evidence-based research from influences that unnecessarily limit progress or application is therefore essential.

Re: Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)
Submitted electronically via https://osp.od.nih.gov/comment-form-measuring-and-rewarding-scientific-impact/

Dear Colleagues at the NIH Office of Science Policy:

On behalf of the Gerontological Society of America (GSA), the nation's oldest and largest interdisciplinary organization devoted to the study of aging, I am pleased to submit these comments in response to NOT-OD-26-087. GSA's more than 6,000 members span the biological, behavioral, social, and health sciences and include researchers, clinicians, and educators working across the full spectrum of the aging enterprise. This response also draws on input from GSA-affiliated researchers with direct experience in NIH-funded science and policy. We commend NIH for undertaking this reflection and for seeking input from the community that will ultimately be governed by any new indicators.

Aging research is an instructive test case for this effort. It is inherently longitudinal, team-based, and translational, and it sits at the intersection of nearly every discipline NIH supports. Citation and publication counts, in particular, can be poorly correlated with genuine improvements in health and longevity. Alzheimer's disease research offers a cautionary example: for many years, imaging of amyloid plaques was treated as the gold standard for staging disease, and publications and citations surged as more researchers gained access to imaging facilities. Over time, however, the field learned that small soluble amyloid fibrils (monomers and dimers of amyloid protein), rather than the plaques themselves, appear to be the more direct driver of disease progression, and that multiple genetic and biological pathways contribute to the disease.

More recently, blood-based biomarkers for Alzheimer's disease have been developed. Blood has the advantage that many markers can be assessed simultaneously, offering the potential to build a pattern of markers that better signals disease progression and suggests causal pathways in ways the amyloid plaque signal that long dominated the field could not. Yet if success continues to be measured through publication counts and citations, it is still the older imaging research on amyloid plaques that dominates the top of those tables.

A single dominant metric, in other words, can crowd out messier but more accurate science for years at a time. We believe any new framework for measuring and rewarding scientific impact should be built with, not around, fields like ours, and should be designed with an eye toward this kind of risk. We offer the following comments organized around the categories identified in the notice.

Rigor and Reproducibility

Much of the foundational evidence base in aging research comes from long-running cohort studies, some spanning decades, involving older adults with heterogeneous health trajectories, multiple comorbidities, and evolving diagnostic criteria. Standard replication metrics developed with single-endpoint, short-duration studies in mind may not fit this reality well. We also note a structural weakness in replication as currently practiced: replication attempts are frequently motivated by an initial challenge to a finding, and successful replications are less likely to be published than failures to replicate, which can distort the literature over time. We recommend that NIH:

- Reframe replication initiatives as replication-and-generalization initiatives, incentivizing researchers to test how far an effect extends to other models, populations, or contexts rather than only whether it can

be repeated under near-identical conditions. This shifts the incentive from simply challenging a finding to understanding how far it extends, and treats generalization across clearly defined populations of older adults, including by age cohort, sex, health status, care setting, socioeconomic conditions, geography, and, where relevant to the scientific question, race and ethnicity, as an important contribution to rigorous science.

- Support harmonization and re-analysis studies across existing longitudinal cohorts (e.g., the Health and Retirement Study, the National Health and Aging Trends Study, the Baltimore Longitudinal Study of Aging) as a cost-effective and high-value form of reproducibility work.
- Require or strongly encourage sharing of unpublished as well as published replication attempts, to counteract the file-drawer problem in which only failures to replicate see print.
- Clarify how causal inference will be defined and credited in observational aging research, where randomized designs are frequently infeasible or unethical, so that rigorous quasi-experimental and natural-experiment approaches are not disadvantaged relative to trial-based work.

Data, Software, and Model Sharing

GSA members rely heavily on shared infrastructure such as the National Archive of Computerized Data on Aging and public-use files from federally supported cohort studies, and NIH's sustained investment in that infrastructure has been invaluable. The harder challenge lies in incentivizing sharing of individually developed data, software, and models, where researchers may reasonably see career or financial risk in releasing materials before they have fully mined them. We encourage NIH to:

- Require that investigator biographical sketches identify, for each listed publication, where associated data, models, or software can be accessed. Applied consistently over time, this would normalize sharing as a routine expectation of being an NIH-funded researcher rather than a special favor.
- Credit the sustained curation, documentation, and technical support that keep shared aging datasets usable over decades, not only the initial act of data deposit.
- Continue and periodically revisit NIH's work on standardized outcome measures that allow results to be combined or compared across studies, recognizing that instruments and research directions evolve and that standard measures need scheduled review rather than indefinite fixity.
- Ensure any new incentive structure accounts for the additional privacy, consent, and re-identification safeguards required when sharing data on older adults, particularly those with cognitive impairment or residing in long-term care settings.

Training and Mentorship

The biomedical and behavioral aging research workforce is not growing quickly enough to meet the needs of an aging population, and current challenges facing early-career investigators make sustained, high-quality mentorship more important, and more strained, than at any point in recent memory. Mentorship of the kind that produces strong independent researchers takes substantial time, yet it carries no direct financial reward and competes with grant-writing, supervision of research staff, and administrative demands. We recommend that NIH:

- Work with academic and institutional partners to formally recognize mentoring of junior researchers as part of the teaching role for senior investigators with established research records, giving institutions a concrete mechanism to protect mentors' time rather than relying on goodwill alone.
- Track the career outcomes of trainees and mentees over time, including retention in aging-focused research, rather than relying solely on point-in-time productivity counts.

- Credit mentors for sustained, longitudinal investment in early-career investigators, including those supported through T32 and K-series awards, and for mentoring across career stages and disciplinary boundaries, including clinician-scientists and other dual-role trainees whose paths to independence differ from PhD-only investigators.

Collaboration

Advancing the science of aging almost always requires integrating biological, clinical, behavioral, and social science expertise, and NIH has taken real steps to recognize this through the multiple-PI mechanism and collaboration-focused review criteria. Recognition at the point of reward, however, still accrues overwhelmingly to individuals rather than teams: NIH's signature individual-investigator honors, such as MERIT and Director's Pioneer awards, have no team-based counterpart. We recommend that NIH:

- Establish a team-based analogue to its flagship individual awards, recognizing that the most consequential advances increasingly emerge from social and scientific interaction among researchers rather than from any single investigator working alone.
- Develop team-science metrics that credit distinct forms of contribution (e.g., cohort stewardship, biostatistical design, implementation science, community engagement) rather than defaulting to author-order or single-PI conventions poorly suited to large, multidisciplinary teams.
- Pilot early-career-stage convenings, organized around career stage rather than shared topic, that bring together researchers from different fields and departments with substantial unstructured time for discussion. Topic-focused workshops tend to draw researchers who already share interests and language; career-stage convenings are more likely to spark collaborations across genuinely different fields.
- Recognize contributions to practice-translation collaboratives that bring researchers together with health systems and community-based organizations, such as models built on frameworks like the Age-Friendly Health Systems initiative's 4Ms (What Matters, Medication, Mentation, and Mobility).

Entrepreneurship and Translation

Translation in aging research is not limited to commercial products, and even when a researcher successfully develops a genuine practical advance, a host of non-scientific obstacles can still keep it from reaching patients or consumers, from market access barriers to entrenched competitors. We encourage NIH to broaden its definition of translational impact to include the adoption of evidence-based practices, care models, and clinical workflows by health systems, payers, and community organizations, not only patents, licenses, or start-up formation, which will otherwise systematically undercount translational work in geriatrics, gerontology, and long-term services and supports. We also encourage NIH to consider a modest expansion of program staff capacity dedicated to post-discovery translation, distinct from core review responsibilities, whose role would be to identify research portfolios nearing practical application and connect investigators with the business, regulatory, or dissemination expertise needed to carry findings the rest of the way.

Foundational Scientific Exploration

Basic biology of aging research, including work on the hallmarks of aging and geroscience, exemplifies high-risk, high-reward science with a long horizon to clinical relevance, and scientific curiosity should remain a legitimate driving force in what NIH funds. At the same time, some subfields within aging research, caregiving research among them, show signs of having grown repetitive as available tools and paradigms are exhausted. NIH's existing High-Risk/High-Reward program is well positioned to help revitalize such areas, and we recommend NIH consider expanding it along two lines particularly relevant to aging research: a multiple-PI variant requiring senior investigators from different fields, intended to spark new approaches through the collision of disciplinary

perspectives; and a dedicated early-stage-investigator track, since researchers earlier in their careers are often less invested in established research pathways and better positioned to pursue genuinely novel directions.

Public Impact

Loss of public trust in biomedical research, most visibly around vaccine science in recent years, is among the most serious challenges facing the research enterprise, and it is a challenge NIH cannot address through communications alone. GSA has invested substantially in this space through our National Center to Reframe Aging, which applies peer-reviewed communications science to help the public and policymakers understand the value of aging research and correct persistent misconceptions about aging and older adults. We believe NIH can extend this kind of public-facing translation down to the level of the individual grant, and recommend that NIH:

- Require grant applications to describe a plan for sharing findings with the public, whether through social media, community presentations, or other direct engagement, and require progress reports and renewals to report on audience reach, engagement, and any resulting feedback.
- Recognize measurable shifts in public or provider understanding, adoption of research-informed communications by other organizations, and downstream effects on health outcomes, cost of care, and public trust in science as legitimate indicators of scientific impact in their own right.

Closing

GSA appreciates NIH's commitment to modernizing how scientific impact is measured and rewarded, and we would welcome the opportunity to serve as a resource as this work continues. If you have any questions or want any additional information, please contact Patricia D'Antonio, VP, Policy & Professional Affairs at pdantonio@geron.org.

Respectfully submitted,

James C. Appleby, BSPharm, MPH, ScD (hon)
Chief Executive Officer

269. The Sijbrandij Foundation

I am responding: On behalf of an organization

Name:

Name of Organization: The Sijbrandij Foundation

Type of Organization: Non-Profit Research Organization

Role: Organizational Official

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: At the Sijbrandij Foundation, we have mapped a concrete set of Patient First reforms, of which the initiatives referenced below are examples. We would welcome the opportunity to share the full agenda and the supporting evidence for each.
Reproducibility matters most where it protects patients, and its standards should fit the setting. In rare and advanced disease, where any one center sees too few cases to power a conventional study, NIH should reward fit-for-purpose, context-driven evidence and the replication or validation that de-risks a finding on the critical path to a therapy or diagnostic, rather than treating large-N replication of already-cited results as the default unit of rigor.
Measurable indicator: whether a replication or validation study changed a downstream decision to advance or halt a candidate that patients could receive.

2. Data, Software, and Model Sharing: NIH should measure whether health and research data are usable by the individuals who generated them: whether patients can obtain the underlying data, direct it to clinicians and researchers of their choice, combine it across institutions, and contribute it to research. Interoperability and patient-directed data release should be treated as scientific infrastructure, not merely administrative functions.
This is a concrete part of the Foundation's agenda:
patient control of their own tissue and its molecular data
HIPAA modernization that makes it easier for patients to gather and move their records
EMR interoperability so systems like Epic and Cerner exchange data with others
patient-directed release that lets a person share their data with any clinician or researcher they choose
Measurable indicators: time to complete a data release; completeness of the released record; portability across systems; and documented reuse in research or care.
Safeguards: patient-submitted data must be matched by rigorous consent, privacy protection, and data-quality safeguards, and incentives should reward returning value to the contributors.

3. Training and Mentorship: Workforce metrics should reward the mentors who build national capacity to bring discoveries to patients, including clinician-scientists, trialists, and regulatory and manufacturing scientists, not only those who train the most prolific publishers.

Measurable indicator: trainees' later contributions to patient-facing outcomes, such as trials led and therapies and diagnostics advanced, tracked over time.
Implementation: extend the trainee information NIH already collects to include progress toward new

treatments, tests, and other patient benefits, and recognize mentorship of trainees who pursue this work in career evaluations. This can be phased in using data NIH already holds.

4. Collaboration: Team science should credit the full chain that moves a discovery to patients, including patients, advocacy organizations, and the regulatory and manufacturing partners without whom access does not happen , using a contributor taxonomy that names these roles. Our substantive recommendations sit under Translation, Data Sharing, and Public Impact.

5. Entrepreneurship and Translation: NIH should recognize that translational impact includes not only developing a new therapy or diagnostic, but removing the regulatory, manufacturing, reimbursement, and institutional barriers that prevent an existing scientific capability from reaching people. For patients with rare or advanced disease, that path is often the binding constraint on benefit.
The Foundation is advancing a concrete agenda of such reforms, which serve as worked examples of translation-enabling change:
modernizing early-phase trial pathways — a notification pathway for Phase 1 safety studies under IRB oversight, and investigator choice of any federally compliant IRB;
expanded access after Phase 1, including conditional approval, so promising therapies are not lost in "invisible graveyards";
fit-for-purpose ("GMP-light") manufacturing for low-volume personalized products, verifying the output rather than only the production process;
regulatory pathways for approved algorithms and processes, not only approved molecules, to enable truly personalized medicines; and
context-driven evidence for reimbursing rare-disease therapies.
NIH should treat this policy-translation work as a creditable form of translational impact, and assess it through verifiable artifacts along a clear arc: a published evidence base, a drafted regulatory or legislative change, documented endorsement from affected professional and patient communities, and ultimately adoption or implementation.
Measurable indicators: time from discovery to a benefit a patient can receive; the number of patients who benefit, including through earlier or expanded access; contributions that make trials faster and easier to scale, such as making the real-time clinical-trials pilot permanent; and documented movement from an evidence base to an adopted change.
Implementation: fold these contributions into the biosketch and progress report NIH already collects, and give reviewers explicit authorization to weigh them alongside, or above, publication and citation counts.
Unintended consequence to avoid: over-weighting near-term commercial return would discourage unprofitable but high-value work, including for rare diseases. Translation measures should be read alongside the access and equity measures below.

6. Foundational Scientific Exploration: NIH should credit the mentors who build national capacity to bring discoveries to patients, such as clinician-scientists, trialists, and regulatory and manufacturing scientists, assessed by trainees' later contributions, such as trials led and therapies or diagnostics advanced. This area is secondary to our submission, and we defer to the workforce community for detailed indicators.

7. Public Impact: A discovery has limited public impact if people cannot learn that it exists, access the relevant trial or diagnostic, or reach the clinicians able to use it. NIH should therefore measure not only

whether an advance was developed, but whether the systems around it allow people to benefit from it. Concrete dimensions of access the Foundation works on include:
Whether patients being told about relevant trials, including in oncology;
coverage of exploratory diagnostics such as raw genomic sequencing;
the freedom to see an out-of-state doctor or nurse, so that expertise is not bounded by geography
Measurable indicators: whether affected patients could find and reach an advance (trial and diagnostic awareness and access); equity of that reach across populations and geographies; and adoption into clinical practice — reported publicly and prominently, so that the headline of NIH's impact is health delivered to patients, not papers published.

8. Other Areas: The ultimate purpose of biomedical research is not to maximize publications, approvals, or institutional compliance; it is to improve the health and lives of individuals. In clinical settings, this means orienting the system to maximize patient survival and benefit rather than to minimize institutional or practitioner liability. NIH's impact framework should give greater weight to work as it moves closer to meaningful health benefit, while preserving appropriate measures for foundational research whose effects emerge over longer horizons.
Three cross-cutting safeguards should govern any new indicator:
Feasibility across career stage and institution. Impact should be assessed at the level an investigator can reasonably influence — early-career researchers credited for their contribution to a larger translational chain; foundational scientists judged on rigor and originality; and outcomes like approval or population health assessed at the team, institution, or portfolio level.
Guard against proxy metrics. NIH should not replace citation counts with new activity counts. Datasets shared, collaborations formed, or policy proposals written should matter only when there is credible evidence they contributed to reuse, adoption, access, or health benefit.
Involve patients in defining the metrics. NIH should include patients and advocacy organizations in designing the indicators it will reward, so the endpoints reflect what patients actually value.

AMERICAN COLLEGE of RHEUMATOLOGY
Empowering Rheumatology Professionals

Date:	August 19, 2026
Subject:	Response to NIH Request for Information (RFI) on Measuring and Rewarding Scientific Impact
Notice Number:	NOT-OD-26-087
Submitted By:	Linda Hiraki, MD, ScD, Chair, ACR Committee on Research
Contact Info:	Linda Hiraki Email: linda.hiraki@sickkids.ca
	Connie Herndon (ACR Staff) Email: cherndon@rheumatology.org

Thank you for the opportunity to provide comments on the National Institutes of Health (NIH) Request for Information, Measuring and Rewarding Scientific Impact (NOT-OD-26-087). On behalf of the American College of Rheumatology (ACR), we appreciate NIH's commitment to strengthening the biomedical research enterprise by promoting transparent reporting, rigorous replication, careful interpretation of research methods and analyses, and the ongoing refinement of scientific knowledge. These principles are fundamental to maintaining public trust in science and ensuring that research findings are reliable, reproducible, and ultimately beneficial to patients and society.

The ACR recognizes the importance of meaningful approaches to assessing scientific impact that extend beyond traditional metrics such as publication counts, citation indices, or funding awards. We agree that a comprehensive evaluation of research contributions should also consider factors such as mentorship, data sharing, development of scientific resources, contributions to team science, and the translation of research findings into clinical practice and improved health outcomes. This comprehensive evaluation is especially important for fostering collaboration among investigators in the U.S. and internationally, ensuring a broad and equitable approach to scientific questions.

At the same time, it is important to recognize that academic institutions already devote substantial resources to oversight and training researchers in these areas. Through NIH-supported training programs, including T32 institutional training grants and related career development initiatives, trainees receive extensive instruction in rigorous research design,

reproducibility, responsible conduct of research, scientific communication, and data stewardship. In addition, institutions have established faculty evaluation and promotion processes that assess research productivity, scholarly impact, educational contributions, and service to the scientific community.

While the ACR supports broadening the definition of scientific impact, we note that there is considerable variation across institutions in how faculty performance and research contributions are evaluated. Institutional missions, organizational structures, available resources, and disciplinary priorities differ significantly, leading to diverse evaluation frameworks. As a result, the development of a single, uniform NIH-driven approach to measuring scientific impact would prove difficult to implement equitably across the biomedical research landscape. Such an effort could also create additional administrative and reporting requirements that increase the burden on investigators and institutions without necessarily improving the quality of assessment.

The ACR also has concerns regarding how measures of public impact would be defined, assessed, and applied. Public engagement and societal influence are important outcomes of scientific research; however, these measures can be difficult to quantify objectively and may vary substantially across research disciplines, career stages, and institutional settings. Clear, transparent, and validated criteria would be necessary to ensure that assessments of public impact are fair, consistent, and do not inadvertently disadvantage researchers whose work contributes significantly to scientific advancement but whose impact may not be immediately accessible to broader audiences.

Overall, the ACR believes that academic institutions are best positioned to evaluate the full scope of faculty contributions and research impact because they have direct knowledge of institutional missions, disciplinary expectations, and individual career trajectories. While NIH plays a critical role in supporting and advancing biomedical research, we believe the primary responsibility for measuring and evaluating these outcomes should remain with institutions. NIH should continue to encourage and support best practices in research assessment while avoiding the creation of duplicative processes that could increase administrative burden and divert time and resources away from scientific discovery.

Thank you for considering the ACR's comments on this important issue. We appreciate NIH's ongoing efforts to strengthen the biomedical research workforce and promote high-quality, impactful research.

272. American Association for the Advancement of Science

I am responding: On behalf of an organization

Name:

Name of Organization: American Association for the Advancement of Science

Type of Organization: Professional Organization/Association

Role: Organizational Official

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: • Recognize both reproducibility and replicability: Assessment frameworks should recognize contributions that strengthen both reproducibility and replicability, which are distinct dimensions of scientific rigor. Such frameworks include data and code sharing, transparent reporting, and independent replication efforts.

• Build on existing community standards: NIH should work with publishers, funders, scientific societies, and organizations such as the Center for Open Science to build upon established community efforts rather than creating new, duplicative requirements. Existing initiatives, including the Transparency and Openness Promotion (TOP) Guidelines, provide a strong foundation for advancing reproducibility across disciplines. So do reporting frameworks like MDAR, STAR methods, or field-specific efforts like CONSORT for clinical trials.

• Reward transparent communication of evidence: NIH should reward practices that make the strength of evidence transparent. This starts with sound experimental design and inclusion of the full range of high-quality data needed to reproduce a study. Study limitations, for a given work, should be explicitly communicated in manuscripts and abstracts. Journals play an important role in helping authors accurately communicate uncertainty and contextualize findings before publication, strengthening both scientific rigor and public understanding. (Research shows that making limitations clear is among the key contributions of journals, for papers that were previously on preprints.) Such efforts in communicating uncertainty can be further supported by communication teams committed to accurate dissemination (i.e., When “Opposite” Scientific Findings Collide; Replacing Public Doubt with Public Confidence: Experiments in Building Trust at Science).

• Encourage correction of the literature, where needed: Authors should not be punished for correcting errors. Such correction is courageous; it also helps build public trust. Journals that are improving policies and workflows that prioritize a reliable correction process play a key role in this process, especially when they emphasize public communication.

• Reward replication as scientific discovery: Replication should not be viewed solely as a mechanism for confirming prior findings or identifying errors. When well-designed studies yield different results, they often reveal previously unrecognized complexity or methodological limitations that deepen scientific understanding. Such findings ultimately strengthen the scientific record. Research assessment systems

should recognize high-quality replication studies, including those that do not reproduce earlier results, as valuable contributions. When part of the published record, such findings enable future researchers to build on a more complete and reliable evidence base.

• Recognize disciplinary differences in reproducibility: Approaches to reproducibility vary across disciplines. NIH should avoid creating universal metrics that disadvantage fields with different research norms and practices. Through ongoing work to improve structured reporting across Science journals, AAAS has found that the information needed to support reproducibility, or the approach by which that information is gathered, can differ by discipline. Providing better support for authors to improve the completeness and quality of the scientific record should be flexible enough to reflect related differences.

2. Data, Software, and Model Sharing: • Data should be evaluated not only by whether they are shared, but also by whether they are discoverable, reusable, and ultimately used to enable new science.

• Reduce burden while improving reporting: Incentives for data and code sharing should be paired with investments in tools that reduce the administrative burden of compliance. At Science, AAAS is evaluating AI-assisted workflows that automatically generate structured reporting (e.g., MDAR checklists) from submitted manuscripts for editorial review. Early experience suggests that automated reporting can improve the completeness and consistency of research documentation while reducing effort for authors and editors. NIH should encourage innovations that make transparent reporting easier to achieve, not simply another compliance requirement.

• Invest in data infrastructure, not just data sharing: Data sharing alone is not sufficient. To maximize the value of federally funded research, NIH should continue to encourage deposition of data into trusted, discipline-specific repositories that curate submissions, apply standardized metadata, and enable broad discovery and reuse. Resources such as the Protein Data Bank demonstrate how well-curated community databases can accelerate scientific progress, including enabling advances in AI-based protein structure prediction. Publishers play an important complementary role by encouraging or requiring deposition in these repositories.

• Reward data quality, not just data availability: NIH should consider indicators that assess not only whether data and code are shared at the time of publication, but also whether they remain Findable, Accessible, Interoperable, and Reusable (FAIR) over time. Advances in automated assessment now make it increasingly feasible to evaluate FAIR compliance, metadata completeness, and data usability at scale, providing more meaningful measures of scientific value than indicators of data availability alone.

• Measure reuse as scientific impact: As data sharing becomes more common, NIH should look beyond whether data are deposited to whether they are reused. Data citations provide a practical means of recognizing the scientific value of shared datasets and could complement other indicators of research impact. Tracking data citations would also recognize researchers whose datasets enable new discoveries, extending research assessment beyond traditional publication and citation metrics.

3. Training and Mentorship: • AAAS appreciates that training and mentorship are essential dimensions of scientific impact. Biomedical research advances through the findings generated by individual investigators and the development of people, teams, and institutional environments capable of

producing rigorous, ethical, collaborative, and publicly valuable science over time. NIH should therefore recognize effective training and mentoring as substantive contributions to its mission.

• At the same time, AAAS urges NIH to proceed carefully in developing indicators for these activities. The fact that an activity or outcome can be counted does not necessarily mean that it is a valid measure of quality or impact. Training and mentorship often produce effects that are developmental, relational, cumulative, and visible only over long periods. Easily quantified indicators, such as the number of trainees supervised, trainee publication counts, placement in academic positions, or subsequent receipt of NIH funding, may provide some information, but none is sufficient to establish effective training and mentorship occurred. If treated as proxies for quality, these indicators could also create unintended incentives and obscure the contributions of teams and institutions.

• The goal should not be to produce a universal "mentorship score." Rather, NIH should develop credible and context-sensitive evidence that enables the agency to recognize excellent mentorship, identify opportunities for improvement, and hold investigators, research teams, programs, and institutions appropriately responsible for developing the biomedical workforce. We offer the following recommendations toward this end:

1. Recognizing training and mentorship as scientific impact. Training and mentorship help determine whether the biomedical research enterprise can produce reliable knowledge, adapt to emerging scientific challenges, and translate discoveries into benefits for the public. Effective mentors transmit more than technical knowledge; they help developing scientists strengthen research judgement, responsible research practices, communication and collaboration skills, professional networks, scientific independence, and capacity to work across sectors and disciplines.

NIH should distinguish among related but different functions: (i) Research supervision includes oversight of work, safety, and compliance. (ii) Training develops scientific, technical, ethical, and professional competencies (e.g., science communication). (iii) Mentorship provides sustained career and psychological support, including guidance, feedback, sponsorship, and support for increasing independence.

These functions often overlap but employing or supervising a trainee should not by itself be treated as evidence of effective mentorship. NIH should also recognize that mentorship is often provided by a network that may include principal investigators, other faculty members, laboratory staff, peers, former trainees, professional staff, and collaborators inside and outside of the institution. Assessment and incentives should recognize these distributed contributions rather than attributing all mentoring outcomes to a single principal investigator.

2. Use a multidimensional portfolio of evidence. No single indicator can adequately capture mentoring quality or its effects. NIH should consider a portfolio organized around four complementary domains: mentoring practices, trainee experiences, developmental outcomes, and institutional conditions.

Mentoring Practices. Relevant evidence could include: Development and periodic review of individualized mentoring or professional-development plans. Clear expectations concerning

responsibility, authorship, publication, data stewardship, intellectual credit, communication, and conflict resolution. Mentor participation in evidence-informed preparation or professional development. Use of mentoring teams, peer mentoring, and access to career-specific mentors rather than reliance on a singular individual. Availability of a confidential and workable process for changing mentors or addressing serious mentoring problems.

These indicators are relatively feasible to collect, but NIH should avoid reducing them to compliance checks. The presence of a mentoring plan, for example, reveals little unless the plan is used, revisited, and experienced as helpful by the trainee.

Trainee Experiences. Confidential trainee feedback should be a central component of assessment. Possible indicators include trainees' perceptions of clarity of expectations and fairness in the allocation of credit; support for scientific independence and intellectual ownership; access to professional networks, sponsorship, and career information; supportive and safe environment that provides for the ability to raise questions, acknowledge mistakes, or express concerns without retaliation; and support for professional goals across the full range of biomedical careers.
Mentor self-reports should not be the sole evidence of effectiveness. At the same time, NIH will need to protect confidentiality, particularly in small laboratories, departments, and training programs where critical responses may be identifiable. In many circumstances, trainee-experience data may initially be most appropriate for aggregation and improvement at the program, department, or institutional level.

Developmental Outcomes. NIH should focus on whether trainees are developing the capabilities and agency needed to pursue their goals. Possible indicators include growth in research, technical, communication, teamwork, leadership, and career-management competencies; growth in adjacent skill development relevant to trainees' goals (e.g., science communication, community engagement, science policy, etc.); understanding and application of rigorous and responsible research practices; increasing scientific independence, responsibility, and confidence; progress toward appropriate educational or training milestones; and movement into careers aligned with trainees' interest, skills, and goals.
Outcome evidence should be interpreted in context and over an appropriate period. A developmental outcome observed several years later may be more meaningful, but it is often difficult to attribute to a single mentor, grant, or training experience.

Institutional Conditions and Accountability. Mentorship quality is shaped by departments, training programs, and institutions, not solely by individual effort. Relevant indicators could include whether workload, promotion, and recognition systems meaningfully value mentorship; whether mentors receive sufficient time, preparation, and institutional support; availability and quality of mentor-development programs; access to independent ombuds, grievance, and mentor-rematching processes; and support for team, peer, cross-disciplinary, and networked mentoring models.
Assessing institutional conditions is important because NIH should not reward individual mentors for outcomes produced by well-resourced environments while penalizing others for structural conditions outside of their control. Conversely, institutions should not receive credit merely for adopting formal policies that are not consistently implemented.

3. Define career success broadly. NIH should avoid defining successful training primarily through

academic placement, publication output, or subsequent NIH funding. The biomedical research enterprise depends on professionals working across academic research, industry, government, clinical practice, public health, nonprofit organizations, policy, education, research administration, communication, and other areas.

Treating entry into a tenure-track academic position or receipt of an NIH award as the preferred outcomes would undervalue many careers through which biomedical training benefits the public. It could also encourage mentors and institutions to steer trainees toward a narrow range of paths or to disregard trainees whose goals lie outside of academic research.

A more appropriate approach would assess whether trainees received strong preparation, understood the range of opportunities available to them, developed relevant competencies and networks, exercised informed agency in their career decisions, and moved toward work aligned with their goals. NIH should recognize that career paths are increasingly nonlinear and that the public value of research training may emerge through many occupations and sectors.

4. Pilot and validate indicators before using them for high-stakes decisions. AAAS recommends that NIH develop a limited common core of measures while allowing for different career stages, disciplines, research settings, grant mechanisms, and institutional types. Mentoring an undergraduate researcher, doctoral student, postdoctoral scholar, clinical-scientists, staff scientist, or early-career faculty member involves different objectives and constraints. Laboratory-based, clinical, computational, community-engaged, and team-science environments may also require different evidence.

NIH could take the following ordered steps:
o Develop a concise common framework through consultation with trainees, mentors, institutional leaders, workforce researchers, social scientists who conduct mentorship research, and professional societies.
o Pilot the framework in selected institutional training grants, career-development awards, and research programs.
o Combine confidential trainee feedback with mentor, program, institutional, and administrative evidence.
o Test measures for validity, reliability, administrative burden, privacy risks, susceptibility to gaming, and differential effects across institutional types.
o Examine whether indicators predict meaningful developmental outcomes rather than merely correlating with institutional prestige or existing resources.
o Use early results primarily for formative feedback and program improvement.
o Introduce consequential uses in funding or renewal decisions only after the measures have demonstrated sufficient validity and fairness.
NIH should also evaluate the measurement system itself over time. Indicators can change behavior, sometimes in ways that undermine the underlying goal. A measure that initially appears useful may become less informative once it becomes a high-stakes target.

5. Reward quality and improvement while guarding against unintended consequences. NIH could recognize training and mentorship through structured narrative or portfolio-based evidence in relevant

grant applications and progress reports. Reviewers could be asked to consider the quality of mentoring practices, evidence of trainee development, responsiveness to feedback, and contributions to team and institutional mentoring. NIH could also support protected effort, mentor development, institutional capacity-building, and recognition for demonstrated excellence or meaningful improvement.

Indicators should inform expert judgement rather than be mechanically combined into a numerical score or ranking. NIH should explicitly guard against several foreseeable consequences:
o Box Checking: Completion of mentor training or a mentoring plan becomes a substitute for effective practice.
o Gaming: Investigators document meetings or activities that trainees do not experience as meaningful.
o Selection bias: Mentors become reluctant to work with trainees who may need additional support or whose career paths could lower conventional outcome metrics.
o Narrow definitions of success: Academic placement, publications, or NIH funding are treated as the preferred result.
o Attribution errors: Outcomes produced by multiple mentors, teams, and institutions are attributed to one principal investigator.
o Privacy and retaliation risks: Trainees believe that candid feedback can be identified and used against them.
o Institutional inequities: Institutions with greater administrative capacity appear more effective because they can collect and present more sophisticated data.
o Added uncompensated labor: New expectations place disproportionate burdens on individuals already performing substantial mentoring service.
o Short-term outlook: Immediate, easily counted outputs displace attention to development that occurs over longer periods of time.
o Metric substitution: NIH replaces an overreliance on publication and citation metrics with another reductive set of quantitative targets.
Guardrails should include multiple sources of evidence, confidential trainee input, contextual review, recognition of team mentorship, consideration of career stage and opportunity, technical assistance for institutions with fewer resources, and mechanisms for identifying and correcting adverse effects.
The most useful framework will combine evidence about mentoring practices, trainee experience, developmental outcomes, and institutional responsibility while acknowledging that some of the most significant effects of mentorship are relational, cumulative, and visible only over time.

AAAS encourages NIH to adopt a measured, evidence-building approach – define the qualities it seeks to promote, pilot a concise and multidimensional framework, validate indicators across research contexts, protect trainees, and use the resulting evidence to encourage improvements as well as accountability. This approach would better align incentives with NIH's mission while avoiding the creation of another narrow metric that rewards what is easiest to count rather than what matters most.

4. Collaboration: • One mechanism is through authorship metrics, which are typically defined as scientists who have made substantial contributions to the conception or design of the research; the acquisition, analysis, or interpretation of data; or the creation of new software used in the work. NIH should consider using more detailed contribution summaries that outline specifically the manner to which an individual contributed to the research, such as the Contributor Roles Taxonomy (CRediT) model encouraged in Science publications.

• Not all collaborative projects result in authored papers, and collaboration can be measured both qualitatively (knowledge sharing, publication, citations, new funding awards, products) and quantitatively (number of institutions, types of institutions, disciplines, countries, funding sources, etc.).

• Qualitative metrics may require a broad array of approaches that are unique and dependent on the nature or stage of research. We recommend that NIH take this opportunity to support social science research into measuring collaboration before determining appropriate metrics – both qualitative and quantitative.

• With the prospect of artificial intelligence becoming a tool in the conduct of research, one can argue that AI itself can be considered a "collaborator." While NIH has existing policies and guidelines with respect to the use of AI in the drafting of grant proposals and writing of research papers, NIH should consider developing guidance on measuring the use of AI in the conduct of research. For example, the compilation of data, tables and graphics, and the analysis of data, tables, and graphics.

5. Entrepreneurship and Translation: • Translating and integrating new discoveries and technologies into products for people may be due to a need to incubate research for a longer period or require an advancement in a specific technology or set of technologies to translate from a conceptual to a production phase. This is further encumbered by the fact that the processes for advancing translational research through various stages (early-stage, mid-stage, late-stage) will be unique and dependent on the specific experiment.

• Gaps for moving from bench to bedside may fall outside the research lab. Furthermore, the difficulty of scaling from the research bench to a commercial product may be due to the lack of advanced manufacturing to move from conceptual to the production stage. These are issues that have often little to do with the research that served as the foundational innovation.

• Metrics for success come in different forms: reducing risk, improving efficacy, opening new pathways for research, advancing scalability, patentability, publication metrics, number of patients served, number of start-ups created, jobs created, etc.

• We urge caution when developing metrics that can be applied across translational sciences as they may be misleading, ineffective, and even damaging. This is especially true when applying metrics that are ineffective or misleading for determining grant awards.

• The federal government, however, does support programs like STTR, SBIR, ARPA-H, technology transfer, NCATS) that are developed to bridge the so-called "Valley of Death." A landscape analysis of how effectively differing incentives can bridge this divide on different institutions, infrastructure needs, fiscal gaps (both public and private), and expertise of individual researcher, and/or stage of career may serve as a useful first step.

6. Foundational Scientific Exploration: • Academia performs both foundational research and high-risk, high-reward research supported by specific federal programs (e.g., Common Fund, ARPA-H), and it is important that metrics for both pathways remain separate.

• Both basic and high-risk, high-reward research contain some form of uncertainty, but in different ways that necessitate different metrics. With basic research, the uncertainty is due to exploring the edge of human knowledge – we simply do not know what can be learned and what benefits it may bring in other areas outside the realm of initial exploration. In this case success is broad: increasing fundamental scientific knowledge and understanding of the underlying foundations of phenomena and observable facts or refining our understanding of something we've only begun to explore.

• With high-risk, high-reward research, the goal is generally known, but how to achieve that goal involves risks and uncertainty undertaken by the researcher, and thus success can be more narrowly defined. Success in this case could be accomplishing the goal in the initial proposal or simply advancing a few steps closer to solving the problem.

• Conflating the metrics of success for these two types, or research would mean undercounting the advantages each one brings to the United States. Metrics for high-risk, high-reward research typically follow contributions to core knowledge (e.g., theoretical, empirical); level of uncertainty whether for risk of failure or success; the novelty and creativity; the length of time needed for the research; and the potential outputs such as commercial viability.

• Measuring novelty may depend on whether it is applied to novel knowledge that expands existing or introduces new scientific frontiers of understanding or to the application of foundational research in novel ways (e.g., honeybee algorithm) that are not necessarily considered high-risk but involve creative approaches. Each comes with different risks and uncertainties.

7. Public Impact: N/A

8. Other Areas: N/A

273. University of Pittsburgh

I am responding: On behalf of an organization

Name: Michael Holland

Name of Organization: University of Pittsburgh

Type of Organization: Not Applicable

Role: Organizational Official

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: The priority for understanding the efficacy of NIH's training and mentorship programs needs to be systematic, comparable data across institutions. The Institute for Research on Innovation and Science (IRIS) has built the infrastructure necessary to directly and dynamically measure the exact number, roles, and compensation of individuals supported by federal grants, including undergraduate and graduate students, postdoctoral researchers, and technical staff. Through its formal partnerships with U.S. Census Bureau infrastructure for privacy-restricted microdata, IRIS is able to link university grant and administrative data to IRS W-2 earnings data and Social Security Administration files. This permits tracking the longitudinal career paths and economic impacts of NIH-funded researchers and trainees, thus directly quantifying the impact of NIH biomedical research workforce development programs with policy-relevant resolution for the academic, industrial, governmental and non-profit sectors. Rather than continuing to seed the creation of new measures or small-scale, non-comparable studies, NIH needs to provide stable, long-term operational support to scale appropriately designed research infrastructure (whether that is IRIS, RTI International, ORISE or OSU's Ohio Education Research Center) that can rigorously examine the efficacy of NIH's training and mentorship portfolio across all NIH-funded institutions. Currently, IRIS is forced to fund itself inefficiently through a model of institutional memberships funded by Senior Research Officers and a mix of discrete sponsored research projects. A stably funded analytic infrastructure would allow NIH and research institutions to better tailor training and mentorship programs for the more than 60% of biomedical research workforce with advanced degrees that now works outside of academia according to NSF's recent Survey of Doctorate Recipients.

4. Collaboration: N/A

5. Entrepreneurship and Translation: As discussed in the recent NSF-funded "Workshop on Identifying and Removing Gaps and Barriers to Translating Research to Practice" that included broad federal agency participation, four recurring "valleys of death" were identified that commercial translational efforts face: [1] spinning out a technology and forming a startup; [2] finding product-market fit and launching a minimum viable product in a complex market; [3] demonstrating the first full-scale commercial product or facility; and [4] proving that the product is stable, profitable, and scalable.
Moving discoveries along these translational barriers requires replacing disconnected handoffs with a

coordinated system across academia, industry, philanthropy, government, and nonprofits. NIH has developed several effective mechanisms, including NIAID's Antiviral Drug Discovery (AViDD) Centers for Pathogens of Pandemic Concern program and NIDCR's Accelerating Product Excellence in Innovation and for Clinical Adoption (APEx) program, that integrate innovation and entrepreneurial efforts within an institute's mission. Other Institutes can adapt these mechanisms to their particular missions and needs. Additional options for NIH to support systematic coordination across these barriers are organized into the following four pillars. These can replace disconnected handoffs with a continuous loop of learning, feedback, adaptation, and application.

Pillar 1: Strengthen Connections to Market Signals and Industry Vetting

• Integrate industry-informed priority setting at the earliest research stages where goals and objectives are set.

• Co-develop challenge statements with industry input that can directly shape federally-funded research agendas

• Use milestone-based funding to facilitate industry engagement in translational pathways

• Embed industry fellows within research and startup ecosystems to provide continuous, insider market validation

Pillar 2: Expand Researcher and Student Exposure to Real-World Challenges and Entrepreneurship

• Expand support for experiential learning programs that connect research with industry

• Support adoption of Department of Defense's "Hacking for X" course methodology to teach students and faculty members how to use startup lean innovation and rapid prototyping to solve the real-world challenges industry faces in bringing products to market.

Pillar 3: Strengthen Translational Pathways and Coordination Across the Innovation Lifecycle

• Link follow-on sector-specific translational programs into integrated, lifecycle-spanning funding pathways. NIDCR's APEx is a particularly strong example of this.

• Develop translational pathways to impact for behavioral health interventions beyond traditional patent and startup models

Pillar 4: De-Risk Translational Progress and Enable Scalable Investment Pathways

• Provide rapid-access administrative supplements that enable investigators to quickly demonstrate specific commercialization-relevant milestones. Retaining consulting engineers in the review process can help agencies assess whether these milestones reflect real development, production, integration, and adoption requirements rather than academic indicators of progress.

• Establish risk-sharing approaches, including milestone-based supplements and co-investment models

• Develop predetermined global IP strategies and partnerships with shared cost and return structures. NSF's longstanding Industry-University Cooperative Research Centers program's approach to IP is worth examining.

The central challenge is therefore not simply to help more technologies cross individual valleys of death, but to build an innovation ecosystem capable of learning, adapting, and carrying promising ideas across the full journey to impact. The report can be found at https://tinyurl.com/2vwudhm8.

6. Foundational Scientific Exploration: Bottom-up, mission-driven strategic planning essential to build the support within the research community and the policy community for continued funding of bold and innovative research directions. Substantive strategic plans for basic research are required if policymakers and agency leaders are to justify major federal R&D investments, shape funding allocations, and design large-scale initiatives.

The NIH-Wide Strategic Plan outlines peer-review mechanisms, broad translational pipelines, and grant

lifecycle adjustments (like eliminating letters of intent or capping direct costs). It is a guide for how the agency distributes research awards, rather than a scientific strategy document. NIH strategic planning at the level of the Institutes and Centers can be characterized as top-down, disease-focused, and operational. Institute-level strategic plans focus on justifying the broad remit of an entire institute's mission area, defining very high-level areas of opportunity that lightly shape individual investigator-initiated R01 grant funding priorities and have a goal of balancing the competing interests of patient advocacy groups and academic researchers. Change in public health burden via domestic disease prevalence, life expectancy, clinical trial translations, and structural health equity has been only loosely correlated with the funded portfolio of awards (see Gao, T., Han, O., Li, G. et al. Allocation of the National Institutes of Health funding and burden of disease in 2008–2021 in the United States. npj Health Syst. 2, 41 (2025). https://doi.org/10.1038/s44401-025-00048-x).

Each NIH Institute and Center needs to engage in bottom-up, mission-driven strategic planning. These plans will enable budget formulation that aligns resources with specific scientific campaigns. They can scope and provide evaluation criteria for the mid-scale and large-scale investments that reduce scientific uncertainty and advance each Institute's progress on attaining its mission. Bottom-up community-wide planning does not inherently shift basic research to applied, but it forges sub-discipline alignment and helps small, disparate research groups come into greater agreement on technical definitions and help frame essential research infrastructure needs, whether that is the development of new instrumentation or the funding of national or regional-scale research cores that support broad user access.

The Department of Energy's Basic Energy Sciences Advisory Committee (BESAC) "Basic Research Needs" workshop reports provide a clear example for the NIH Institutes and Centers to model their bottom-up strategic planning efforts after. Aside from having the practical utility of defending budget requests for the DOE Office of Science, these reports successfully build a unified community voice that resonates well in federal science policy circles and are regularly used to highlight competitive gaps against international rivals (such as Europe and China) in key fields.

7. Public Impact: The Entrepreneurship and Translation topic above is framed explicitly in terms of products. There is no debate that drugs, devices, and clinical therapies are essential, but patient self-management of chronic diseases is increasingly essential to improve health behaviors, health outcomes, and quality of life and, in some cases, has demonstrated effectiveness for reducing health care utilization and the societal cost burden of chronic conditions (Allegrante JP, Wells MT, Peterson JC. Interventions to Support Behavioral Self-Management of Chronic Diseases. Annu Rev Public Health. 2019 Apr 1;40:127-146. doi: 10.1146/annurev-publhealth-040218-044008. Epub 2019 Jan 2. PMID: 30601717; PMCID: PMC6684026).

For community-engaged research that produces programs, interventions, services, or civic technologies that can transform lives rather than drugs, devices, or clinical interventions, their social impact often falls short because most universities' innovation infrastructure assume for-profit commercialization. Bench science researchers (often in medicine, natural sciences and engineering) have access to well-defined support systems that improve the likelihood that their promising research outputs can sustain, scale, and spread for maximum impact. Existing support systems (e.g., NIH's Clinical and Translational Science Institutes, NSF's Innovation Corps, Small Business Innovation Research/Technology Transfer) facilitate the translation pathway for products. As a result, public impact of bench science is optimized, funder investments show greater return, and research teams are able to hand off their research-based products and direct their energy to the next pressing research question.

Existing translational pathway support mechanisms of entrepreneurship training, seed funds, licensing

agreements, gap funds for prototyping or regulatory pathway planning, and coaching resources are not comfortable fits for community-engaged researchers (often in the social sciences) who want to see their research products and programs progress from idea to evidence-based output to sustainable public impact (Burgio, L. D., Disentangling the translational sciences: A social science perspective. Research & Theory for Nursing Practice, 24(1), 56-63 (2010); Sheridan, S. M., DiLillo, D., Hansen, D. J., DeKraai, M., Koenig-Kellas, J., Swearer, S. M., & Wheeler, L. A. Enhancing Lives via Interdisciplinary Translational Science (EnLITS): A circumplex model for the social-behavioral-educational fields, CYFS Working Paper No. 2016-1 (2016). Available at cyfs.unl.edu).

Not only are most VCs not interested in funding non-profit companies or technologies intended for the government sector, the range of sustainable business models for programs and services is larger than that for a technology-based startup company. Social entrepreneurs need to understand non-profit and government business models, they need help in developing funding strategies that will be complex mixes of fee for services rendered, philanthropic funding, and non-research agency state or federal grants. This lack of support and clear steps in the community-engaged translation pathway leads to under realized public impact, low return on funding agency investments, and university researchers expending undue time and resources on promising outputs neither they nor their partners are equipped to sustain.

There is a need to develop and scale a fit-for-purpose, implementation approach that can scale and sustain community engaged programs, inspired by the translational infrastructure for STEM innovations, that will support a “translation mindset” from the earliest stages of community-engaged researchers’ projects.

I am responding: On behalf of an organization

Name: Lizbet Boroughs

Name of Organization: Association of American Universities

Type of Organization: Professional Organization/Association

Role: Other

Role - Other: Senior Associate Vice President, Government Relations and Public Policy

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: The ability to reproduce research findings is essential to the integrity of biomedical science. However, a range of interconnected, systemic challenges can make replicating important studies difficult. Overcoming these obstacles requires a comprehensive approach that addresses every stage of the research process, from study design to data processing. Scientific standards serve as a foundational tool in advancing and ensuring research reproducibility.

AAU applauds recent standardization initiatives, including Stanford's Center for Open and REproducible Science (CORES), whose work, such as its recent symposium, is actively redefining how open data, code sharing, and transparent methodologies are taught and embedded into research workflows. Another example is the recent conference at Frederick National Laboratory for Cancer Research to promote standardization and greater sharing of data through its Scientific Standards Hub initiative.

In response to this RFI, AAU recommends the following:

• NIH should increase its investments in metascience and portfolio analysis to obtain additional clarity on areas of research where replication efforts will have the greatest scientific and public health impact. NIH's Pilot of the Science of Scholars Program should be expanded to include funding support and an opportunity for scholars to publish their findings.
• NIH should continue its investments in shared infrastructure such as data repositories, development of tools, and promulgation of baseline data requirements to encourage replication.
• NIH should build on its existing efforts to encourage professional recognition for reproducibility intramurally, through extramural research institutions, and collaboration with scientific societies.
• NIH should continue to incentivize replication adoption through prizes such as the DataWorks! Prize and Replication Prize to boost current replication efforts and encourage a culture change in biomedical research that results in replication activities being normalized as part of conducting research.

2. Data, Software, and Model Sharing: AAU supports NIH's goals of catalyzing collaborations and accelerating scientific impact. Data is at the core of fostering collaborations and accelerating scientific impact. The successful sharing of scientific data, software, and models is predicated on NIH maintaining its commitment to critical infrastructure support. Data support beyond the term of a grant is necessary to foster access to high-value data sets and promote data reuse.

AAU Recommends:
• NIH is encouraged to support the institutional policies and practices articulated in the AAU-APLU Accelerating Public Access to Research Data Initiative. This report discusses the strategies and approaches to establishing community data-sharing norms and expectations; developing discipline-specific data management plan templates and supporting trusted disciplinary repositories; promoting common metadata and interoperability standards; establishing long-term preservation and governance systems; and creating incentives and recognition for data sharing and data citations.
• NIH should adopt the FAIR (Findable, Accessible, Interoperable, and Reusable) principles, already reflected in its Data Management and Sharing Policy, as part of organizing a framework for future data and model sharing indicators, and calibrate any new reporting requirements to this existing standard rather than establishing a duplicative metric structure.
• NIH is encouraged to continue collaborating with the National Institute of Standards and Technology and its efforts to develop a research data framework. Developing and adopting standard metadata approaches could facilitate the use of metadata across datasets and disciplines, reducing barriers to data sharing and reuse – as AAU shared in its comments on NIH's Enhancing Public Access to the Results of NIH-Supported Research.
• NIH is encouraged to align any changes to its Draft Controlled-Access Data (CAD) policy and proposed revision to NIH Genomic Data Sharing (GDS) policy to reduce barriers to data access. AAU's comments to NIH on its Draft Controlled-Access Data (CAD) policy and proposed revision to NIH Genomic Data Sharing (GDS) policy, submitted March 18, 2026, include additional details.
• NIH's recent Implementation Update on its data management sharing (DMS) plan was welcome. AAU shares NIH's hope that implementing this new format will ensure NIH's data-sharing goals are achieved while reducing administrative burden and improving reporting efficiency. AAU welcomes continued collaboration with NIH on reducing administrative burden.

3. Training and Mentorship: AAU encourages NIH to leverage the agency's long-established investments in mentor training and in career and professional development programs; build on established policies; and advance evidence-informed recommendations from dedicated reports. Across AAU institutions, effective mentorship is viewed as an essential component of graduate and postdoctoral training, and many institutions have developed department-level metrics and assessment processes to identify, evaluate, and strengthen mentoring effectiveness.

AAU Recommends:
• NIH should invest in scaling proven evidence-based mentoring and career and professional development within T-32s grant mechanisms and other programs. For example, the NIH Broadening Experiences in Scientific Training (BEST) funding mechanism was established to "seek, identify and support bold and innovative approaches to broaden graduate and postdoctoral training, such that training programs reflect the range of career required for a robust biomedical, behavioral, social and clinical research enterprise."
o It is notable that BEST programs are not intended to be "alternative career programs," but rather are designed to provide critical career development skills that will benefit all trainees, regardless of career trajectory.
o The program enabled 17 institutions (10 in 2013 and 7 in 2014) to build the infrastructure, curriculum, internships, and training opportunities to expose trainees to the myriad of career options in research

and associated career tracks, while emphasizing workforce sustainability through evaluation of longitudinal outcomes.
o The awardee sites were part of a comprehensive cross-site evaluation designed to understand trainee agency, time to desired careers, and culture changes at academic institutions and have led the way in recent efforts to track career outcomes. Including publishing data and additional information about their graduate programs and graduate student career placements and outcomes.
• NIH should encourage the continued use and advancement of myIDP (My Individual Development Plan). Since the development of myIDP in 2012, myIDP has emerged as an influential career-development tool to help NIH-funded graduate students and postdoctoral scholars assess their skills, interests, and values and explore scientific career options within and beyond the traditional academic pathway.
• NIH should coordinate cross-NIH efforts with established NIGMS activities to support translational pilots that integrate evidence-based practices into mentorship training. These investments could continue to provide NIH with the evidence needed to make strategic decisions about which innovations to scale.
o For example, The pd|hub Mentorship Action Collaborative is a five-year NIH NIGMS-funded project led by Professional Development Hub (pd|hub) in partnership with the Center for the Improvement of Mentored Experiences in Research (CIMER) to develop, test, and disseminate evidence-based resources that strengthen career-related mentoring for graduate students and postdoctoral scholars.
o The initiative aims to improve mentor-mentee career conversations, enhance career resilience and workforce preparation, and integrate mentorship with institutional career-development programs to support diverse biomedical career pathways.
• NIH should support assessment of mentoring effectiveness and capitalize on frameworks being developed to more holistically evaluate faculty work to include various forms of evidence that can recognize effective mentoring in promotion and annual review. For example, the TEval Network, and the American Academy of Arts and Sciences' project on Modernizing Academic Appointment and Advancement

4. Collaboration: AAU supports NIH and the National Science Foundation's (NSF) efforts to promulgate successful approaches to team science, and to explore ways to assess and recognize contributions to team-based science. Many AAU institutions have a significant history of providing structural support for collaborative science, ranging from co-locating equipment for shared departmental use, physically embedding data collection within academic hospitals to improve data access, to recognizing collaborative science in institutional tenure and promotion policies.

Documenting best practices for collaborative science and measuring contributions to team science should include entities outside biomedical research, such as NSF and NASEM. NASEM has shared extensive research in 2015 and 2025 on existing best practices and evaluation gaps for teams and individual contributors.

AAU Recommends the following to foster team science:
• NIH should consider supporting research to measure the implementation of NIH-funded team science and cross-disciplinary models utilizing tools included in NASEM's The Science and Practice of Team Science (2025). Tools exist to measure performance output, project outcomes, team dynamics, and career impact. However, "(f)unders need to provide more funding mechanisms for the scientific study of

science teams. Indeed, major funding bodies such as the National Science Foundation and National Institutes of Health emphasize the critical importance of team science in solving complex global problems, but the support needed to fund the study of science teams is lacking. This disparity is problematic given the complexity of studying science teams, which requires both significant financial resources and specialized methodological approaches tailored to scientific collaboration contexts."
• The report states that assessments of contributions to team science might vary among disciplines, invention reports, patents, and the development of tools with specialized datasets. Funders should work with the scientific community to examine approaches such as "Individual Contribution Portfolios which track specific roles using taxonomies like CRediT (Contributor Roles Taxonomy), verifiable data/software deposits, and mentorship quality rather than just authorship."
• Assessments of individual contributions could include future projects or grants following the initial collaboration, and the development of new technologies.

AAU notes that NIH's Proposal to Cap Simultaneous Research Project Grants per Principal Investigator, if implemented, would likely discourage interdisciplinary and collaborative research. As requested in AAU's comments, clarity from NIH is needed on how the proposed process for team-based and cross-institutional research grants would be measured toward possible caps on simultaneous grants. A working group like the Advisory Committee to the Director's Working Groups on Re-envisioning NIH-Supported Postdoctoral Training should examine how potential caps might affect scientific teams, interdisciplinary research, and data sharing.

5. Entrepreneurship and Translation: AAU supports NIH's goal to "translate discoveries into products for people." AAU consistently supports entrepreneurship, technology transfer, and translation as core mechanisms to convert university research into societal and economic benefits.

For 45 years, the Bayh-Dole Act ((35 U.S.C. § 200 et seq. and 37 C.F.R. Part 401) has served as biomedical research's most enduring metric of entrepreneurship. By allowing universities to retain title to inventions arising from federally funded research and requiring reporting on invention disclosures, licensing activity, and commercialization outcomes, the statute already generates the kind of measurable, longitudinal translation data this RFI seeks. Therefore, NIH does not need a new data architecture to measure entrepreneurship and translation; rather it needs to draw more fully on the invention utilization and licensing data universities already report under the Bayh-Dole Act.

A thriving Bayh-Dole ecosystem depends on three conditions that any new metrics initiative should protect rather than disturb. First, predictability. Technology transfer offices, industry licensees, and venture investors structure years-long commercialization timelines around a stable set of statutory obligations and layering new NIH-specific reporting or performance metrics on top of existing Bayh-Dole compliance risks, fragmenting that framework and discouraging the private investment the statute is designed to attract. Second, patience. Translation from discovery to product routinely spans a decade or more, and metrics that reward near-term commercialization signals over sustained investment in early-stage, higher-risk inventions will distort the discovery pipeline. Third, administrative proportionality. Universities, particularly those with smaller technology transfer staffs, already carry substantial invention reporting burdens, and NIH should build any translation indicators on existing iEdison and annual utilization reporting rather than creating a parallel collection requirement.

AAU has a long-standing position on this point and NIH has repeatedly considered and rightfully declined petitions to exercise march-in rights over drug pricing, concluding in each instance that the statute's "practical application" requirement is satisfied once a patented invention is on the market and available to the public. AAU has explained that exercising march-in rights for reasons other than exigent health or safety needs, particularly if the scope of that authority is broadened beyond Congress's original intent, would introduce substantial market uncertainty and chill university licensing activity, discouraging the private sector investment needed to carry federally funded inventions from the laboratory to the clinic. NIH's metrics initiative should reinforce, rather than complicate, the statute's core bargain: predictable ownership and licensing terms in exchange for the obligation to bring inventions to the public. AAU recommends the following on entrepreneurship and translation:

• NIH should base any future entrepreneurship and translation indicators on existing Bayh-Dole invention utilization and licensing data rather than creating new parallel metrics, and ensure any new indicators preserve the predictability, patience, and administrative proportionality on which a thriving technology transfer ecosystem depends.
• NIH should continue to support entrepreneurship education and workforce development that prepare graduate students and postdoctoral scholars to engage in innovation, commercialization, and venture creation.
• AAU would like to further engage with NIH to reduce administrative barriers to technology transfer by streamlining research contracting, intellectual property management, and public-private partnerships.
• NIH should continue to support and expand innovation/entrepreneurship competitions and comprehensive entrepreneurial ecosystems that include incubators, accelerators, and commercialization and proof-of-concept grants through its SBIR and STTR programs and other innovative initiatives such as the Research Evaluation and Commercialization Hubs (REACH) and the NIH Catalyze programs established by the National Heart, Blood, and Lung Institute.
• AAU recommends that NIH, and the federal government more broadly, protect and strengthen the Bayh-Dole framework that allows universities to retain and commercialize inventions arising from federally funded research, and continue to support university startups and small businesses through Small Business Innovation Research and Small Business Technology Transfer programs and other entrepreneurship-focused funding mechanisms.
• Any framework for measuring and rewarding scientific impact, at NIH or elsewhere in the federal government, should treat that decentralized ownership model as an asset to be strengthened rather than a variable to be re-engineered on an agency-by-agency basis.

• AAU also urges continued investment in SBIR and STTR programs, which remain among the most effective vehicles for converting federally funded discoveries into viable companies. These award-based mechanisms complement Bayh-Dole by supplying the early-stage, non-dilutive capital that allows university spinouts and small businesses to de-risk technologies before they can attract private investment. As other countries deploy substantial state-directed capital to accelerate commercialization of their own research base, sustained and predictable funding for SBIR, STTR, and related entrepreneurship-focused mechanisms across NIH and other federal science agencies is a matter of national competitive urgency, not simply a program-level budget line.
• More broadly, NIH should encourage research institutions to continue to draw on recommendations from PTIE (Promotion & Tenure Innovation & Entrepreneurship), a national initiative that promotes

recognition of innovation, entrepreneurship, commercialization, and other societal impacts within faculty promotion and tenure systems. PTIE provides guidance on aligning academic incentives with public impact by rewarding activities such as technology transfer, startup creation, industry engagement, translational research, and broader societal contributions, alongside traditional publications and grants.

6. Foundational Scientific Exploration: The research ecosystem and academic enterprise depend on talent and talent development. Paradigm-shifting breakthroughs from foundational scientific exploration and high-risk, high-reward research rely on consistent, sustained support for workforce training and development.

Continuing federal investment in the full spectrum of STEM disciplines alongside the critical technologies, recognizing that foundational research in physics, chemistry, biology, computer science, engineering, geosciences, social, behavioral and economic sciences, and mathematics enables breakthrough innovations across all technological areas. Sustained investment in training and technologies is the bedrock of successful scientific exploration. Foundational science is the substrate on which technological and scientific progress is built to produce knowledge as a public good, and it remains largely federally funded.

Many AAU institutions have broadened their respective faculty policies over the past decade to recognize and encourage research engagement beyond the historic “publish or perish” model. Broadened policies encourage graduate students, postdoctoral scholars, and faculty to consider undertaking higher-risk research with institutional support for longer commitments.

AAU recommends for foundational science:
• NIH should continue its High-Risk, High-Reward program. The program recognizes established and early-career investigators and continues to serve as a strong model for academic institutions.
• NIH should continue its engagement with the scientific community to explore options for funding support to encourage community- and policy-engaged research.
• NIH should monitor its Center for Scientific Review’s recent policy realignments to ensure the process emphasizes scientific merit and reduces reputational bias.

7. Public Impact: AAU supports NIH’s efforts to explore approaches for assessing and recognizing the public impact of research. Developing such assessments is inherently complex. In biomedical research, for example, the pathway from a scientific discovery to widespread clinical adoption often spans decades. As a result, equating measures of public impact solely with direct contributions to near-term health outcomes could unintentionally discourage investment in foundational research that underpins future breakthroughs.

History demonstrates that transformative advances often emerge from long-term, fundamental scientific inquiry. Longitudinal studies, basic science investigations, and discoveries in seemingly unrelated fields frequently lay the groundwork for major medical innovations. More than 75 years after its inception, the Framingham Heart Study continues to shape evidence-based approaches to cardiovascular health. Similarly, NIH-funded research on mRNA technology required more than two decades of sustained scientific progress before enabling the rapid development of vaccines, while advances in HIV research contributed to the emergence of breakthrough cancer immunotherapies. Scientific discoveries often

generate benefits well beyond their original field of inquiry, underscoring the importance of recognizing the broad and often indirect pathways through which research creates public value.

Many of the necessary processes for a particular discovery to yield "public impact" involve factors beyond NIH's scope. AAU supports efforts to forge stronger connections among universities, industry, and government to accelerate discovery, innovation, and solutions to major societal challenges. The National Science Foundation studies the economic and societal impacts of scientific funding, including biotechnology and biomedical-adjacent fields. The Agency for Healthcare Research and Quality conducts implementation science. The Center for Medicare and Medicaid Innovation assesses health care delivery and payment reforms that can incentivize widespread adoption of clinical practices.

AAU recommends the following on public impact:
• NIH should explore elevating reports and national networks aimed at advancing public impact research, such as highlighting policies and practices advanced by Advancing Research Impact in Society (ARIS), a national organization that strengthens the research ecosystem to support meaningful real world impact, including public impact, by fostering Broader Impacts (BI), Research Impact (RI), and Societal Impact (SI) across all disciplines.
• NIH could consider elevating pathways modeled after institutional programs in the spirit of projects selected for ARIS Impact Innovation Award, such as Penn State's Evidence to Impact Collaborative. In addition, these projects foster transdisciplinary research, research translation, and reducing barriers between basic research and application.
• NIH should consult recent research by the Pew Charitable Trusts that highlights the need to expand faculty reward systems so that promotion and tenure processes value societal impact alongside scholarly impact, including research that informs policy, engages communities, advances innovation, and addresses real-world challenges
• Public impact indicators should be designed as distinct from, not duplicative of, the entrepreneurship and translation indicators addressed elsewhere in this response. Commercialization success, measured through licensing revenue, startup formation, or patent counts, captures the pathway by which a discovery reaches the public, not whether the public actually benefited from it. Treating the two categories interchangeably risks rewarding research for its commercial traction rather than its demonstrated contribution to health outcomes and could create conflicting incentives within NIH's own metrics framework.
• NIH should also account for the fact that public impact often depends on institutional infrastructure, including data management, regulatory compliance, and grants administration capacity. AAU recommends NIH define public impact indicators separately from entrepreneurship and translation metrics to avoid conflicting incentives. NIH should elevate recommendations in the American Academy of Arts & Sciences series of ARISE (Advancing Research in Science and Engineering) initiatives aimed at organizing research to more effectively translate discoveries into advances in health, energy, environment, security, and economic competitiveness. NIH's ability to heighten community awareness of existing recommendations could encourage the cross-sector collaborations necessary to operationalize advances.

8. Other Areas: Measuring and rewarding scientific innovation involves a complex ecosystem that extends well beyond federally sponsored research. While NIH is a critical participant in that ecosystem, other federal sectors, including the National Science Foundation, the U.S. Department of Energy, and the

White House Office of Science and Technology Policy, also play a role. The impact of any federally proposed scientific metrics and incentives has ramifications well beyond the biomedical sector.

AAU suggests NIH sponsor conversations to collaborate with the National Academies of Sciences, Engineering, and Medicine (NASEM) and the American Academy of Arts and Sciences, scientific societies, and associations that establish professional standards, academic institutions that conduct research and train future scientists, and industry leaders to ensure fulsome discussions regarding potential scientific metrics and incentives.

AAU also suggests that the agency consider two additional levers to incentivize the cultural changes needed to achieve its objectives through existing and newly created funding programs: 1) build flexibility into grant programs to encourage behaviors that promote the broader societal and public impact of research, similar to the NSF's Broader Impacts. Such incentives could include enhanced mentoring, improved instruction, greater data access and sharing, entrepreneurship, public engagement, and related activities: and 2) award grants to entire academic departments, rather than individual investigators, to pilot and expand incentives and faculty reward structures in areas outlined in this RFI. We believe that both recommendations would help achieve the desired outcomes by encouraging institutional change, developing more meaningful metrics, and advancing the priorities identified in this RFI.

Finally, as new metrics are promulgated by NIH, AAU requests that a thoughtful consensus process be undertaken to ensure the feasibility of, and mechanisms for, federal reporting. Further, AAU requests that the current funding climate be integrated into consideration of any new mandatory metrics and incentives. The current research and teaching climate is challenged by delays in Congressional appropriations and agency allocations, declining trends in graduate and PhD admissions, driven in part by research funding uncertainty, changes to federal student loans, and concerns about potential new grant requirements under OMB's Uniform Guidance.

Thank you for the opportunity to share AAU's views on Metrics and Incentives for Scientific Innovation. AAU greatly appreciates NIH's efforts to engage the biomedical research community, and we welcome further collaboration. If there are questions about AAU's comments, please contact Lizbet.Boroughs@aau.edu.

Jayanta "Jay" Bhattacharya, M.D., Ph.D
Director, National Institutes of Health (NIH)
Office of Science Policy
9000 Rockville Pike
Bethesda, MD 20892

RE: Request for Information on Measuring and Rewarding Scientific Impact
Notice Number: NOT-OD-26-087

Dear Dr. Bhattacharya:

The American Urological Association (AUA) commends the National Institutes of Health (NIH) for issuing RFI NOT-OD-26-087 to modernize how scientific impact is recognized and incentivized and appreciates the opportunity to provide comments.

The AUA is a leading advocate for the specialty of urology and has more than 24,000 members throughout the world. Our members represent the world's largest collection of expertise and insight into the treatment of urologic disease. Of the total AUA membership, more than 17,000 are based in the United States and provide invaluable support to the urologic community by fostering the highest standards of urologic care through education, research, and the formulation of health policy.

As the world's largest urological association, the AUA recognizes that traditional publication and citation metrics fail to adequately reflect the value of translating research into patient care. The focus areas identified by NIH in the RFI reflect the increasingly interconnected nature of the biomedical research enterprise. Rigor and reproducibility, data and resource sharing, training and mentorship, collaboration, translation, foundational discovery, and public impact should not be viewed as discrete activities, but rather as mutually reinforcing components of a research ecosystem that advances knowledge and ultimately improves human health.

Below are the AUA's comments on select focus areas:

FOCUS AREA **– Rigor and Reproducibility.** *Reproducible and replicable biomedical approaches are foundational to rigorous research. New strategies are needed to identify areas ripe for replication and reproducibility efforts, as well as incentives and infrastructure to support the reproduction and replication of existing findings. NIH also seeks comment on rigor, including with regard to defining causal research.*

Both NIH and the Congressionally Directed Medical Research Programs (CDMRPs) at the Department of Defense require Research Sharing Plans in their grants applications. These planning documents explain how investigators will make data and resources

AUA 2027 San Diego MAY 21-24
AUAnet.org/AnnualMeeting

accessible to the public, government, and scientific community. It must detail what data is shared, when it is shared, and justify any exceptions.

A robust data management and sharing plan should clearly describe how final research data, software, model organisms, research tools, and materials will be made accessible to the scientific community while adhering to applicable legal, regulatory, and ethical requirements. The plan should also outline measures to protect participant privacy, proprietary commercial information, and third-party intellectual property. When data or resources cannot be shared, investigators should provide clear justification, such as limitations related to cost, feasibility, confidentiality, or intellectual property considerations.

Application submission and tracking begin through the eBRAP system for pre-applications and are later processed through Grants.gov for full proposal submission. Data management and sharing plans are expected to align with the FAIR principles, ensuring that research data are Findable, Accessible, Interoperable, and Reusable in accordance with federal and defense-funded medical research standards.

FOCUS AREA **– Training and Mentorship.** *Indicators to quantify and reward the effort put into stabilizing and growing the biomedical workforce through effective mentoring.*

Training and mentorship serve as critical tools essential to sustaining the future of the biomedical research workforce in the United States. The ability to quantify research training program impact has been traditionally measured through individual-focused metrics such as publications, citations, and receipt of federal research funding of a mentor's subsequent mentees. As the landscape of biomedical research and clinical care delivery continues to rapidly evolve, respective evolution in the way we assess our ability to educate, train, and equip the next generation of clinician-investigators and scientists is paramount.

Firstly, valuable transformations to the current model should incorporate emerging research outputs that have not been captured and considered in the traditional model. These outputs are well established and well-regarded avenues for research productivity in the modern healthcare ecosystem. Potential new indicators to quantify and reward effort put forth into effective mentoring including measurement of mentee activities including:

- Unfunded research collaborations with patient advocacy and support networks
- Initiation of unfunded multi-disciplinary research collaborations
- Participation in population health research initiatives
- Participation in prevention health research
- Investigator initiated studies and clinical trial participation
- Private industry, foundation or professional society research funding

A second prospective method to enhance the ability to evaluate research mentoring impact could involve design and implementation of a research skill milestone

assessment for distribution for research mentees participating in federally funded research training and education programs such as NIH F32, R13, R25, T35, T32 programs. This would allow for standardized feedback from mentees on progression along landmark research milestones designated by leading research education experts. This concept stems from the foundational theories of clinical competency measurement implemented by the Accreditation Council for Graduate Medical Education.

Unintended ramifications of implementing some of these proposed changes could include a deemphasis on peer-reviewed publication in established scientific journals and degradation of the scientific peer-review process outside of federal funding mechanisms. These unintended consequences could be mitigated by continuing to incorporate the landmark pillars of peer-reviewed publication and federal funding in research training and mentorship evaluation and focusing on expanding, not removing, traditional measurement metrics.

The RFI notes that NIH is particularly interested in specific examples and to that end, the AUA offers the following snapshot:

- Six out of seven of the AUA's Office of Research grant mechanisms require mentorship, beginning with medical students and continuing through the career continuum to early-career investigators.
- For some awards, the AUA requires mentors to submit a List of Previous Mentees as our peer reviewers want to see the success of the mentor's previous trainees (e.g., remain in academic positions, success in securing independent funding).
- For some awards, the AUA weighs the mentor equally or more so in evaluation of the application. Some of our grants are truly about mentorship as opposed to the research project, supporting the building of a successful urologist and physician scientist workforce.

In addition, the AUA supports physician scientists to remain in research with the RSTAR mechanism. This award provides salary support to clinicians with career development awards to encourage them to be physician scientists. We also have a recognition award, the Distinguished Mentor Award, to honor longstanding, successful mentors of the AUA.

FOCUS AREA **– Collaboration.** *New frameworks for recognizing and valuing contributions to large-scale, interdisciplinary team science.*

In contemplating this focus area, the AUA offers lessons learned from our Office of Research's solicitation of feedback from members on current research funding mechanisms and what types of research they would like to see.

The results of this survey led in part to the development of the upcoming Urology Care Foundation (UCF) Transformative Research Award (TRA). This new award mechanism provides two years of funding to support high-risk, paradigm-shifting, and collaborative

research. One of the ways that applicants can do this is through cross-disciplinary collaborations with other fields, such as gynecology, neurology, cardiology, and radiology. The AUA's other funding mechanisms all require descriptions of the research team, including important roles such as biostatisticians and subject matter experts in other fields when warranted.

Drawing on these lessons, the NIH could incrementally strengthen team science by incorporating cross-disciplinary collaboration and team dynamics into grant review criteria, placing greater emphasis on a project's potential to drive scientific advancement than on preliminary data alone. Additionally, Research Performance Progress Reports (RPPRs) could shift from focusing primarily on publication counts to highlighting team-based outcomes, including shared data resources, collaborative intellectual property development, cross-disciplinary partnerships, and mentorship contributions.

FOCUS AREA **– Entrepreneurship and Translation.** *Incentives for researchers moving discoveries from bench to bedside.*

In contemplating this area of focus, the AUA offers lessons from its Innovation Nexus program. The AUA Innovation Nexus is a year-round incubator and accelerator program launched by the AUA to support urology startups. It connects innovators, clinicians, researchers, investors, and strategic partners to move ideas from concept to commercialization.

Grounded in operational insights from the Office of Research and the Nexus Program, the AUA has determined the following specific indicators, implementation strategies, equity considerations and risk mitigation frameworks to assist the NIH in establishing modern evaluation standards.

- The NIH should expand research impact metrics beyond traditional publication measures to include objective indicators of translation and commercialization. These could include advancement along Technology Readiness Levels (TRLs), demonstrating progress from early concept validation to clinical prototype development; intellectual property and commercialization outcomes, such as patent filings, granted patents, and licensed technologies; de-risking and capital formation milestones, including participation in translational training programs, investor showcases, SBIR/STTR funding, and private investment; and regulatory and clinical achievements, such as FDA IDE or IND approvals, clinical trial initiation, and early implementation within healthcare systems.
- The NIH can integrate recognition of translational research into existing funding and review processes with minimal administrative burden. This could include adding an optional "Translational and Entrepreneurial Outcomes" section to the biosketch, allowing investigators to highlight patents, licensed technologies, startups, regulatory approvals, and commercialized products alongside traditional publications.

- Peer review criteria could also place greater emphasis on translational progress by evaluating technology de-risking and commercialization potential within the Impact and Approach scoring categories.
- A modernized evaluation framework should account for differences in career stage and institutional resources. For early-career investigators, translational and commercialization achievements can provide meaningful evidence of impact before long-term citation records are established.
- The framework should also recognize that researchers at resource-limited institutions may have less access to technology transfer and commercialization infrastructure. National specialty society programs, such as the AUA Innovation Nexus, can help level the playing field by providing mentorship, investor access, regulatory guidance, and industry connections that support innovation regardless of an investigator's home institution.

Potential drawbacks of expanding translational research metrics should be addressed through thoughtful safeguards. Increased emphasis on entrepreneurship may create real or perceived conflicts of interest, which can be mitigated through standardized disclosure requirements and by separating scientific review from commercial evaluation. Finally, while translational impact should be recognized, these metrics should be applied primarily to applied and translational research programs, ensuring that foundational basic science continues to be evaluated based on its potential for scientific discovery and long-term impact.

FOCUS AREA **– Foundational Scientific Exploration.** *Safely embedding support for high-risk, high-reward basic research, which carries a risk of failure but can yield massive breakthroughs.*

The aforementioned TRA is also relevant here, as the AUA is encouraging researchers to think about old urology problems and develop new tactics to address them through this mechanism.

FOCUS AREA **– Public Impact.** *Novel approaches to measure a study's broader societal footprint, such as its effect on actual health outcomes, public trust, accessibility, and clinical practice.*

A potential drawback to these new metrics is that different communities require different outcomes. For example, rural urology patients would be interested in research that measures the number of patients treated or helps to increase the number of physicians and their access to those patients. However, populations in more urologist-dense areas of the country may benefit from more subtle metrics, such as the specific skills of a physician or hospital system, and both would benefit from patient education improvements. Confining all research within one area of urology to the same metrics might allow for direct comparisons but could inadvertently fail to show the benefits of some of the projects to certain populations. There are also no universally agreed upon metrics on things such as public trust, accessibility, and clinical practice.

American Urological Association

Notably, UCF Humanitarian grants require an estimate of how many people were reached/impacted through this work as a deliverable. For AUA research grants, we ask the following of our awardees in their progress reports:

- What is the impact or potential impact of the results of the project for the practice of urology and for urology patients?
- Describe how findings, results, and/or techniques that were developed or other products may make an impact on the base of knowledge in urology. Summarize using language for the lay audience.

***

The AUA thanks NIH for the opportunity to comment on this important RFI and welcomes continued engagement.

Sincerely,

Mark T. Edney, MD, MBA
Chair, Public Policy Council, American Urological Association (AUA)

H. Henry Lai, MD
Chair, Research Council, American Urological Association (AUA)

1. Rigor and Reproducibility: It is now possible to flag areas of science at high risk of retractions before they occur. Individual topics have structural vulnerabilities to cascading errors. These are measurable based on the network structure of papers, citations, authors, and retractions. A model built on detecting these vulnerabilities predicts a topic's future retraction rate (Pearson r = 0.714). These forecasts can help target the limited resources for reproducibility research into the areas where they are most needed. The attached response describes these vulnerability measures and predictive model in more detail.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: We can identify which papers are likely to inform future innovation and patenting, years in advance of the decade long path from paper to patent. Models using trajectories of knowledge flow can segment scientific articles into groups where those with the highest prediction scores are patented at ten times the rate of the bottom group. As an article-level metric, it can be used for program evaluation, portfolio analysis, and policy forecasting. The attached response describes the model and its time-series performance.

6. Foundational Scientific Exploration: We can identify signals of nascent fields that will lead to a breakthrough, before landmark studies are published. Network signals in the scientific literature, such as scientists flocking into a new topic and network dynamic instability, often precede the breakthrough itself. Two models, one developed by NIH and one from an independent research group, validate this approach. These signals can measure progress toward breakthroughs and could inform funding toward the most promising scientific topics. The attached response details both models and further use cases.

7. Public Impact: It is now possible to forecast which lines of biomedical research will yield an FDA-approved therapy roughly a decade before approval, in most cases before the pivotal phase 2 study begins. Recently published prediction models accomplish this with an F1 scores of 0.75-0.84. These forecasts can measure portfolio progress toward this applied health impact, while there is still time for decisions to make a difference. The attached response details the modeling approach in more detail.

Description: Detailed response from B. Ian Hutchins at the University of Wisconsin-Madison on the subjects of Rigor and Reproducibility, Entrepreneurship and Translation, Foundational Scientific Exploration, and Public Impact

From: B. Ian Hutchins, Ph.D., Assistant Professor, Information School, University of Wisconsin-Madison

To: Office of Science Policy, Office of the Director, National Institutes of Health

08/19/2026

Recent advances have made it possible to forecast the impact of biomedical research in advance. Researchers have created methods to forecast which lines of research will lead to novel therapies a decade before approval, which nascent fields are most likely to lead to transformative breakthroughs, what areas of science are headed for a wave of future retractions, and which papers will fuel downstream innovation and patents. This response highlights four cutting-edge methods that accomplish these goals and align with the impact areas requested in this RFI.

This is not the first time that I have developed new methods for measuring biomedical research impact. My previous measures of scientific influence (the Relative Citation Ratio) and early indicators of clinical translation (the Approximate Potential to Translate) are now built into the iCite and iSearch tools that program staff use regularly. The methods highlighted below are extensions of that work into some of the harder questions highlighted in this RFI.

All four make extensive use of prediction for a structural reason: there is a fundamental disconnect between agency decision-making timelines (typically 4-5 years) and the long timelines for these decisions to bear fruit (10+ years for innovation and patents, 15-20 years for therapeutic development, and longer for foundational basic science breakthroughs). In addition to identifying the most promising research investments, prediction is necessary for measures that indicate whether research initiatives are moving in the right direction within the necessary decision-making timeframes at NIH. **The payoff from this year's funding will not be directly visible for 10-20 years, so prediction is how to measure it within a decision cycle**.

While I do not provide explicit policy recommendations, I hope to present valuable information and resources that can help NIH to measure the impact of biomedical research investments.

Executive Summary

1. It is now possible to forecast which avenues of research are most likely to yield FDA-approved therapeutics. Our recently published machine learning method [1] predicts which lines of research into human disease will have novel therapies approved, approximately a decade in advance, forecasting future **Public Impact** of biomedical research investments.
2. Recent advances in **Foundational Scientific Exploration** methods have made it possible to identify scientific topics that are poised for breakthrough discoveries. NIH's own model [2] predicts breakthrough discoveries in topic areas that later culminate in Nobel Prize-

Information School
University of Wisconsin–Madison 330 N. Orchard St. Madison, Wisconsin 53715
608-262-5672 Email: bihutchins@wisc.edu hutchinslab.github.io

winning studies; another model [3] using a similar general approach forecasts exceptional growth of research topics, a phenomenon correlated with future breakthrough discoveries.

3. **Rigor and Reproducibility** initiatives have drawn an equivalence between transparency and rigor; my lab has pursued a complementary avenue of attempting to identify areas of science that are particularly at risk for having articles retracted in the future. We have identified vulnerability measures that flag which areas of science have elevated risk of unreliable information transmission through a combination of concentrated author-citation networks and previous retractions [4]. These have enabled us to generate a predictive model that estimates the future rate of retraction in different scientific topics—a modeling approach that might help target limited reproducibility resources to areas where it would be most valuable.
4. By leveraging artificial intelligence approaches, our lab has developed **Entrepreneurship and Translation** forecasting tools that identify which papers are most likely to be used and cited in patents granted by the USPTO [5]. These models identify patterns of cross-domain knowledge flow that typically precede patents.

Public Impact

We can predict an FDA-approved therapy a decade in advance

The development of novel therapeutics is a lengthy process, typically taking 15-20 years, that draws from fundamental research discoveries to inform downstream innovation and applied clinical work. In principle, targeted efforts by the scientific community and science funders could accelerate the discoveries that drive therapeutic development. In practice, it is challenging for scientists, funders, and pharmaceutical companies to identify the most promising research avenues at an early stage.

It is now possible to predict which research will yield an FDA-approved therapy a decade in advance, most often before the relevant phase 2 trial has begun. In order to identify which lines of research will yield future FDA-approved therapeutics [1], we took a three-stage approach: we (a) pruned the entire biomedical knowledge graph of paper-to-paper citations, then (b) partitioned this using machine learning into time-series topic clusters, and (c) generated a predictive model to forecast, based on historical data, which of these topics would later contain the pivotal papers used in FDA decision-making to approve a new therapy. This approach gives models with an F1 score of 0.84 and predicts 65% of therapies before their phase 2 trials have even been initiated (Figure 1).

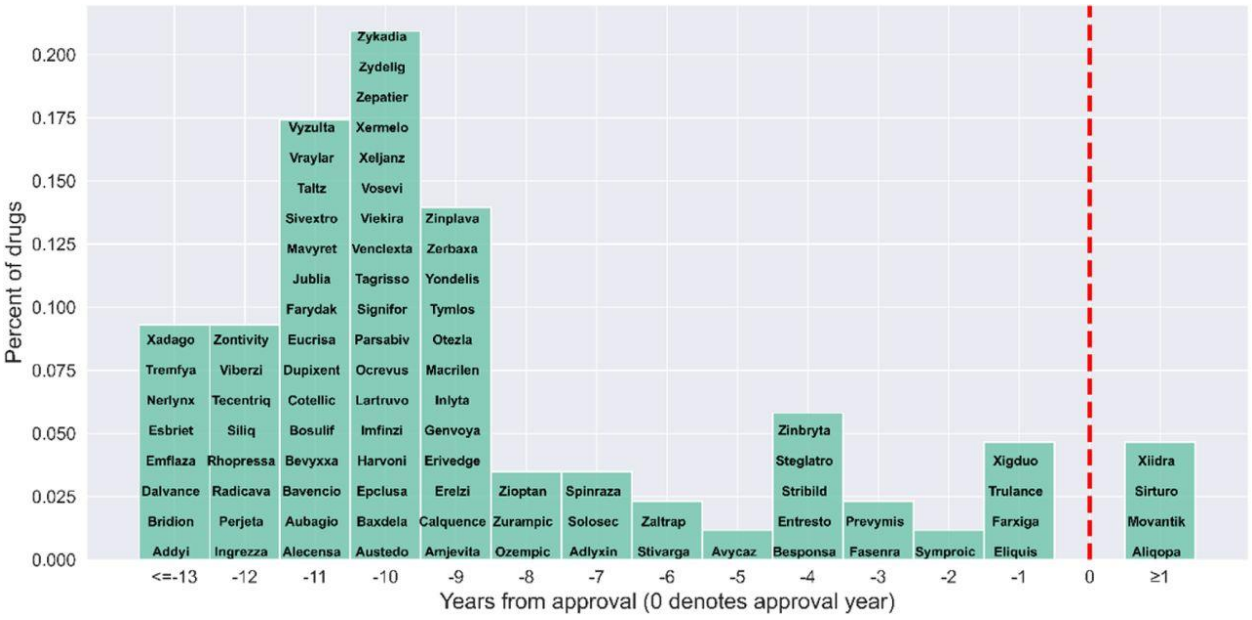

Figure 1. Drug approval forecast that were detected before FDA approval (left of dotted line) as well as the number of years pre-approval that each therapy was predicted [1].

This type of modeling approach gives information early enough that decisions about which research investments are the most promising can still be made, while there is still time to accelerate discovery. In addition, such probabilistic forecasts can be used as an early measure of whether a given part of the research portfolio is likely to yield this type of applied Public Impact outcome in the foreseeable future.

Foundational Scientific Exploration

We can identify a transformative breakthrough while it is still forming

Only a small subset of basic research ideas ultimately goes on to make major transformative breakthroughs. Most such breakthroughs are not immediately recognized even by peers—it is only after broad adoption by the community that recognition eventually accrues. However, the process by which this occurs, involving substantial time, effort, and resources to vet an idea and convert it to broad practice, leaves signatures in the scientific knowledge network. Some of these are quantifiable before landmark studies appear, and indicate the active preparation of a nascent field toward a breakthrough.

The NIH model predicting future transformative breakthroughs uses co-citation networks to partition the literature into time-series topics [2] (financial disclosure: I am a co-inventor on patent no. 12,536,216 covering this methodology). This approach sharpens the signals of future breakthrough that are embedded in the knowledge network compared to the direct-citation approach used in our FDA prediction study. In fact, as in the cancer immunotherapy example below that won a Nobel Prize, network signals like the flocking of scientists into a new scientific topic or high levels of dynamic instability precede the prize-winning work itself (Figure 2). This means that we can identify a transformative breakthrough while it is still forming.

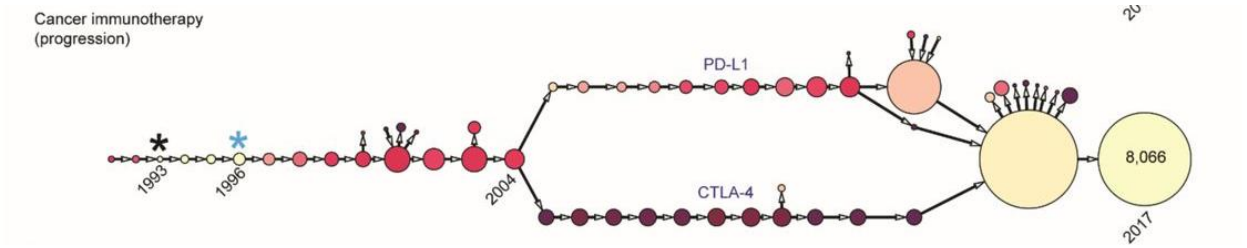

Figure 2. Time series of co-citation network topic clusters for cancer immunotherapy breakthrough [2]. First signal detection in 1993 (black asterisk), seminal paper appeared years later (blue asterisk). This lineage split into distinct research trajectories that covered the PD-L1 and CTLA-4 proteins before re-merging into a large cancer immunotherapy cluster concomitant with the validation of these lineages for clinical use.

Another independent research group has used a similar approach to detect a phenomenon related to breakthroughs: extreme growth of research topic clusters [3]. This is based on the observation that research topics derived from citation knowledge networks typically undergo large growth spurts alongside their emerging policy-relevance. This identification was one of the goals of the Foresight and Understanding from Scientific Exposition initiative, and this type of modeling approach is very effective at forecasting such extreme growth (Figure 3). While this modeling approach was not as tuned to biomedical research as the NIH model, it performed well across diverse areas of science including those outside biomedicine.

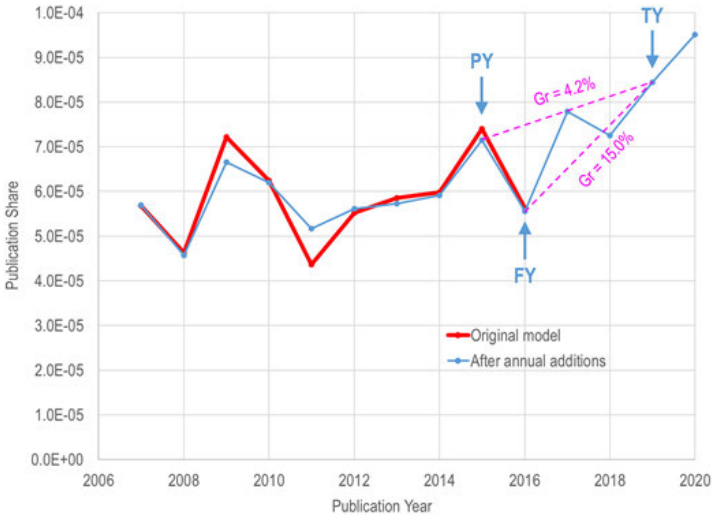

Figure 3. Forecasting extreme growth of topic clusters [3]. Target Year (TY) forecasts made from information available in the Forecast Year (FY) predict extreme topic growth with high accuracy.

There are three new possibilities raised by these studies. First, contributions to emerging breakthroughs in the existing scientific portfolio can be measured with these approaches. Second, methods to identify breakthrough foundational science can enable funding to be delivered to the most exciting scientific opportunities if the signals are used in decision-making. Finally, the fact that there are multiple distinct modeling approaches enables a direct test of a prevailing hypothesis among funders: that targeted funding can rapidly accelerate breakthroughs. If a randomized, controlled trial approach is employed, the effectiveness of targeted funding at accelerating science can be measured using one model to detect breakthrough signals, and the other to measure the ongoing effects of targeted funding in that randomized design.

Rigor and Reproducibility

We can detect which areas of science are headed for a wave of retractions

Much of the recent effort on scientific rigor and reproducibility has focused on ensuring transparency in scientific articles. This is valuable, but transparency alone does not guarantee rigor; studies can be flawed and transparent at the same time. Retractions are a highly visible marker of flawed studies, and the community has rightly highlighted the risk of cascading errors through subsequent use and citation of retracted works. Despite this awareness, prior work has not measured the systematic vulnerabilities in the literature to such cascading failures.

Our recent work developed network science methods to assess two particular vulnerabilities arising from retracted articles [4]. The first draws on the observation that individual scientists tend to publish multiple articles that are later retracted, either due to research misconduct, inadequate methods, or insufficient supervision. Scientific topics within a field, if sufficiently exposed through citation connections to a body of work from an individual scientist whose work is later retracted, may in effect be building a house of cards. In addition, topics represent the collective effort of scientists with similar goals, research norms, and common analytical approaches. Because of this, vulnerabilities inherent to these collective properties may be measured empirically as concentrated retractions occurring within individual topics independent of multiple-retraction author risk.

Our recent analysis employing this framework shows both vulnerabilities: at the extremes, research topics within ten fields of biomedical research that we examined had between 39% and 94% of their papers citing work from an individual author, making the topic extremely vulnerable if that author's work should later come into question. We similarly observe a wide variance in the percentage of topic papers citing retracted works. This is partly due to multiple retractions from individual authors, but much of the effect remains even if multiple retractions per author are removed, suggesting other vulnerabilities at play [4]. Building on this analytical framework, we have developed a machine learning model to predict what fraction of articles within a topic will be retracted in the coming years (Figure 4). This shows that **we can detect which areas of science are headed for a wave of retractions before they happen**.

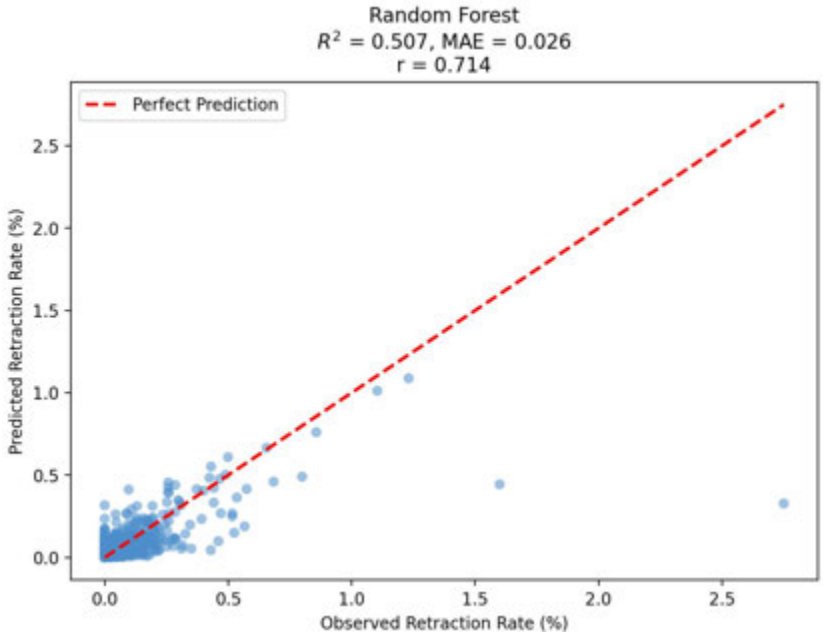

Figure 4. Machine learning predicts the future retraction rate of papers within topic clusters with high accuracy (each point, one topic cluster).

This is a highly accurate prediction system (Pearson $r = 0.714$) that may be valuable for identifying topics that are at high risk of having papers retracted in the future. Of course, determining the reproducibility of high value discoveries is an important complementary approach. However, reproducibility research is expensive, and this type of approach could be used to further target reproducibility efforts: looking at the intersection of high value discoveries that are also uniquely vulnerable.

Entrepreneurship and Translation

We can tell which papers are going to fuel future patents

Only a minority of papers are ever used and cited in a patent. Furthermore, unless the authors of a paper reduce their discoveries to practice themselves, this process takes on the order of a decade to translate. Building on my prior work developing the Approximate Potential to Translate measure, we have combined content analysis of scientific articles with network analysis and machine learning to predict which papers are most likely to contribute to future innovation and patents. Our machine learning model takes advantage of a novel property of scientific articles: the pattern of which types of papers cite a given article and how quickly that happens carries significant predictive power about whether a patent building on this work is likely in the future. Our model [5] shows that, between articles in the group with the lowest machine learning prediction scores and those with the highest, there is a tenfold difference in the observed number of patented papers in the subsequent years (Figure 5).

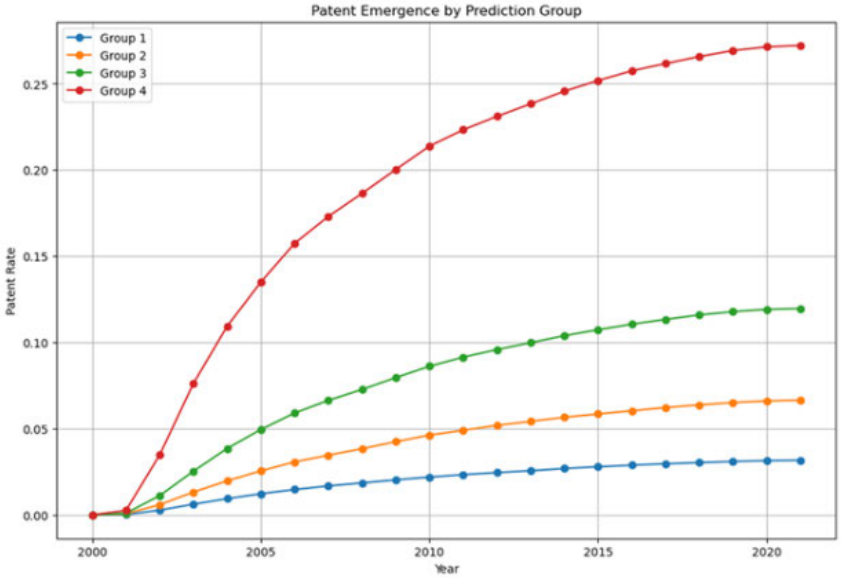

Figure 5. Observed fraction of patented papers, stratified by groups with differing patent prediction scores (group 1 lowest, group 4 highest).

We can tell which papers are going to fuel future patents and which are not: the top group translates to ten times as many patents per paper as the bottom group. Being able to forecast which discoveries are likely to contribute to downstream innovation would be a valuable impact measure. Like other article-level measures that I have developed in the past, this type of measure can be used in program evaluation, portfolio analysis, and policy forecasting.

Analytical Use

As this RFI acknowledges, the value of biomedical research is multifaceted, and the community needs multiple measures to reflect that. One common feature of many of the measures described here is that they examine scientific topic clusters rather than individual papers or grant applications. This is because many of the questions posed in this RFI are more complex than simpler measures of research success like number of papers or citation impact. Development of novel therapeutics and emerging scientific breakthroughs are fundamentally collective efforts of groups of researchers working toward common goals. These are best captured by larger clusters of research of the types used in these studies [1-3]. Likewise, reproducibility (or research integrity and retraction risk, a negative facet of that concept) is in part due to the research norms and common analytical approaches in these communities [4]. This cannot be fully captured by looking at individual papers, but rather by examining the surrounding scientific context as well. Importantly, capturing this context does not require new data collection. Existing NIH data infrastructure can be easily adapted to integrate this topic cluster-level information and map it onto the appropriate papers and applications. That is because the links needed to map topic clusters to these documents are already present in their reference lists. NIH has already prototyped topic cluster analysis [2], so this could be readily incorporated into the iCite or iSearch platforms, as the Relative Citation Ratio and Approximate Potential to Translate have.

Re: NOT-OD-26-087. Request for Information on Measuring and Rewarding Scientific Impact

Submitted via comment form: https://osp.od.nih.gov/comment-form-measuring-and-rewarding-scientific-impact/

Dear Director Jorgenson:

On behalf of the Physicians Committee for Responsible Medicine, a 501(c)(3) nonprofit organization supported by nearly one million members and supporters worldwide working for effective, efficient, and ethical medical research and product testing, thank you for the opportunity to provide input on how to incentivize and reward rigorous, reliable research that delivers value to the American public.

Biomedical research still focuses heavily on the biology of other species, with as many as 100 million dogs, cats, monkeys, mice, rats, and other animals being used in U.S. laboratories each year.[1] But animals do not make reliable models of human biology and diseases and do not reliably predict human clinical outcomes, contributing to failures and wasteful spending in drug development and regulatory testing, and putting clinical trial participants at risk by failing to predict unsafe or ineffective products.[2] Investment in animal experimentation does not deliver value to the American public.

Fortunately, human-based research methods, including new approach methodologies (NAMs), have rapidly advanced and continue to improve, providing more reliable models of human biology and disease and more predictive testing than animal experiments. Models such as organoids and organs-on-chips are derived from donated human cells and tissues and can replicate the structural, functional, mechanical, and

other biophysical properties of the human body at the tissue and multi-organ levels.[3] In the last decade, human-based methods have improved in their degrees of biological complexity and their breadth of application, making them powerful tools to better understand and treat disease.

Recognizing the failures of animal experimentation and promise of nonanimal, human-based approaches, in April 2025, the NIH launched an initiative to prioritize human-based research and reduce animal use.[4] We applaud the steps the NIH has already taken to implement this initiative, including: establishing the Office of Research Innovation, Validation, and Application (ORIVA),[5] investing $150 million in human-based research projects under the Complement-ARIE program,[6] and developing infrastructure like the Standardized Organoid Modeling Center.[7]

To build on agency-wide efforts in this regard, we encourage the NIH to further incentivize and reward the replacement of animal experimentation with innovative, ethical, and effective nonanimal, human-based approaches. The recommendations below elaborate on this central aim, helping to ensure that the agency supports the most impactful science and delivers optimal value to the American public.

Thank you for your attention to these recommendations. We welcome further dialogue to aid their implementation.

Sincerely,

Mikalah Singer, JD, LLM
Science Policy Specialist
Physicians Committee for Responsible Medicine

1. RIGOR AND REPRODUCIBILITY

The Physicians Committee supports the NIH's increasing focus on rigorous and reproducible biomedical research—particularly its recognition that translatability is a key related factor. The August 2025 Leading in Gold Standard Science implementation plan highlighted bolstering human-based research technologies and expanding efforts of the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) as ways to advance more reproducible and replicable biomedical approaches.[8] Animal experiments have historically suffered from poor rigor and reproducibility. Although this impacts translation rates, no number of measures to improve the rigor and reproducibility of animal experimentation will make it optimally translatable due to inherent limitations in model validity.

Thus, shifting to nonanimal, human-based approaches is crucial for improving translatability. As this shift unfolds, we must ensure that the development and adoption of NAMs is not hindered by the unwarranted insistence to benchmark against animal experiments and that the problems of rigor and reproducibility that have plagued animal experimentation are not repeated. *To ensure that human-based methods are optimally reproducible, the NIH should support standardized validation efforts, infrastructure projects and collaboration to facilitate centralized and accessible resource sharing, update in vitro reporting guidelines, and encourage preregistration.*

Recommendation 1.1. Establish standardized validation efforts for all model types.

Because of the novelty of NAMs, further investment is needed to establish confidence in their ability to model human biology and clinical characteristics. Historically, benchmarking nonanimal methods has involved comparisons to the results of animal tests, but stakeholders increasingly recognize this as problematic. Formal validation practices for NAMs in regulatory toxicology are moving away from comparisons to non-human animal test results and instead are incorporating human data, resulting in the acceptance of human-specific approaches that outperform animal tests.[9] Patient-derived data should be used as benchmarks to corroborate findings from human disease models and to establish model validity. Other considerations that are crucial for

validation efforts include fitness for purpose, human biological relevance, technical characterization, data integrity and transparency, and independent review.[10]

Validation of human disease models should continue to be refined and tailored according to each specific use, to help build confidence among researchers, industry, and regulators. Sequencing, imaging, and other data-driven approaches can accelerate model validation by enabling deep resolution and high-throughput comparisons between experimental platform readouts and gold standard clinical characteristics.

The need to validate NAMs is a frequent topic of interest as federal scientific agencies and other regulatory bodies around the globe increasingly turn to their use, but animal-based methods have never been held to the same standards—until now. The August 4th Guidance on Applications for Studies with Animal Models published by National Cancer Institute (NCI) Director, Anthony Letai, highlights new requirements for grant applicants to include plans to validate animal experiments with human-based models.[11] *Building on NCI's guidance, we recommend that the NIH prioritize the development of standardized validation efforts for animal- and nonanimal-based research models, ensuring that the framework emphasizes human biological relevance, reliability, and fitness for purpose, rather than concordance with historical animal data. Measurable indicators can include the number of new, validated, and human-based methods.*

Recommendation 1.2. Establish *in vitro* reporting guidelines.

Reproducibility across experiments and research labs is crucial for building trust in NAMs and other human-based methods and maximizing the translatability of findings. *To improve reproducibility, the NIH should establish standard* in vitro *reporting guidelines, require all grantees to follow these standards, and encourage publishers to require these standards.* Several examples of *in vitro* reporting guidelines exist that the NIH could build from or point toward.[12] Measurable indicators could include the number of updated reporting guidelines implemented by publishers and improved reproducibility of published studies.

Recommendation 1.3. Encourage prospective study registration.

To ensure the rigor and reproducibility of studies that use NAMs, the NIH should encourage investigators to prospectively register study designs and analysis plans. (Prospective registration includes preregistration in a registry database and the publishing of registered report article types.) This recommendation is in line with recommendations 2.1 and 2.2 within the final report of the ACD Working Group on Enhancing Rigor, Transparency, and Translatability in Animal Research, which aimed to raise awareness and understanding of prospective registration and to develop and implement a program to evaluate the impacts of prospective registration on research quality.[13] *We support these recommendations and urge the NIH to also implement them in the context of NAMs.* The benefits of prospective registration with regard to research quality, transparency, and reproducibility will help continue to build scientific confidence in human-based methods. Measurable indicators include the number of preregistered study designs.

2. DATA, SOFTWARE, AND MODEL SHARING

NAMs and other human-based methods are powerful tools to accelerate biomedical research discovery. A 2022 survey found that biomedical researchers are eager to use 3D human *in vitro* models, but cite complexity, standardization, entry costs, and lack of ready-to-use systems as barriers.[14] Addressing these issues will enable broader validation, reproducibility, and scaling. We applaud the steps the NIH has already taken toward these goals, but to maximize the value of continued investments, *we recommend placing an increased focus on democratizing human-based technology: supporting coordinated NAMs infrastructure to make human tissues, cells, and data more accessible and make platforms more operational.*

Recommendation 2.1. Expand human-based research specific infrastructure to facilitate resource sharing.

The Office of Research Infrastructure Programs (ORIP) 2026-2030 Strategic Plan builds on the 2025 NIH-wide initiative by setting out a strategic priority to expand infrastructure, and the NIH has already started to provide awards in this area to benefit

[13] ACD Working Group on Enhancing Rigor, Transparency, and Translatability in Animal Research. Final Report. Published June 11, 2021. Accessed August 12, 2026. https://www.acd.od.nih.gov/documents/presentations/06112021_ACD_WorkingGroup_FinalReport.pdf

[14] Busek M, Aizenshtadt A, Amirola-Martinez M, et al. Academic User View: Organ-on-a-Chip Technology. *Biosensors*. 2022;12(2):126. https://doi.org/10.3390/bios12020126

human-based research,[15] including C06 construction grants.[16] To further incentivize the uptake of human-based methods and maximize the value of existing investments, NIH should support funding opportunities within the existing mechanisms. Several P-series mechanisms can be used to support biotechnology resources, facilities, and program development that would incentivize resource sharing and facilitate the creation of high-quality data and tools, maximizing research investments and catalyzing collaborations. Examples include *PN2 (Research and Development Center), P30 (Center Core Grants), and P41 (Biotechnology Resource Grants) mechanisms* that can be used to incentivize new programs, facilities, institutions, groups, and labs dedicated to using human-based methods. Specifically, we recommend increased support for biobanks through such mechanisms, including a national resource for iPSC acquisition and differentiation, with diverse cell and tissue types, disease status, deep phenotypes, genotypes, and demographics. We also urge the NIH to reward investigators for collecting samples and data with community co-leadership, cultural sensitivity, reciprocity, and regular evaluation. Finally, we recommend the agency prioritize infrastructure and resource sharing for nonanimal-derived biomaterials and antibodies. *Measurable indicators can include the number of biobanks, breadth and depth of shared resources, and rates of utilization by the research community.*

Recommendation 2.2. Support artificial intelligence and computational tools to facilitate data sharing.

During drug development, millions of animals are used every year in the United States to test compounds that have already been shown to be safe. Research teams often choose to repeat animal experiments rather than manually search massive existing datasets. Tools such as artificial intelligence will accelerate biomedical research discovery and facilitate more efficient data sharing. *In collaboration with the Food and Drug Administration, NIH should create funding opportunities to promote the development of tools like Insilica's ToxIndex, which promote data reuse and reduce expensive and duplicative animal experiments.*[17]

Recommendation 2.3. Create a centralized database of human-based models.

Existing databases of NAMs are limited to regulatory applications or do not cover the entire spectrum of research areas. For example, the NIH Collection of Alternative

[15] National Institutes of Health Office of Research Infrastructure Programs. Strategic Plan Infrastructure for Innovation Fiscal Years 2026-2030. Accessed August 10, 2026. https://orip.nih.gov/sites/g/files/mnhszr376/files/ORIP-Strat-Plan-Final-11-25-2025-508-updated-compressed-Final-508.pdf

[17] ToxIndex. Insilica. Accessed August 10, 2026. https://toxindex.com/

Methods for Regulatory Application (CAMERA) provides information on 50 NAMs and is searchable by test method type, predicted endpoints, measure effect, and regulatory and test guidelines,[18] but there is a need for a broader centralized information database that aggregates human-based models across all areas of research and applications. This platform would improve uptake of NAMs; enable more accessible retrieval of information about models' capabilities and validation status; and help investigators, peer reviewers, and animal oversight committees better determine appropriate rationales for animal use versus replacement models. *NIH should develop an easily searchable, centralized database of human-based methods across all research areas, characterized by level of development, validation status, and context of use, and linked to publications. Measurable indicators can include creation of this resource, number of entries, and rate of utilization by the research community.*

3. TRAINING AND MENTORSHIP

As NIH continues to embrace human-based research and move away from unreliable animal-based methods, training and education in NAMs and other human-based methods is a key consideration,[19] and according to the 2023 final report of the Advisory Committee to the Director Working Group on Catalyzing the Development and Use of Novel Alternative Methods to Advance Biomedical Research, constitutes one of the highest priority needs for advancing NAMs.[20]

To promote the growth and stability of the biomedical research workforce, we recommend the prioritization of interdisciplinary education and training in biomedical research, bioengineering (including microfabrication and microfluidics), pharmacology, toxicology, computational biology, and AI through the support of curricula and training center development.[21] Because animal-based methodologies were the default in biomedical research for decades, undergraduate and graduate curricula are still largely based on these approaches, creating a workforce that lacks the necessary skills to advance the development, usability, qualification, and application of NAMs. Additionally, budgetary constraints and concerns limit the willingness of institutions and individual PIs to pursue the development of new curricula and implemention of training programs on human-based methods.

[21] Moruzzi A, Shroff T, Keller S, Loskill P. Training the Next Generation of Researchers in the Organ-on-Chip Field. *Education Sciences*. 2023;13(2):144. https://doi.org/10.3390/educsci13020144

There are several existing mechanisms NIH has in place that will promote the growth and stability of the biomedical research workforce, as the NIH moves away from animal experiments toward a more human-focused landscape. Such mechanisms, in addition to the infrastructure-focused mechanisms in sections 1 and 2 of this response, support education projects (R25), career development (K-series), fellowship (F-series), and training (T-series) grants. Within these mechanisms, NIH can support the agency-wide human-based initiative by providing funding for institutional programs, conferences for training, and independent-investigator career development. *Incentives, including funding, will provide direct benefits to institutions and investigators willing to lead the charge, and address the current educational gap in human-based approaches to better support the scientific workforce.*

We recommend evaluating the number of career development and path-to-independence grants, the plateauing rates of PhDs going into industry versus academia, and the economic value to training PhDs, such as wages and economic productivity, as specific measurable indicators to assess and quantify the impact of training and educational support.

4. COLLABORATION

This administration has highlighted team-based research as critical for leading us into the new age of science.[22] To best support interdisciplinary and convergent collaboration, NIH should place additional focus on transparency of research, accessibility of technologies and data, and incentives that support team-based outcomes rather than individual accolades.

Recommendation 4.1. Continue to leverage public-private partnerships to advance interdisciplinary, cross-sector NAMs development.

Public-private partnerships demonstrate the value of collaboration and are already being used to support the development, validation, and deployment of advanced human-based research technologies, including NAMs. These technologies are often developed by small businesses and industry innovators but require coordinated federal engagement to reach scale and regulatory acceptance. The Validation and Qualification Network (VQN) of NIH's Complement-ARIE program demonstrates how well-

[22] Kratsios M. Science A New Golden Age. Office of Science and Technology Policy. July 2026. Accessed August 10, 2026. https://www.whitehouse.gov/science/

structured public-private partnerships can align federal agencies, regulators, industry, and nonprofit stakeholders around shared technology deployment goals. As human-based methods are increasingly implemented, the Complement-ARIE VQN model is especially valuable because it treats validation and regulatory preparedness for NAMs as a shared responsibility, coordinating across agencies and collaborators to develop common frameworks, standardized reporting, and regulatory-ready data packages. *The public-private partnership model should be used as an example of the importance of collaboration in science, and we recommend that model developers and engineers should collaborate directly with disease researchers to advance human-based science.*

Recommendation 4.2. Incentivize team-based science through high-priority challenge initiatives.

As highlighted in the July 2026 Report to the President, many of the current funding mechanisms favor small teams led by independent investigators, rather than larger-scale, moonshot projects that require collaboration across disciplines and sectors.[23] For example, the Complement-ARIE *NAMs Reduction to Practice Challenge* aimed to accelerate the development and validation of combinatorial NAMs that can transform the way biomedical research, drug development, and clinical trials are conducted. The NIH, in collaboration with the Environmental Protection Agency (EPA) and Food and Drug Administration (FDA), specifically sought multidisciplinary teams to compete for significant funding for their projects. Challenges like this support teams and projects in a way that would not be possible using smaller funding mechanisms.

We recommend prioritizing funding opportunities and challenges that promote collaboration across sectors, disciplines, and career levels. A measurable indicator may include the number of supported awards in areas where collaboration is particularly relevant such as new model development for specific disease areas where engineers and scientists working as a team are paramount.

5. ENTREPRENEURSHIP AND TRANSLATION

The July 2025 Report to the President notes that despite massive increases in biomedical research funding over the past three decades, the rate of significant breakthroughs and drug approvals has slowed down.[24] The following recommendations

[23] Kratsios M. Science A New Golden Age. Office of Science and Technology Policy. July 2026. Accessed August 10, 2026. https://www.whitehouse.gov/science/
[24] Kratsios M. Science A New Golden Age. Office of Science and Technology Policy. July 2026. Accessed August 10, 2026. https://www.whitehouse.gov/science/

will incentivize, assess, and integrate the impact of innovative and entrepreneurial efforts critical to translating research into clinical advances.

Recommendation 5.1. Bolster support for human-based methods to drive innovation and translation of discoveries into products for people.

The NIH can better advance the translation of discoveries into products for people through programs that promote the development and use of human-based methods. Research using animals often does not translate to humans because there are insurmountable species differences in anatomy, physiology, lifespan, disease characteristics, and more, leading to nine out of ten new treatments that appear successful in animals later failing in humans.[25] Additionally, many treatments that may have been safe and effective in humans risk being prematurely delayed or discarded due to misleading results in animals.[26]

We recommend that the NIH continue to prioritize human-based research in order to overcome species-specific translatability issues. The NIH should critically review how animal experiments have led to clinical benefits, and use drug attrition as a measurable indicator for success.

Recommendation 5.2. Promote stronger research assessment reform.

The July 2026 Report to the President notes that the current scientific landscape, particularly within academia, rewards publications over commercialization, which impacts when products and treatments reach patients. Prioritizing publications over scientific impact may affect multiple processes within the scientific enterprise, including grant evaluations, hiring and tenure assessments, and public trust. *We recommend that NIH support stronger research assessment reform, assessing scientists for potential and actual impact, rather than bibliometrics, including during the grantmaking process.*[27] The NIH should use resources created by the Declaration on Research Assessment (DORA), which advances practical and robust approaches to research assessment reform.[28]

[27] Bailey J. Biomedical Research Must Change—But a Shift Toward Human-specific Research Methods Is Only Part of What Is Needed. Alternatives to Laboratory Animals. 2021;49(3): 69-72. https://doi.org/10.1177/02611929211030417

[28] San Francisco Declaration on Research Assessment. DORA. Accessed August 10, 2026. https://sfdora.org/read/

Recommendation 5.3. Increase support for collaborative infrastructure projects to promote human-based model development.

The NIH has already funded the establishment of several regional human-based methods centers through grants and cooperative agreements (U2C and U24), such as the Translational Centers for Microphysiological Systems (TraCe MPS)[29] and Tissue Chip Testing Centers.30 Such centers accelerate the translational use of human-based methods from drug development through regulatory acceptance and adoption for industrial use, as well as provide resources for the validation of methods to improve the evaluation of drug efficacy and toxicity. However, support for the TraCe MPS program is ending, creating a challenge for investigators to secure funding from other sources—including from funding opportunities that involve competition with animal-based infrastructure programs—and threatening to stall important progress toward the broader adoption of these technologies. *We recommend that the NIH expand funding for human-based infrastructure projects and ensure mechanisms are in place for awardees to be eligible for sustained financial support. Measurable indictors can include additional human-focused infrastructure projects supported, the number of models developed at such programs, and the broader uptake of these models by the research community.*

Recommendation 5.4. Incentivize collaboration between industry and academic institutions to democratize human-based models.

Small- and medium-sized businesses (SMBs) are central drivers of innovation in human-based research technologies,[31] and during the past two decades, the human-based methods industry has increased substantially, with growth projections continuing.[32] The Small Business Innovation Research (SBIR) and Small Business Technology Transfer (STTR) programs support small business entrepreneurs. To bolster the development of human-based technologies and improve translation from bench to bedside, these programs should prioritize projects that replace animal use and generate data suitable for regulatory confidence, with bridging mechanisms between Phase II and later-stage support. Additionally, the NIH should encourage the model developers it supports to market to academic labs just as much as the pharmaceutical industry, to make human-based approaches more accessible at all levels of the scientific enterprise.

[32] Organoids and Spheroids Market (2025-2030). Grand View Research. April 2025. Accessed August 19, 2026. https://www.grandviewresearch.com/industry-analysis/organoids-spheroids-market; Sharma R. Microphysiological System Market. Data Intelo. April 2026. Accessed August 19, 2026. https://dataintelo.com/report/microphysiological-system-market

To incentivize entrepreneurial efforts in human-based research, NIH should prioritize funding opportunities that directly support collaboration between industry and academic institutions or aim to transition promising research and development to market such as RC3 and R43 grants, and U-series cooperative agreements. Measurable indicators of success can include academic utilization of commercial human-based models.

6. FOUNDATIONAL SCIENTIFIC EXPLORATION

The NIH's mission focuses on enhancing health, lengthening life, and reducing illness, including basic research to investigate the causes and mechanisms of human diseases. Human-based methods are paramount to advancing translational research and have already been shown to overcome existing, unavoidable, species-specific differences between non-human animals and humans, but human-based methods also play a vital role in basic research too.

Recommendation 6.1. Prioritize human-centered methods for basic research.

Human-based methods use human cells, tissues, and data to improve our understanding of human biology and disease mechanisms, building the foundation for translational success. *NIH should prioritize increased uptake of human-based methods by embedding these approaches within the academic enterprise and ensuring that all areas of NIH-supported research, including basic research, are human relevant.*

Researchers can be reluctant to onboard new approaches due to the risk involved, whether related to high up-front costs, lack of training, funding, or institutional support, or the inherent process of failing, troubleshooting, and repeatedly trying again. This is all compounded by the fact that most grants require demonstrating preliminary data, which is difficult to generate if an investigator does not yet have funds to implement new approaches. These inherent risks contribute to the slow uptake of otherwise promising human-based methods.

To incentivize researchers to embrace human-based models, the NIH should support investigators to adopt these models and to afford to take risks in their research. Several mechanisms have been used to incentivize high-risk, high-reward research (DP1, DP2), but should be implemented to specifically support projects that use and develop human-based methods. Exploratory grants or smaller pilot program support, including R21 grants (which do not require preexisting data and are smaller than standard R01 grants), may attract scientists with smaller labs or at less prestigious universities which would refocus support for the individual scientist and revitalize America's scientific

enterprise. Additionally, larger-scale pilot programs to support institutions operationalizing human-based methods into departments, research groups, and facilities would take the pressure off individual researchers to adopt new technologies without existing institutional support. To ensure these mechanisms support human-based science, funding opportunity language should specifically state that projects proposing animal use are not eligible.

Research involving human subjects, communities, and populations is also critical for advancing foundational knowledge about human health. *We recommend that the agency shift funds from animal experimentation toward human-centered basic research aimed at understanding disease risk, prevention, and non-biological health influences. Measurable indicators can include relative investment in animal- and human-based basic research projects.*

Recommendation 6.2. Reward researchers using nonanimal methods to answer novel scientific questions.

The NCI Guidance on Applications for Studies with Animal Models notes that scientistic studies should be "inspired by asking great questions with high potential or human impact," and that the "best and most relevant scientific methods" should be used to accomplish that goal.[33] *The NIH should encourage researchers to consider novel scientific questions that have not been asked before or have only been attempted to be answered using animals, and to do so with approaches that reflect human biology rather than nonhuman animals.*

7. PUBLIC IMPACT

NAMs and other human-based research methods provide more reliable tissue and disease modeling than animals, leading to more predictive clinical testing and improving the efficiency of federal research expenditure. Moving away from animal experimentation and supporting a scientific landscape built on human-based methods means that more treatments—that are safer and more effective—will make it to patients and at a faster pace. Ultimately, this shift will improve health outcomes, clinical practice, economic growth, public trust, and societal benefit.

Recommendation 7.1. Facilitate a systematic review of clinical translation of animal experiments.

[33] Letai A. Guidance on Applications for Studies with Animal Models. National Cancer Institute. Published August 4, 2026. Accessed August 10, 2026. https://www.cancer.gov/grants-training/nci-bottom-line-blog/2026/guidance-animal-models

Continued support for projects involving animal experiments impacts clinical translation and harms the American public. To achieve the federal goal of improving clinical translation and reducing the use of animals, the NIH should prioritize synthesizing: the failures of animal experiments to model human biology and translate to clinical advances; and the capabilities and needs of nonanimal approaches. *We recommend that the NIH support systematic reviews on these topics, especially in high-priority areas like infectious diseases and neuroscience, where animals are still perceived by some as scientifically necessary, or where key modeling capabilities need further development.*

Recommendation 7.2. Track and report number of animals used and funding for projects involving animals and human-based methods.

There is growing support from the public to move away from animal use. A 2024 national survey showed that more than 85% of Americans agreed that animal-based research should be phased out in support of methods that do not use animals,[34] and a 2026 Gallup poll found that a majority of Americans view medical testing on animals as morally wrong.[35] In addition to the recommendations made throughout this response, to address this growing public interest, improve public trust in science, and foster transparency and accountability, *we recommend that the NIH accurately track and publicly report of the number of animals used by funded facilities and funding toward projects involving animals and NAMs.*

The Office of Laboratory Animal Welfare currently requests only crude numbers for animal use every four years from U.S. facilities. Yet more than 95% of the animals reported to OLAW are excluded from the federal Animal Welfare Act, which is overseen by the USDA, meaning those animals are never accurately counted by any federal agency. The Federal Animal Research Accountability Act (H.R. 3295) would require the NIH to annually collect from each funded facility the number of animals bred, housed, and used in the previous year—sorted by species and level of pain and distress—and make those reports publicly available. *We recommend that the NIH either proceed with the bill's approach or implement a system requesting only the total number of animals by species (not including pain and distress categories). In either case, the NIH should make individual facility numbers available to the public, as the United States Department of Agriculture does.*

[34] Morning Consult. Physicians Committee for Responsible Medicine. U.S. Gen Pop Beliefs on Animal Testing. 2024. Accessed August 11, 2026. https://pcrm.widen.net/s/qzfxtfh7bw/animal-testing-survey
[35] Brenan M. Moral Acceptability Falls for Several Behaviors. GallUp. June 9, 2026. Accessed August 11, 2026. https://news.gallup.com/poll/710981/moral-acceptability-falls-several-behaviors.aspx

A 2023 NIH presentation showed that competitive awards using NAMs grew steadily each year since 1981, reaching ~8% in 2021.[36] A 2024 GAO report estimated that, in recent years, animals were used in ~41% of intramural projects and ~25% of extramural projects.[37] These data are crucial for justifying large-scale human-based initiatives, tracking progress toward goals, and rebuilding public trust and accountability. *Aggregate funding rates toward projects involving human-based methods and animals should be reported at least annually. Individual grant data regarding NAM and animal use should also be reported in RePORTER—the latter, for example, by incorporating information from grant application form G.220.*

Recommendation 7.3. Require animal use transparency in grant application abstracts.

The National Cancer Institute has already announced new guidance to promote additional transparency related to animal use.[38] Starting October 5, 2026, grant applicants will need to include a justification for animal use and explanation for why nonanimal methods would not be sufficient to address the question at hand *in the abstract of the grant application*, which will make make this information publicly accessible via RePORTER. *NIH should implement this requirement agency-wide to improve transparency and public accountability toward animal replacement goals.*

CONCLUSION

As elaborated throughout the entirety of this response, NIH can support human-based research methods through improving resource and data sharing, increasing training and education opportunities, facilitating collaboration, and incentivizing model use and development. In addition to the aforementioned recommendations, w*e recommend that the NIH take into account all recommendations, implementation approaches, and measurable indicators, including (A) successful clinical trial outcomes, (B) translatability to humans, (C) funding for training in human-based methods, (D) improved accessibility of data and methods, (E) public opinion, and (F) investment in animal experiments compared to NAMs made in this response when determining how to incentivize and reward rigorous research that delivers to the American public.*

Response to NOT-OD-26-087: Measuring and Rewarding Scientific Impact

Submitted by: Woods Hole Center for Oceans and Human Health (COHH), Woods Hole Oceanographic Institution

COHH sits at the intersection of oceanography, toxicology and public health — a model of exactly the convergent, team-based science this RFI is asking NIH to better measure. Our comments draw on that vantage point: NIH-funded centers where marine science directly protects human health (harmful algal bloom toxins, seafood safety, weather-linked ocean hazards, coastal community exposure).

Rigor and Reproducibility

- Environmental and oceanographic exposure data are inherently variable (seasonal, geographic, climate-driven); metrics should credit field/monitoring protocols and standardized reference methods as rigor indicators. Current rigor metrics lean heavily on replication, which is not always feasible with environmental data. Instead, metrics should also credit the practices that make rigor achievable *without* literal replication.
- Reward development and adoption of community reference materials and interlaboratory calibration exercises (e.g., algal toxin standards) that make replication across labs feasible.
- Distinguish reproducibility expectations for controlled lab studies vs. field/environmental causal research, where true replication is often impossible and triangulation across methods should count instead. i.e., testing the same causal question with multiple independent methods where convergent findings across these approaches substitute for direct replication.

Data, Software, and Model Sharing

- Invest in long-term environmental monitoring datasets (e.g., HAB toxin time series, coastal water quality) as high-value shared infrastructure, even when they don't generate a single high-impact paper.
- Credit contributions to shared data standards and interoperable databases that link oceanographic, environmental, and health/exposure data (a persistent bottleneck in oceans-and-human-health work).
- Value tool/model reuse metrics (downloads, citations of software/datasets) alongside traditional publication metrics.

Training and Mentorship

- COHH-style centers train scientists who must be fluent across disciplines (marine science/oceanography + epidemiology/toxicology); metrics should recognize cross-disciplinary training investment, not just trainee publication counts.
- Track placement and career trajectories of trainees into public health, regulatory, and translational roles, not only academic tenure-track outcomes.
- Recognize mentorship of early-career investigators bridging environmental science and health, a workforce pipeline NIH doesn't currently track well.

Collaboration

- Team science in Oceans and Human Health requires oceanographers, chemists, toxicologists, clinicians, and community/public-health partners; authorship-order-based credit systems undervalue this. Support adoption of contributor role taxonomies (e.g., CRediT) in NIH reporting/review.
- Credit infrastructure-building roles (shared field stations, monitoring networks, sample repositories) that enable others' science but rarely appear as first/last-author output.
- Recognize interdisciplinary collaboration and capacity building as research outcomes; sustained OHH partnerships across disciplines and communities develop expertise, methods, and response capacity that enable more effective science and public-health action.
- Recognize center-level and network-level impact (e.g., NIEHS/NSF Oceans and Human Health Centers) as a unit of assessment, not only individual PI metrics.
- NIH should continue to support researchers to collaborate broadly (including foreign collaborations) and to attend scientific meetings where ideas are exchanged, which improves the research.

Entrepreneurship and Translation

- Unlike the traditional "bench to bedside" model of translation, in the field of oceans and human health research translation often takes the form of providing information and methods that county, state or federal agencies can use to carry out their mission to protect human health. For example, OHH research has improved tools and information for monitoring, forecasting, and responding to harmful algal blooms (HABs), including methods for species and toxin detection that inform shellfish closures and other public health actions. Related to this, the collaborative, interdisciplinary networks established through OHH research programs have built regional capacity and strengthened decision-making and coordination for HAB response. Metrics should capture the transfer and adoption of policies and practices, not just commercialization.
- Credit collaboration with NOAA, EPA, FDA, and state health departments as a translation pathway distinct from industry partnership.

Foundational Scientific Exploration

- High-risk work on emerging marine hazards (novel toxins, range expansion of pathogens/HABs) often lack preliminary data to demonstrate feasibility. Under current review criteria that weigh preliminary data heavily, this puts exploratory research on emerging threats at a disadvantage. Metrics and review criteria should support and invest in high-risk research.

Public Impact

- To better assess and recognize the public impact of research such as that conducted by interdisciplinary programs like the OHH program, NIH should collect information about actions and impacts that have been enabled by the research, such as coastal community health advisories, seafood safety guidance, reduced illness from HAB exposure, and public trust built through community-engaged monitoring.
- Consider community and stakeholder engagement metrics (co-developed research questions, public data dashboards and portals, advisory contributions, co-created outreach materials) as evidence of public impact.

Cross-cutting considerations for NIH to weigh

- Metrics should be field-appropriate: what counts as rigor/impact in bench biomedical science doesn't map cleanly onto environmental/field-based research that benefits human health.
- Interdisciplinary contributions should be explicitly valued: Addressing complex environmental health challenges requires sustained collaboration across disciplines with different methods and outputs; NIH evaluation should recognize the added value and effort required to integrate diverse forms of expertise.

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: AI-enabled scientific production creates a production–verification asymmetry: literature searches, candidate hypotheses, code, analyses, and manuscripts can be generated increasingly quickly, while independent validation, provenance review, causal interpretation, and responsibility for consequential judgments remain scarce. NIH should therefore treat verification capacity—not simply output production—as a central constraint on scientific impact.

NIH could identify areas especially suitable for replication based on their systemic importance and evidentiary risk. Relevant considerations include the extent to which other studies or clinical decisions depend on a finding; whether an influential result has been independently validated; the sensitivity of the finding to analytical choices; conflicts among existing results; reliance on difficult-to-audit data or AI-generated workflows; and the potential consequences of an erroneous conclusion. Citation counts alone should not determine replication priority because visibility may reflect cumulative advantage or collective attention rather than evidentiary importance.

Indicators of rigor should include independent replication and validation; robustness across reasonable specifications; transparent provenance of data, software, models, and analytical decisions; correction of errors; publication of credible negative findings; and evidence that consequential AI-generated outputs were understood and independently evaluated by accountable human researchers. Replication attempts should receive credit for the quality of the test and the information they generate, regardless of whether the original result is confirmed.

NIH should support replication, correction, and validation as first-class scientific activities. Possible incentives include dedicated replication supplements, renewal credit for projects that enable or complete independent validation, support for maintaining reproducible research artifacts, and recognition of researchers who identify and responsibly correct consequential errors. Review criteria should distinguish scrutiny and stewardship from the production of additional claims.

These indicators should not become another count-based checklist. The number of replications, robustness checks, or deposited files is not by itself evidence of rigor. Applicants should instead provide a concise impact-pathway statement identifying the relevant contribution, the validation performed, the evidence supporting each claimed link, and the remaining uncertainty. Links could be labeled “observed,” “projected,” or “not yet observable.”

NIH could pilot this approach in selected programs, train reviewers with anchored examples, and monitor reviewer agreement, reporting burden, strategic behavior, and whether the criteria actually increase independent validation and correction. Indicators that encourage superficial compliance, excessive burden, or avoidance of uncertain research should be revised or retired.

This concern is increasingly important under AI because methodological convenience can be mistaken for epistemic gain. See, for example, Messeri and Crockett, "Artificial Intelligence and Illusions of Understanding in Scientific Research," Nature 627:49–58 (2024), https://doi.org/10.1038/s41586-024-07146-0.

2. Data, Software, and Model Sharing: Shared data, software, and models are scientific public goods. Their value often materializes outside the originating team through independent reuse, validation, avoided duplication, methodological diffusion, and the creation of new research capabilities. Because the originating researchers capture only part of this value, conventional individual-level metrics predictably produce underinvestment in documentation, maintenance, interoperability, and stewardship.

NIH should therefore assess sharing through evidence of an impact pathway rather than through the mere existence or popularity of a deposited artifact. Relevant indicators include the proportion of users who are independent of the originating team; cross-institutional and cross-disciplinary reuse; use in replication or validation; downstream studies or tools enabled; sustained availability; version histories and documented corrections; interoperability with other resources; and evidence that the artifact reduced duplication or enabled work that would otherwise have been infeasible. Downloads, repository stars, mentions, or raw user counts should not stand alone.

AI makes this distinction more important. AI can rapidly generate code, models, datasets, and documentation of uneven quality. The volume of shared artifacts may therefore rise while provenance, validation, security, maintenance, and accountability become more difficult to assess. NIH should request disclosure of consequential AI use, the human validation performed, known limitations, the accountable contributors, and the conditions under which a shared model or dataset should and should not be used.

Incentives should address the underlying spillover problem. NIH could provide supplemental maintenance funding or renewal credit when consequential independent reuse is verified; recognize curation, software engineering, model validation, and stewardship as substantive contributions; support independent audits of widely used resources; and provide continued support for infrastructure whose value becomes evident only after the originating award ends.

My empirical research on multi-sided digital platforms illustrates the broader boundary problem underlying this recommendation. Our longitudinal study of Airbnb in Boston showed how activities creating value for direct platform participants can also reshape neighborhood social organization and affect people outside the focal transaction. The substantive setting differs from scientific sharing, but the general measurement lesson is relevant: evaluating only direct participants misses important spillovers and affected stakeholders. See Ke, O'Brien, and Heydari, "Airbnb and Neighborhood Crime," PLOS ONE

16:e0253315 (2021), https://doi.org/10.1371/journal.pone.0253315.

NIH should pilot these indicators proportionately. Expectations should vary by field, resource type, privacy constraints, career stage, and institutional capacity. The objective should be to recognize verified enabling value—not to impose uniform adoption thresholds or disadvantage necessary resources serving small research communities.

3. Training and Mentorship: Training and mentorship create scientific capabilities whose value is distributed across people, teams, institutions, and time. These contributions may influence the research ecosystem long after the originating grant ends, yet they are poorly represented by publication counts, grant dollars, or the subsequent prestige of a small number of trainees.

NIH should evaluate training through contextualized evidence of capability formation. Relevant indicators could include the development of methodological, computational, clinical, collaborative, and translational capabilities; trainee progression toward greater intellectual independence; transfer of knowledge across disciplinary or institutional boundaries; adoption of rigorous and reproducible practices; preparation for responsible use and validation of AI; sustained mentoring relationships; and the creation of inclusive research environments in which trainees can contribute consequential judgment rather than only execute assigned tasks.

AI makes this broader conception of mentorship more necessary. AI tools can expand access to sophisticated methods and reduce some barriers to participation, but they can also conceal gaps in understanding or substitute automated production for the development of scientific judgment. Effective mentorship should therefore include the ability to interrogate generated methods, recognize uncertainty, document provenance, validate outputs independently, and understand when human expertise remains indispensable.

Assessment should distinguish among mentoring roles. Primary advisors, co-advisors, research staff, collaborators, and peers may contribute differently to technical instruction, professional development, interdisciplinary integration, sponsorship, and research culture. A concise structured description, informed by contributor-role approaches such as CRediT, would be more informative than assigning all trainee outcomes to a single principal investigator.

NIH should recognize mentoring and capability-building through role-specific review credit, support for protected mentoring time, continuation funding for demonstrably effective training infrastructures, and team-level recognition where multiple contributors created the capability. Evidence should be appropriate to career stage and time horizon. Early indicators may concern emerging skills, independence, and reproducible practices; later indicators may include sustained scientific, clinical, public-sector, or entrepreneurial contributions.

Raw numbers of trainees, completion rates, publications, or placements should not stand alone. These outcomes depend on field conditions, institutional resources, labor markets, trainee interests, and prior advantages. NIH should also avoid creating incentives to select only trainees who appear most likely to produce easily measured outcomes.

A pilot could ask applicants for a short training-impact pathway: mentoring contribution -> capability developed -> evidence of increasing independence or responsible practice -> subsequent scientific or public value. Reviewers would assess the credibility of relevant links and acknowledge that downstream outcomes may not yet be observable.

4. Collaboration: Modern collaboration creates an attribution and information problem. A visible output may combine conceptual work, data collection, software development, model construction, prompting, AI-generated analysis, human correction, project coordination, and consequential scientific judgment. Publication position and principal-investigator status reveal increasingly little about this division of labor.

NIH should require concise, structured descriptions of accountable contributions. CRediT's contributor-role taxonomy provides a useful foundation, but it should be extended to include consequential AI use, human validation of generated work, responsibility for key decisions, and changes in roles over the life of a project. The purpose should not be to reward every listed role equally. It should be to make contribution, provenance, and accountability more observable.

Collaboration should also be assessed beyond the focal team. Relevant evidence includes the integration of otherwise disconnected disciplines or institutions; the creation of reusable interfaces, methods, or shared language; diffusion of knowledge across organizational boundaries; resolution of coordination problems; and the development of capabilities that allow others to collaborate effectively. Such bridge-building may generate substantial network value even when it does not produce a large number of papers for the person performing it.

My research on organizational innovation networks provides empirical support for evaluating collaboration contextually. In "Core or Periphery: Examining Where to Allocate Heterogeneous Inventors and the Impact on Firms' Innovation," my coauthors and I show that the value of locating heterogeneous inventors in core or peripheral network positions depends on problem complexity and actor characteristics. The implication for research assessment is that there is no universally optimal collaborative profile: the contribution of a role depends on the architecture and task of the team. Strategic Management Journal 47:331–363 (2026), https://doi.org/10.1002/smj.70005.

NIH should match recognition to the level at which collaborative value is created. Individual reviews can recognize accountable roles and judgment; team or project reviews can recognize integration, validation, and shared infrastructure; and program-level assessment can examine institutional concentration, bridging, and the diversity of methods and perspectives across a portfolio.

Structured role descriptions can themselves be gamed. NIH should therefore avoid converting contribution labels into a point system. Reviewers should consider the relationship between claimed roles, research artifacts, decisions, and outcomes. NIH should pilot the approach, monitor contribution-label inflation and administrative burden, and revise the taxonomy as human–AI research arrangements evolve.

5. Entrepreneurship and Translation: Entrepreneurial and translational impact should be assessed as a staged pathway, not inferred from patent counts, startup formation, licensing revenue, or other highly visible endpoints alone. These outputs may be useful evidence, but they do not necessarily establish

technical validity, clinical value, adoption, accessibility, or contribution to the NIH mission.

A translational impact pathway might proceed from a reliable result or capability to independent validation, technical maturation, regulatory or clinical milestones, adoption, and ultimately health or public value. Not every project will traverse the entire pathway, and downstream outcomes may require many organizations and years. Applicants should identify which links are observed, projected, or not yet observable and provide evidence appropriate to the stage of development.

Potential indicators include independent technical validation; demonstrated reproducibility outside the originating team; clarification of a consequential clinical or user need; achievement of regulatory, manufacturing, interoperability, or implementation milestones; adoption by clinical, public-sector, or industry partners; evidence of accessibility and usability; and learning that credibly reduces technical, regulatory, or market uncertainty. A well-validated failure may create substantial value by preventing costly downstream investment or redirecting a field.

NIH should match incentives to the relevant bottleneck. Early projects may need support for validation and de-risking; intermediate projects may need assistance crossing organizational or regulatory boundaries; and mature projects may warrant recognition for verified adoption, accessibility, or public benefit. Researchers who create enabling methods, data, standards, or validation capabilities should receive credit even when another organization completes commercialization.

AI increases the need for staged validation. AI can make prototypes, analyses, claims, and business narratives cheaper to produce, but it does not automatically resolve reliability, provenance, accountability, regulatory readiness, or real-world adoption. Visible production can therefore overstate translational maturity.

NIH should also distinguish private value from public value. Commercial success can coexist with unequal access, displacement of costs, or effects on people outside the focal transaction. Translation assessment should consider who benefits, who bears risks or costs, and whether the innovation advances health outcomes and accessibility.

These criteria should remain contextual and should not be combined into a universal translational score. Appropriate pathways differ across therapeutics, devices, diagnostics, software, policy, and service innovations. NIH could pilot pathway-based assessment in selected translational programs and compare it with current milestone and output measures.

6. Foundational Scientific Exploration: Foundational exploration produces uncertain, delayed, and often widely distributed benefits. A project may create a new method, problem formulation, dataset, research community, or well-validated negative result long before its downstream impact becomes observable. Assessment based primarily on publications, citations, or near-term translation can therefore shift effort toward safer and more immediately legible work.

AI may intensify this bias. By lowering the cost of searching, generating, and refining work in well-represented areas, AI can increase individual productivity while directing researchers toward similar data, methods, benchmarks, and questions. Hao et al. report an association between scientists' use of AI

and increased publication and citation impact alongside contraction in the collective range of topics studied. Although observational, this finding illustrates why individual productivity and portfolio-level exploration should be assessed separately. See Hao et al., Nature 649:1237–1243 (2026), https://doi.org/10.1038/s41586-025-09922-y.

NIH should recognize the option value created by foundational work. Relevant evidence may include a new problem formulation; a method or capability that opens previously inaccessible questions; a credible result that rules out an important path; bridges between previously disconnected research communities; independent follow-on exploration; or preservation of scientific options in areas that would otherwise be neglected.

Because these outcomes have different time horizons, applicants should distinguish observed contributions from projected pathways and outcomes that are not yet observable. Reviewers should evaluate the quality of the question, the credibility of the search or test, the capability created, and the information gained—not require a speculative claim of eventual clinical impact.

Incentives should include protected portfolio space for exploratory and high-risk research, longer evidence windows, support for replication of surprising foundational findings, and recognition of well-documented failure. Milestone reviews should focus on learning and capability formation rather than require that uncertainty disappear according to a predetermined schedule.

Portfolio diversity should be managed at the program level, not converted into a score assigned to individual investigators. NIH could monitor concentration in topics, methods, institutions, data sources, and scientific approaches while preserving expert judgment about field-specific opportunities. Large and small teams, central and peripheral network positions, and established and emerging fields can play complementary roles.

The objective is not to reward novelty as an abstract property. It is to prevent assessment criteria—especially in an AI-enabled environment—from systematically eliminating uncertain but potentially transformative scientific options.

7. Public Impact: Public impact emerges through a pathway connecting scientific contribution, reliable knowledge or capability, independent validation, adoption, and public value. Because this pathway is distributed across organizations and time, neither citations nor a single downstream outcome can adequately attribute impact to the originating research.

NIH should permit multiple forms of evidence while requiring respondents to identify the relevant causal links and remaining uncertainty. Potential indicators include incorporation into clinical guidelines or practice; verified use by health systems, public agencies, or community organizations; improvements in accessibility or affordability; contributions to health outcomes; independently documented economic or workforce effects; adoption of reusable tools or standards; public access to understandable research information; and evidence supporting public trust. Applicants should distinguish direct evidence from plausible projections.

Public-impact assessment should also consider distribution and externalities. An intervention may

generate aggregate benefits while leaving some communities unable to access it or imposing risks and costs on people outside the focal project. NIH should ask who benefits, who remains excluded, which stakeholders are affected, and whether claimed impact depends on complementary infrastructures or institutions.

Collective perception is itself relevant to public impact. Citations, rankings, media narratives, and apparent scientific consensus influence what researchers, policymakers, clinicians, and communities believe is promising or trustworthy. AI-generated summaries and evaluation narratives can accelerate such feedback before underlying claims are adequately verified.

My research with Ilami, Comola, and Prina on networked risk perception shows in another setting how beliefs and behavior can become community-level, mutually reinforcing phenomena rather than independent individual responses. The same general mechanism may affect scientific and public attention, although it requires direct empirical testing in this context. See Ilami et al., "Networked Risk Perception and Behavioral Bubbles," arXiv:2606.22599 (2026), https://doi.org/10.48550/arXiv.2606.22599.

NIH should recognize activities that support credible public impact, including transparent communication, correction of errors, community engagement, accessible resources, implementation partnerships, and responsible stewardship after an award ends. These activities should not be judged through communication volume or media attention alone.

Time horizons and expectations should vary by research type and career stage. Foundational researchers should not be required to demonstrate immediate public adoption, while translational claims should be supported by stage-appropriate validation. Public-impact indicators should inform contextual expert judgment rather than be aggregated into a universal score.

8. Other Areas: CROSS-CUTTING FRAMEWORK: SCIENTIFIC-IMPACT ASSESSMENT AS AN ADAPTIVE INTERVENTION IN AN AI-TRANSFORMED RESEARCH ECOSYSTEM

Central recommendation

NIH should treat scientific-impact assessment as an adaptive intervention in a multilevel research ecosystem, not as a search for a more comprehensive scalar metric. AI is rapidly changing the production economics and information structure of science, exposing weaknesses in output-based measures. NIH should assess contextualized pathways of contribution, validation, diffusion, and public value; match indicators and incentives to the level at which value is created; and revise criteria as the scientific system responds.

Why AI makes this necessary

AI lowers the marginal cost of searching literature, generating hypotheses, writing code and text, exploring parameter spaces, and producing candidate analyses. These capabilities can expand productivity and access to sophisticated methods, but costs fall unevenly. Verification, provenance, causal interpretation, high-quality data, judgment, and responsibility for consequential decisions remain

scarce. The result is a production–verification asymmetry: more claims and artifacts can be generated than the scientific system can independently evaluate.

AI also increases attribution and information asymmetry. Evaluators may not observe how AI was used, whether researchers understood a generated method, how much human validation occurred, or which contributors made the consequential decisions. Meanwhile, already measurable outputs become cheaper to produce, while stewardship, contradiction resolution, mentoring, integration, and validation remain difficult to count. Rewarding what becomes abundant because it is measurable can move effort away from what has become scarce.

Individual gains may also diverge from collective outcomes. AI can increase the productivity of individual researchers while concentrating attention on similar questions, methods, data, and benchmarks. Agentic systems may accelerate these dynamics by coordinating multi-step production and reproducing successful strategies at scale.

A multilevel ecosystem perspective

Scientific impact emerges through interactions among researchers, teams, institutions, funders, journals, infrastructures, communities, and AI systems. Assessment is part of this causal system: what NIH measures changes what scientists produce, disclose, share, verify, and avoid. Effects also travel across levels. A shared dataset may look modest at the individual level but generate substantial downstream spillovers. A highly visible line of research may look successful locally while narrowing a portfolio's scientific diversity.

This proposal extends the sociotechnical ecosystem perspective I developed in "A Sociotechnical Ecosystem Perspective of Sharing Economy Platforms," a chapter in the Cambridge University Press volume Reengineering the Sharing Economy: Design, Policy, and Regulation, for which I served as lead editor. That perspective treats system boundaries, externalities, affected stakeholders, information, and governance as interdependent design choices. DOI: https://doi.org/10.1017/9781108865630.003.

The impact-pathway instrument

Rather than requesting a longer inventory of outputs, NIH should pilot a short, structured impact-pathway statement:

accountable contribution -> reliable result or capability -> independent validation -> reuse or adoption -> NIH mission or public value.

Respondents would identify which links are relevant and label each as "observed," "projected," or "not yet observable." They would name the evidence supporting each claimed link and state important uncertainties. Reviewers would judge the credibility and strength of the relevant links, not reward the mere number of links completed.

Five broad evidence categories could make the pathway operational:

1. Accountable contribution and provenance, including human and AI roles, human validation, and responsibility for consequential decisions.

2. Validation, correction, and stewardship, including replication, robustness, negative findings, error correction, version histories, and maintained research artifacts.

3. Spillovers, diffusion, and bridging, including independent reuse, avoided duplication, cross-institutional adoption, and knowledge crossing disciplinary or sectoral boundaries.

4. Capability, exploration, and portfolio diversity, including workforce development, protected exploratory options, new methods, and bridges across research communities.

5. Translation and public value, including validated technical, regulatory, clinical, policy, entrepreneurial, accessibility, and adoption pathways.

Diagnosis-to-design logic

Each instrument should answer a specific failure mechanism. Attribution and information asymmetry require structured contribution descriptions and AI provenance. Verification scarcity requires recognition and funding for replication, correction, and stewardship. Spillovers and network effects require following value beyond the originating team through independent reuse, bridging, diffusion, and adoption. Cumulative advantage and collective perception require program-level attention to concentration, methodological and topical diversity, and the distribution of opportunity. Delayed and cross-level outcomes require matching the evidence horizon and reward to the level at which value is created. Indicator endogeneity requires treating assessment criteria as revisable interventions.

Use a menu, not a checklist. Relevant evidence will depend on the contribution, field, time horizon, and career stage. Where quantification is appropriate, NIH should prefer verifiable and denominated signals, such as the share of users independent of the originating team, rather than raw downloads, mentions, patents, startups, or revenue. No universal set of indicators should be collapsed into a cross-field league table.

Implementation

NIH can begin without creating an entirely new reporting architecture. The current Biographical Sketch Supplement already collects narrative Contributions to Science. NIH could pilot a concise impact-pathway module in one shared-resource program, one team-science program, and one investigator-centered mechanism.

Each pilot could:

1. Request an impact-pathway statement of no more than 500 words, with evidence and an observation-status label for each relevant link.

2. Train reviewers using anchored examples and ask them to identify strong links and inferential gaps.

3. Match recognition or funding consequences to the evidenced link and appropriate level. For example, portfolio diversity should guide program management rather than become an individual score.

4. Monitor burden, reviewer agreement, team and institutional distributions, independent reuse and replication, topic and method diversity, and signs of gaming.

5. Compare outcomes over two or three cycles using staggered introduction or matched programs where feasible, publish aggregate findings, and revise or retire indicators that produce burden, inequity, homogenization, or strategic distortion.

This adaptive approach is consistent with my research on information modulation in multi-agent AI systems, which demonstrates how targeted changes in an information environment can alter collective outcomes without controlling each actor or changing the underlying interaction network. See Chen, Ilami, Lorè, and Heydari, "Adaptive Information Modulation: Designing Governance Mechanisms for Multi-Agent AI Systems," Journal of Mechanical Design 148:041708 (2026), https://doi.org/10.1115/1.4070755.

The goal should not be a perfect metric. It should be an assessment system that creates better incentives, recognizes enabling and distributed contributions, detects its own behavioral and distributional effects, and learns as science and AI coevolve.

Description: This attachment provides an integrated response to the RFI, proposing that NIH treat scientific-impact assessment as an adaptive intervention in a multilevel research ecosystem. It explains how AI is changing the economics and information structure of science; examines attribution, verification scarcity, spillovers, network effects, collective perception, and cross-level consequences; and proposes a causal impact-pathway framework, corresponding indicators and incentives, and a feasible NIH pilot.

280. American Medical Informatics Association (AMIA)

I am responding: On behalf of an organization

Name: Tayler Williams

Name of Organization: American Medical Informatics Association (AMIA)

Type of Organization: Professional Organization/Association

Role: Other

Role - Other: Senior Manager, Public Policy

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: AMIA recommends that NIH more explicitly reward research practices that improve rigor, reproducibility, replication, and generalizability. Current incentives often favor novelty and publication volume, while undervaluing replication studies, methods papers, negative or mixed findings, and cross-site validation. NIH defines scientific rigor as the strict application of the scientific method to ensure robust and unbiased design, methodology, analysis, interpretation, and reporting, and NIH recognizes reproducibility as essential to validating scientific findings.

This is particularly important in informatics, where AI models, clinical decision support tools, digital health interventions, and workflow changes may perform differently across health systems, EHR environments, populations, and implementation contexts. AMIA recommends that NIH recognize methods papers, protocols, analytic code, workflow descriptions, model documentation, implementation guides, technical validation reports, and reproducibility packages as important scientific outputs.
NIH should also create dedicated funding opportunities, study sections, or review criteria for replication and reproducibility research. These applications should not be disadvantaged because they are not "novel". Instead, they should be valued for confirming, refining, or challenging prior findings. The Annual Review of Medicine article on reproducibility failure emphasizes that reproducibility problems arise across the conduct, reporting, and review of biomedical research and require interventions aimed at improving research practices and incentives.

AMIA also recommends that NIH pilot adversarial collaboration in areas where legitimate scientific disagreement persists despite accumulated evidence. Adversarial collaboration brings investigators with opposing views together to jointly design, analyze, and publish studies, often with a neutral arbiter, and aligns with open science practices such as transparency, preregistration, and shared analysis. NIH could test low-cost adversarial reanalysis of existing clinical trial, cohort, EHR, or claims data using shared protocols and publication commitments regardless of outcome.

2. Data, Software, and Model Sharing: AMIA supports NIH's efforts to incentivize data, software, and model sharing as core components of scientific impact. NIH's Data Management and Sharing Policy recognizes that sharing scientific data accelerates discovery by enabling validation, access to high-value datasets, and reuse for future studies.

However, sharing is not simply a compliance activity. Preparing data, software, and models for meaningful reuse requires infrastructure, documentation, governance, privacy protections, and long-term stewardship. NIH should allow applicants to budget adequately for data curation, software maintenance, repository fees, documentation, privacy-preserving infrastructure, and technical support.

For informatics, key outputs include well-documented datasets, data dictionaries, open-source software, analytic code, common data models, validated AI models, model cards, implementation guides, APIs, terminology mappings, and reproducible workflows. NIH should recognize these as scholarly contributions when they enable validation, replication, secondary analysis, or future research.

3. Training and Mentorship: AMIA recommends that NIH broaden how it measures training and mentorship impact. Scientific impact includes preparing researchers, clinicians, informaticians, data scientists, implementation leaders, and team-science contributors to conduct rigorous, transparent, and reproducible research.

Informatics training is especially important because modern biomedical research increasingly depends on data quality, interoperability, AI, software, workflow design, human factors, privacy, implementation science, and responsible data stewardship. NIH should reward mentorship that prepares trainees to work in collaborative, data-driven research environments and to apply reproducible methods across settings.

Mentorship impact should not be measured only by the number of trainees who obtain academic faculty positions. NIH should also recognize trainees who contribute to health systems, public health agencies, government, industry, standards organizations, nonprofit research settings, community-based organizations, and science policy roles.

4. Collaboration: AMIA recommends that NIH better reward collaboration and team science. Informatics research often depends on multidisciplinary teams that include clinicians, informaticians, data scientists, statisticians, software developers, implementation scientists, standards experts, patients, caregivers, public health professionals, and health system leaders.

Traditional authorship and citation metrics may not capture essential team contributions such as data engineering, software maintenance, workflow redesign, standards development, implementation leadership, governance, patient engagement, and cross-site coordination. NIH should encourage applicants and reviewers to identify and value these contributions.

AMIA also recommends that NIH support multi-site studies and implementations that improve generalizability and reproducibility. In informatics, a tool that works in one institution may not work elsewhere unless it is tested across different data systems, populations, clinical workflows, and organizational contexts.

NIH should also consider adversarial collaboration as a structured form of team science for contested questions. A recent JAMA Viewpoint notes that adversarial collaboration is most valuable where scientific disagreement is genuine and consequential and where existing studies are perceived as biased

or inadequate. Such collaborations may include joint meta-analyses, mutually accepted reanalysis of large datasets, codesigned prospective studies, or modeling projects that test how conclusions shift under different assumptions.

5. Entrepreneurship and Translation: AMIA recommends that NIH define translation broadly to include not only commercialization, but also implementation into clinical care, public health, research infrastructure, policy, standards, and health system operations.

In informatics, translation may include deployment of clinical decision support, adoption of interoperability standards, implementation of AI governance frameworks, integration of patient-facing digital tools, use of common data models, or incorporation of research findings into health system workflows. These activities may not always result in patents or products, but they can have substantial public value.

NIH should reward research that demonstrates whether innovations work safely, effectively, equitably, and sustainably in real-world settings. For AI and digital health tools, translation should include external validation, workflow integration, usability, safety monitoring, bias assessment, patient and clinician experience, and evidence of sustainability over time.

6. Foundational Scientific Exploration: AMIA recommends that NIH continue to reward foundational research, including high-risk and infrastructure-focused work whose impact may take years to become visible. In informatics, foundational contributions often include data standards, terminology systems, common data models, software platforms, knowledge representation methods, evaluation frameworks, and methods for measuring data quality, bias, provenance, and interoperability.

These contributions may not produce immediate clinical outcomes, but they enable future discovery, replication, implementation, and translation. NIH should ensure that impact assessment does not undervalue foundational informatics work simply because its benefits are indirect, distributed, or long-term.

AMIA also recommends that NIH support greater standardization of outcome reporting in informatics. Meta-analysis remains underused in the field partly because studies often use inconsistent definitions, measures, outcomes, and implementation descriptions. NIH states that common data elements enhance data interoperability and reproducibility, supporting more consistent data collection across studies and sites.

7. Public Impact: AMIA recommends that NIH measure public impact in ways that reflect both near-term and long-term value. Public impact should include contributions to health outcomes, clinical practice, public health, patient safety, accessibility, trust, health equity, economic value, workforce capacity, and responsible use of technology.

In informatics, public impact may include safer clinical decision support, more transparent AI, improved data exchange, reduced documentation burden, better patient access to health information, improved public health reporting, stronger data quality, or tools that help clinicians and patients make better decisions.

NIH should recognize that public impact often takes time to emerge. Foundational work in data standards, software, methods, infrastructure, and reproducibility may enable future breakthroughs even if immediate outcomes are difficult to measure. NIH should therefore avoid relying only on short-term metrics.

281. Greater Gulf Coast Translational Science Alliance

I am responding: On behalf of an organization

Name:

Name of Organization: Greater Gulf Coast Translational Science Alliance

Type of Organization: Other

Type of Organization - Other: CTSA consortium

Role: Organizational Official

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: Recognize Contributions to Rigor and Reproducibility. Rigor and reproducibility should be evaluated based on the quality of the scientific process, rather than primarily on the number of publications, citations, or other traditional measures of academic productivity. Important indicators include appropriate study design; pre-specification of analyses when appropriate; transparent reporting of statistical methods; appropriate handling of missing data; assessment of model assumptions; sensitivity analyses; validation of analytical approaches; independent replication; transparent sharing of data and code when possible; and sufficient documentation to allow others to understand and reproduce an analysis.

Importantly, these practices often require substantial contributions from individuals whose work may be difficult to capture fully using traditional measures of scientific impact. Biostatisticians and data scientists frequently contribute critically to study design, analytic strategy, statistical methodology, data management, software development, validation, and interpretation. These contributions may determine whether a study produces reliable evidence, yet these contributions may be reflected in ways not fully captured by conventional authorship, funding, or citation indicators. NIH should explicitly recognize methodological contributions as important indicators of scientific impact.

NIH could encourage this recognition by asking investigators to document specific contributions to rigor and reproducibility in grant applications, progress reports, and other assessments. Examples could include development of reproducible analytical workflows; creation and validation of statistical methods or software; independent validation of findings; development of data standards or documentation; replication of important findings; and substantive contributions to study design and analytic integrity. Contribution-based assessment would better reflect the increasingly team-based nature of biomedical research.

Measure Reproducibility. Reproducibility should be considered multidimensional. A single metric is unlikely to adequately capture whether research is rigorous or reproducible. NIH should consider a portfolio of indicators that reflect both the practices used to produce research and the subsequent ability of others to reproduce, validate, replicate, or extend the findings.

Potential indicators include availability of analysis code; appropriate documentation of computational workflows; availability and appropriate governance of data; use of version-controlled software; independent validation; replication studies; transparent reporting of deviations from prespecified analyses; and reuse of data or software by independent investigators. Importantly, these measures should distinguish between computational reproducibility, methodological reproducibility, and biological or clinical replication, which are related but not interchangeable concepts.

NIH may wish to design metrics that emphasize meaningful practice rather than checklist-style compliance. Requiring a reproducibility checklist, for example, does not necessarily produce reproducible science. Measures should emphasize meaningful practices and outcomes rather than compliance alone.

Recognize Replication and Negative Findings. Current incentives often place greater emphasis on novel and positive findings. This may provide fewer incentives for replication studies, confirmation of established findings, and publication of well-conducted studies that produce null or negative results. NIH should consider mechanisms to increase the scientific value assigned to these contributions.

A rigorous replication study that confirms or challenges an influential finding may have greater long-term scientific value than a novel but poorly validated result. Similarly, a well-designed study producing a null result can prevent substantial resources from being devoted to an ineffective intervention or unsupported hypothesis. NIH should explicitly recognize these contributions when assessing scientific impact.

2. Data, Software, and Model Sharing: Reward usable and reusable scientific products. NIH should evaluate datasets, software, and models based not only on their availability or citations, but also on their quality, documentation, interoperability, independent reuse, external validation, and contribution to subsequent discoveries or health improvements. Indicators could include the number and diversity of independent users, successful reproductions, incorporation into new studies, validated clinical or public-health applications, and the populations ultimately benefiting from the work. Publication and citation metrics remain valuable, particularly for foundational research, but they should be complemented by measures of translational and public impact.

Fund the full lifecycle of sharing. Data sharing is not a one-time act of depositing files. It requires data engineering, quality control, curation, metadata, privacy and security review, storage, transfer, software maintenance, user support, model monitoring, and eventual archiving or deprecation. Current budgeting approaches may not always fully account for this operational complexity and the substantial contributions of research software engineers, informaticians, data stewards, system administrators, security specialists, and project managers. These personnel and activities should be explicitly recognized as allowable and reviewable scientific costs. Shared infrastructure and post-award stewardship mechanisms would help prevent each project from rebuilding the same capabilities independently.

Develop consistent, machine-actionable federal standards. NIH should promote common requirements for metadata, data dictionaries, provenance, versioning, quality-control reporting, persistent identifiers, and programmatic access. NIH-supported repositories are extraordinarily valuable, but differences in submission, validation, and export requirements can create technical burdens that greater

standardization may reduce. Greater standardization, reusable validation tools, bulk export capabilities, and standards-based application interfaces—including emerging agent-compatible interfaces—would improve accessibility without lowering scientific or privacy standards.

Advance patient-centered governance and consistent privacy protections. Federal policy should move toward comparable privacy, security, transparency, and accountability standards for health-related data held by academic institutions, healthcare organizations, technology companies, and other commercial entities. The objective should not be to weaken protections for clinical data, but to reduce regulatory asymmetries while enabling responsible research. Individuals should have meaningful opportunities to authorize, direct, and, where feasible, revoke research and AI uses of their data across institutions. NIH could support both a strong patient-control principle and carefully evaluated pilot programs for patient-directed authorization, portability, and consent.

Recognize that responsible sharing is context dependent. A single sharing model will not fit omics, imaging, EHR, real-world evidence, clinical trials, and continuously generated device data. Cancer and molecular research may require particular attention to reference versions, biospecimen provenance, genomic identifiability, and reproducible analytic pipelines. Aging, longitudinal EHR, and real-world evidence research may require continuing attention to consent, decision-making capacity, changing health status, repeated observations, data generated outside healthcare settings, and model performance over time. NIH should define common principles while permitting discipline- and modality-appropriate controlled-access approaches.

Balance sharing with commercialization and intellectual property. Incentives should recognize that immediate unrestricted release can conflict with patent protection, licensing, public-private partnerships, and development of products that ultimately benefit patients. NIH could permit clearly defined and time-limited sharing delays, followed by release of appropriate validation data, documentation, and nonproprietary components. Investigators should not be penalized for using justified controlled-access or staged-release models when necessary to protect participants or preserve a credible path to translation.

Modernize scientific credit and reporting. Contributors who build, validate, document, maintain, and support shared resources should receive visible academic and grant-review credit. As AI increasingly assists manuscript production, evaluative emphasis should shift from publication volume and narrative length toward auditable technical artifacts, including versioned methods, quality-control results, software and model documentation, limitations, failure modes, and reproducible workflows. This can be incorporated into existing publication and grant-review practices without displacing the importance of rigorous peer review.

A practical NIH implementation strategy could begin with common core indicators across programs—usability, independent reuse, validation, stewardship, and demonstrated health or scientific benefit—while allowing field-specific measures. Pilot implementation through CTSA hubs and other shared-infrastructure programs could assess feasibility, administrative burden, and unintended consequences before broader adoption.

3. Training and Mentorship: Assessing the impact of NIH-supported training and mentorship programs requires recognition that outcomes often emerge over long periods of time and across diverse career pathways. The value of mentorship and workforce development may not be apparent during the training period itself; therefore, evaluation frameworks should incorporate longitudinal tracking of mentees across multiple career stages and sectors. Success should be measured broadly and not be limited to traditional academic outcomes or NIH funding alone.

Several indicators could help quantify the effectiveness of NIH training and mentorship investments. These include the ability of former trainees to secure research funding during and after their training, including support from NIH, other federal agencies, foundations, and industry partners. Evaluation should also recognize contributions to funded research projects beyond principal investigator roles, as many scientists build successful careers through collaborative and team-based science.

Retention in scientific and biomedical careers is another important outcome. Metrics should capture whether trainees remain engaged in research-related professions, regardless of whether they pursue careers in academia, government, nonprofit organizations, or industry. Tracking the attainment of a first independent position, whether as faculty or as a scientific leader in another sector, would provide an important indicator of career progression.

The long-term influence of mentoring relationships should also be considered. Former trainees who go on to mentor others, serve as mentors on training grants, or support mentees who subsequently receive career development awards or other research funding demonstrate a multiplier effect of NIH's training investments. These downstream impacts may be among the strongest indicators of mentorship success.

Scholarly productivity should be evaluated using measures that reflect the collaborative nature of modern biomedical research. In addition to first- and senior-author publications, contributions to team science efforts, including publications where a trainee serves in a middle-author role, should be recognized. Similarly, presentations at scientific conferences, including posters, platform presentations, invited talks, and presentation-related awards, can provide valuable evidence of professional development and scientific engagement.

Finally, there is significant concern regarding the reduced availability of support for postdoctoral training as T32 training opportunities are phased out or reduced. This change may disproportionately affect postdoctoral researchers without clinical degrees, who often rely on these programs for protected research time, mentorship, and career development. Any assessment of NIH's training and mentorship ecosystem should consider the potential impact of these changes on the development and retention of the future biomedical research workforce.

4. Collaboration: Reward Team Science. Biomedical research is increasingly interdisciplinary, but academic reward systems often continue to emphasize individual achievement. This can create gaps between collaborative scientific practice and traditional evaluation approaches. NIH should place greater emphasis on the contributions of research teams and on the complementary expertise required to answer complex biomedical questions.

Team science could be evaluated using structured contribution statements that identify the scientific,

methodological, computational, data, mentoring, and leadership contributions of individual team members. Such information could complement, rather than replace, traditional publication metrics. NIH could also encourage institutions to incorporate contribution-based assessments into promotion and tenure processes.

Particular attention should be given to scientific infrastructure and methodological contributions. Individuals who develop datasets, software, analytical pipelines, statistical methods, repositories, or other resources may enable hundreds of subsequent studies while their contributions may be difficult to recognize through conventional metrics. These contributions should be viewed as scientific products rather than merely as service activities.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: To strengthen the public impact of biomedical research, NIH should encourage changes in the culture and reward systems that shape investigator behavior and institutional priorities. Current academic promotion and tenure processes often place primary emphasis on individual achievements, grant funding, and publication metrics, which can undervalue activities that contribute substantially to societal benefit. NIH could help drive change by promoting evaluation frameworks that recognize and reward reproducible and transparent research practices, team-based and collaborative science, and community-engaged research. Importantly, these activities should be considered core expectations of high-quality research rather than optional or supplemental contributions. Indicators of success could include demonstrated adoption of open science practices, participation in multidisciplinary research teams, and meaningful engagement with patients, communities, or other stakeholders throughout the research process.

NIH should also consider mechanisms to ensure that research is responsive to the needs of those most likely to benefit from its outcomes. One approach would be to include patients, community representatives, caregivers, public health practitioners, or other end users in grant review processes when appropriate. Their participation could help assess whether proposed projects address community-identified priorities, have a realistic pathway to implementation, and are likely to produce meaningful societal impact. Potential indicators could include evidence of stakeholder involvement in study design, dissemination activities tailored to affected communities, and measurable adoption of research findings in practice, policy, or public health initiatives.

Achieving these goals will also require changes in workforce development. Training and mentorship programs for graduate students, postdoctoral researchers, and early-career faculty should provide skills and experiences that support community engagement, collaborative science, research transparency, and translation of findings into real-world settings. Evaluating the effectiveness of these efforts could include tracking participation in community-engaged research activities, interdisciplinary collaborations, open science initiatives, and other practices that contribute to public impact.

Collectively, these approaches would encourage a research ecosystem that values not only scientific discovery, but also the extent to which research is rigorous, accessible, responsive to societal needs, and ultimately beneficial to the public. As NIH develops public impact metrics, it will be important to ensure

that they are feasible across disciplines, career stages, and institution types, while avoiding unintended consequences such as excessive administrative burden or overly narrow definitions of impact.

8. Other Areas: Training and Mentorship as Scientific Impact

Scientific impact also includes the development of people who will conduct future research. Training and mentorship should therefore be recognized as meaningful scholarly contributions rather than secondary activities.

NIH-supported training programs can have effects that extend well beyond the immediate products of a project. Effective training in experimental design, statistical reasoning, data science, reproducible research, responsible conduct, and scientific communication can influence the quality of research produced by trainees throughout their careers. NIH should consider measures such as trainee progression into research careers, subsequent research contributions, development of methodological expertise, and continued engagement in rigorous and reproducible research.

Importantly, these measures should be feasible across career stages. Expectations for an undergraduate trainee, early-career investigator, established investigator, and senior team leader should not be identical. Evaluation systems should recognize developmental trajectories rather than relying on a single set of productivity metrics.

The Essential Role of Biostatistics and Data Science

The increasing complexity of biomedical research makes methodological expertise essential to scientific rigor. Biostatisticians and data scientists contribute across the research lifecycle, including formulation of research questions, study design, sampling, data management, statistical analysis, computational methods, interpretation, visualization, and reproducibility.

NIH should explicitly recognize these contributions when defining scientific impact. In many collaborative studies, the quality of the statistical design and analysis is foundational to the validity of the scientific conclusions. Yet conventional metrics can make these contributions difficult to document and reward.

One potential solution is for NIH to encourage standardized contribution reporting that goes beyond authorship. For example, grant applications and reports could describe contributions to study design, statistical methodology, computational methods, data resources, software, validation, and reproducibility. Such documentation would provide reviewers and institutions with a more complete picture of an individual's scientific contributions.

Avoiding Unintended Consequences

Any new system for measuring scientific impact should be implemented cautiously. Quantitative metrics are attractive because they are easy to compare, but overreliance on metrics may create incentives that do not fully align with the intended goals. For example, investigators could prioritize activities that are easy to count rather than activities that are scientifically valuable.

Metrics should therefore be used as evidence to inform expert assessment rather than as automatic measures of scientific worth. NIH should also periodically evaluate whether new measures produce unintended consequences, including increased administrative burden, inequities across disciplines, or incentives for checklist-style or low-value compliance.

Feasibility is particularly important. A system requiring extensive documentation for every contribution could disproportionately burden investigators at institutions with fewer administrative resources and could reduce time available for research activities. New measures should be simple enough to implement while still capturing meaningful contributions.

Recommendations

-Evaluate scientific contributions rather than relying primarily on publications and citations.

-Explicitly recognize methodological, statistical, computational, data, software, and infrastructure contributions.

-Reward team science through structured contribution reporting.

-Recognize replication, validation, and well-conducted null or negative studies.

-Measure reproducibility through meaningful research practices and outcomes rather than checklist compliance.

-Recognize training and mentorship as contributions to the long-term scientific enterprise.

-Use multiple measures rather than a single quantitative metric.

-Ensure that measures are appropriate for different disciplines, career stages, and types of scientific contribution.

-Minimize administrative burden and continually evaluate new metrics for unintended consequences.

-Use metrics to support informed expert judgment rather than replacing expert assessment.

The biomedical research enterprise increasingly depends on interdisciplinary teams, sophisticated data resources, computational methods, and methodological expertise. A system for measuring scientific impact should evolve accordingly. Recognizing the people and practices that make research rigorous, reproducible, collaborative, and useful would strengthen the scientific enterprise and better align incentives with NIH's goal of producing trustworthy knowledge that advances human health.

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: Rigor and Reproducibility. We agree that reproducible and replicable biomedical approaches are foundational to rigorous research. We caution, however, that a distinction needs to be drawn between exploratory research aimed at hypothesis generation and confirmatory research aimed at hypothesis testing. The National Academy of Sciences describes the distinction thus: "Confirmatory research is research that starts with a well-defined research question and a priori hypotheses before collecting data; confirmatory research can also be called hypothesis testing research. In contrast, researchers pursuing exploratory research collect data and then examine the data for potential variables of interest and relationships among variables, forming a posteriori hypotheses; as such, exploratory research can be considered hypothesis generating research."[23]
One way to describe the distinction is that exploratory research is directed towards "unknown unknowns." Boguslav et al wrote: "Research begins with a question. It progresses through accumulating knowledge such that a previously unexplored subject (an unknown unknown) becomes an active research area exploring the questions (known unknowns), until a body of established facts emerges (known knowns)." [57]From a risk perspective, Derbyshire et al. describe unknown unknowns as "…elements of knowledge that would be of importance to assessing the focal risk if they were known but which are presently unknown to anyone including those tasked with making the risk assessment, who, furthermore, lack awareness of not knowing them."[58] Only when something is "known," can it be subject to rigorous, controlled hypothesis testing or considered for utility in applied or translational research.
From the perspective of reproducibility and replicability, exploratory research may yield observations that are, at least in part, irreproducible or irreplicable since it is impossible to control for unknown unknowns. In fact, failure to replicate observations in exploratory research can be useful in that it may expose the presence of unknown factors and prompt further exploratory studies aimed at their characterization. We caution that arbitrary standards focused on reproducibility or replicability could be inherently ineffective if applied to exploratory research could compromise the process of exploration and create impediments to progress.
We endorse efforts to improve the rigor of confirmatory research aimed at testing discrete hypotheses with potential applications in healthcare or industrial development.
We propose the following:

• NIH should increase its funding for education in research methodologies, particularly at the graduate level;

• NIH should assure that investigators have adequate funding for their proposed research and do not feel pressured to “cut corners” to satisfy budget constraints;
• Free dissemination and critique of ideas without political interference or consequences is central to our communal responsibility to conduct rigorous research;
• Federal health agencies need to set an exemplary standard in promulgating only applications of research that has been replicated, distinguishing early-stage findings that are only exploratory, and calling out information that is merely observational or conjecture.

2. Data, Software, and Model Sharing: Data, Software, and Model Sharing. We agree that “sharing scientific data and tools accelerates biomedical research discovery” and urge the NIH to continue efforts to make data sharing a normative practice. We believe the NIH has long set a high standard for making data widely available for scientific research and applications. The sharing of publicly funded research, data collections, analytical tools, and even is increasingly normative. We would emphasize the following:

• The confidentiality of personal, clinical data must remain an overriding principle without compromise;
• Data and research tools made available by the federal government must set a high standard and must represent a complete and accurate representation of data that is collected, or research results generated with public funds. These shared collections cannot be subject to ideological modification or censoring. We note that these collections must be complete datasets and are likely to include content that is not uniformly considered to be accurate or useful. Only information that is formally retracted after scientific critique should be eliminated.

3. Training and Mentorship: Training and Mentorship. We applaud NIH’s continued commitment to training a professional and technical workforce. We call on the NIH to ensure adequate, continuous funding for these programs.

4. Collaboration: Collaboration. We applaud the NIH’s commitment to collaboration. We recommend that the NIH consider collaborations beyond the traditional disciplines of medicine, biology, biochemistry, psychology, informatics, analytics, and physics and promote collaborations also between scientists and individuals expert in management, economics, finance, and public policy. Such collaborations could significantly help bridge the gap between laboratory science and applications in medicine.

5. Entrepreneurship and Translation: Entrepreneurship and Translation. While most discussions of entrepreneurship and the transition from basic to applied or translational science focus on issues of finance, we believe a critical, overlooked aspects of entrepreneurship and translation is technology readiness.
Evidence in engineering suggests that the maturation of technology has predictive value for subsequent development performance including both technical risk, cost, and timelines. The GAO, for example, finds that entering product development with immature technologies leads to greater costs and schedule delays and have higher development costs than those based on mature technologies. This has led agencies including DOD and NASA to incorporate technology readiness assessments in their determination of whether novel technologies are sufficiently mature to proceed into development and production. Our research suggests that pharmaceutical development is similarly dependent on the maturation of the underlying basic science, that few, if any targeted therapeutics are successfully developed until this science passes a passes a quantitatively-defined threshold of maturation, and that

the timelines of clinical development are significantly longer if clinical development commences before this threshold is reached.[6-9, 22, 59] Our work further suggests that innovation can stall when private capital is invested in immature technologies and is, therefore, dissuaded from subsequent investments in the space as it matures. Given the high risk, limited availability, high cost of investment capital for early-stage development, greater focus on characterizing the readiness of basic science for development could radically reshape the landscape of innovation and promote more rapid translation of the most promising technologies.

6. Foundational Scientific Exploration: Foundational Scientific Exploration Our research suggests that the primary contribution of NIH funding to pharmaceutical innovation is its support of basic science. Basic research conducted with federal funding has an essential role in the innovation ecosystem as the primary driver of discovery and development and a source of economic stimulus.

Basic science is defined as "…experimental or theoretical work undertaken primarily to acquire knowledge….without any particular application or use in view" [60], recognizing that NIH spending is inherently "use-inspired" [61]. Our work further suggests that virtually all of this work is performed in public institutions (as opposed to industry) and as noted above, the maturation of this body of research may be a critical determinant of product development success, timelines, and costs. [6-9, 22, 59] Initiating applied, translational, or development work based on an immature body of basic research increases the risk, timelines, and costs to industry.
We would argue that initiatives focused on specific diseases or conditions can only succeed if there is a commitment to establishing a mature body of basic research before considering translation or development. We have studied innovation following passage of the National Cancer Act of 1972. This Act was long considered to have been a failure due to the absence of new therapies or substantial improvement in outcomes for decades after the Act was passed. Our analysis suggest that the Act was, in fact, highly successful. The War on Cancer was launched at the outset of an era that saw the emergence of molecular biology, genomics, and biotechnology and the Act was instrumental in funding much of this foundational work. Our analysis shows that it was only when the foundational, basic research in these areas reached a threshold of maturation that new product began to appear. The last 20 years have seen an explosion of new therapies for cancer and dramatic advances in both treatments and outcomes. [22] Similarly, many early failures of candidate therapies for Alzheimer's involved candidate products that entered development before research on Amyloid was mature while the recent successes uniformly entered development only after that body of research was established. [62]

We would also call attention to the economic efficiencies created by public support for basic science. As described below, the timeline between basic research on drug targets and first approval of a drug associated with that target can be as much as 25 years. [21, 63, 64] This long timeline, coupled with the high cost of capital in industry (10.5%) makes investment in basic science untenable for industry. It is possible to estimate the cost savings provided to industry by NIH funding for basic science that is then transferred to industry through the public domain, workforce training or licensing. Industry typically calculates drug development costs as the sum of spending on the approved drug, an estimate of spending on failed candidate products, and a 10.5% cost of capital. Applying the same calculation to assess the value provided to industry by public funding of basic research, we estimate that the average cost saving to industry is as much as $2.9 billion, an amount roughly equivalent to reported development costs. [20, 21, 65]

Public funding for basic science also creates economic efficiencies through spillovers. Studies suggest that an average of three novel therapeutics are developed for each biological target. [19, 66] This is evident, for example, by the observation that most NIH-funded projects related to at least one drug approval are typically associated with multiple approved drugs. This means that the public investment in basic science is ultimately distributed across multiple approvals, reducing the effective public investment/drug and multiplying the returns from product development.

We believe that a continued government commitment to funding basic science is essential for the future success of pharmaceutical innovation and commercialization. Initiatives that draw resources away from basic science toward applied or translational research in any specific therapeutic or disease area, no matter how well intentioned, represent a threat to future progress.

7. Public Impact: N/A

Description: Comments on NOT-OD-26-087

Date submitted:	August 19, 2026
Title:	Promoting Scientific Impact at the NIH
Submission to:	National Institutes of Health NIH Office of Science Policy
Response to notice:	NOT-OD-26-087: Request for Information on Measuring and Rewarding Scientific Impact, June 18,2026
Comments by:	Fred D. Ledley, M.D. Director, Center for Integration of Science and Industry Professor, Departments of Natural & Applied Science, Management Bentley University Waltham, MA USA
Comment tracking number:	TBD
Document ID:	TBD

Introduction

We are honored to offer our comments on Promoting Scientific Impact at the NIH in response to NOT-OD-26-087: Request for Information on Measuring and Rewarding Scientific Impact.

These comments are informed by my professional experience as the founding director of the Center for Integration of Science and Industry at Bentley University,[i] which has a mission to **"advance the translation of scientific discoveries for public value by engaging science, business, and policy in transdisciplinary dialogue, scholarship, and education."** Our approach is to bring together the perspectives of natural science, business, analytics, economics, law, and policy to better understand, and advance, the path of translational science and the business models that create public value from the fruits of scientific discovery, primarily through pharmaceutical innovation. **A primary focus of our research is on characterizing sources of innovation capital including funding from the public sector, product sales, equity markets, and debt markets, their contributions to pharmaceutical innovation, and their required returns.**

We applaud the overarching aim of the NIH's initiative to "incentivize and reward rigorous research that delivers value to the American public" and "…better align its measures of success with its core mission; generating knowledge that enhances health, lengthens life, and reduces illness and disability." We also agree that many current metrics of scientific success – as well as many criticisms of the NIH – involve "…indicators of productivity, such as publication counts and citation metrics."

We are, however, concerned about disruptions of the NIH over the past 20 months that have reduced the number of basic, applied and translational research projects awarded, reduced the total amount of research funded by the NIH, interfered with peer review, reduced or eliminated Notices of (new) Funding Opportunities, disrupted research careers and collaborations, interfered with the dissemination of research findings to the public, imposed censorship and political criteria for funding, interrupted workforce and professional training programs, and led to the departure of many experienced and dedicated public servants and loss of their accumulated expertise. **We believe the NIH's top priority must be to restore normal operations including a robust process for soliciting, reviewing, and funding scientifically driven research that has long provided the foundation for advances in American prosperity, influence, health, and wellbeing.**

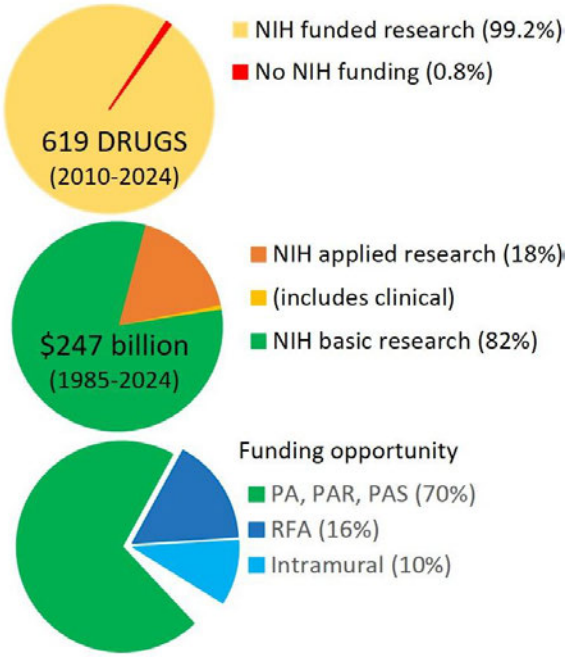
Our perspectives

Our perspectives are based on three principles:

1. **The NIH has a significant impact in advancing healthcare and health outcomes for Americans.**

   Other commentators are more qualified to comment on the NIH's broad impacts on improving healthcare practice and reducing morbidity and mortality in the United States. From a personal perspective, the table below illustrates some of the clinical outcomes I experienced in my pediatric training and the advances that have been achieved to the present day.[ii]

Selected pediatric outcome	Historical	years	Contemporary	years
Infant mortality rate	13/1,000 live births	1980	5.6/1,000 live births	2023
Likelihood of death before age 20a	2.3% live births	1975	1.1% live births	2022
Minimum gestational age considered potentially viable	28 weeks	1971	22 weeks	2013-2018
Childhood acute lymphoblastic leukemia (ALL) survival	57% 5-year survival	1975	92% 5-year survival	2014-2020
Childhood acute myelogenous leukemia (AML) survival	22% 5-year survival	1975-1984	68% 5-year survival	2005-2014
Cystic fibrosis survival	11 years	1978	>65 years	2021-2025
Critical congenital heart disease survival	68% 1-year survival	1979-1993	83% 1-year survival	births 1994-2005
Phenylketonuria (PKU) cognitive outcome (IQ)	<70	1961b	normal	post-screening
Motor vehicle crash deaths — infants	7/100,000	1980	2/100,000	2018-2019
Sudden infant death syndrome (SIDS)	1.5/1,000 live births	1979-1982	0.4/1,000 live births	2024
Measles deaths	35/year	1971-1975	<3/year	2025
Varicella (chickenpox) deaths	138 deaths/year	1973	18 deaths/year	2017-2019
Respiratory syncytial virus (RSV)-associated pediatric deaths	~500 deaths/year	1979-1997	96 deaths/year	1999-2018
Influenza and pneumonia deaths — all ages	24 deaths/100,000	1980	14 deaths/100,000	2024
Pediatric cancer deaths (age 0-19)	4.6/100,000	1980	2.2/100,000	2022

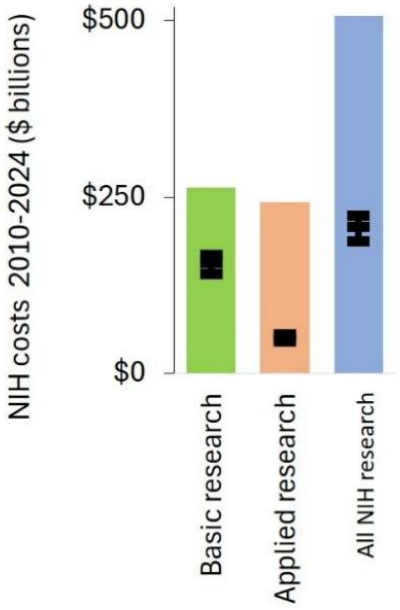


Note: data retrieved with ChatGPTPlus. All data confirmed manually or from second source. accessed August 19. 202. (a) expectancy of survival to age 20: 1975=97.8%; 2022=98.9%; (b) before newborn screening.

   These isolated data are not intended to be representative, but only to provide a snapshot of the profound improvements in pediatric health that have personally impacted American children and families in recent decades. As noted in a 2006 report from the National Academy of Sciences: "*Pediatric health is the cornerstone of the nation's well-being. … These advances would never have happened without the significant and consistent federal investment in pediatric research, supported as a whole or in part by the National Institutes of Health (NIH)."[1]* The purpose of the foregoing is not to focus these comments on pediatrics, particularly in light of longstanding concerns regarding the adequacy of NIH support for pediatric research.[3-6] Similar statements could be made about the role of the NIH in advancing all aspects of American healthcare and health.

2. **The NIH plays an essential role in pharmaceutical innovation, enabling the discovery and development of novel drugs, providing robust data resources and capabilities, and promoting new investment in the biopharmaceutical industry.**

   While industry is primarily responsible for the development, approval, and commercialization of novel pharmaceutical products,[iii] our research (detailed below) demonstrates **that the NIH funds basic or applied research related to >99% of all news drugs before their first FDA approval[iv] with an average NIH cost of ~$1.5 billion/drug, an amount comparable to the investment by industry.** [19-21]



Our work also shows that >80% of this NIH funding involves basic research and that **few, if any novel drugs are approved before the body of basic research achieves a threshold of maturity**. [7-9, 22] This **mature body of basic research is not only essential to assure an useful understanding of drug targets and their involvement in both the normal state and in disease but also to replicate, refute, or refine earlier research and establish the body of reliable evidence required for drug development and regulatory approval** [7, 8, 18, 23].

Little basic research is performed in industry, and the availability of this research in the public domain, through workforce training, or through licensing both **reduces the private investment required to successfully develop new drugs and creates economic efficiencies** for society. Our work also shows that commercialization of these products **generates considerable economic activity, profits greater those of companies in most other sectors of the S&P500,[24] growth of shareholder value,[25, 26] health value for society, job creation, and further R&D activity**.[v] [31-33]

3. **The NIH is highly effective in directing research funding to projects associated with outcomes that advance healthcare practice and health. Changes in this model to prioritize applied or translational research over basic research, move to mission-driven funding mechanisms over investigator-initiated funding, or censor research in specific areas threatens the vitality of the research enterprise that has long provided the foundation for advances in American prosperity, influence, health, and wellbeing. While we endorse a process of continuing assessment and evidence-based improvement of the scientific enterprise, we believe these criticisms are unfounded and that radical reform of the NIH is unwarranted.**

Recent criticisms of the National Institutes of Health (NIH) argue that NIH spending is overly focused on basic rather than applied or translational research and structured around investigator-initiated research rather than mission-driven strategies for addressing the mission of "enhance health, lengthen life, and reduce illness and disability." [37] **Our work (detailed below) demonstrates that ~40% of all NIH funding is productively employed towards new drug approvals including ~60% of all basic science.** [38]

These studies further show that the large majority of NIH funding contributing to drug approvals is provided through investigator-initiated funding mechanisms. Moreover, our analysis suggests that **investigator-initiated mechanisms**

significantly more likely to direct research resources toward drug approvals than program-driven mechanisms. [38]

We would also note that efforts to selectively eliminate funding in selected research areas [39] based on words used in the research proposals runs the risk of creating substantial collateral damage to other research areas. Our analysis suggests that some of the words that have been subject to criticism are significantly associated in funded research projects with words describing other high-priority areas for research and innovation. This research could be inadvertently curtailed if this funding were selectively eliminated based on their word content.[40]

While we recognize there is an uncertain association between NIH funding levels and the US burden of disease, [41-46] **there is a significant association between the number new drug approvals and the US burden of disease [47, 48]** There is also extensive evidence that new drug approvals are significantly associated with increased life expectancy as well as reduced mortality, disability, and functional limitations [49-56]. In this context **the observation that a substantial fraction of NIH funding is productively employed towards drug approvals indicates that the NIH model for funding basic and applied research is effective in directing resources toward outputs that directly contribute to the mission of advancing healthcare and health outcomes**.

Information Requested

We offer the following comments on the requested information:

Rigor and Reproducibility. We agree that reproducible and replicable biomedical approaches are foundational to rigorous research. We caution, however, that a distinction needs to be drawn between exploratory research aimed at hypothesis generation and confirmatory research aimed at hypothesis testing. The National Academy of Sciences describes the distinction thus:

> "*Confirmatory research is research that starts with a well-defined research question and a priori hypotheses before collecting data; confirmatory research can also be called hypothesis testing research. In contrast, researchers pursuing exploratory research collect data and then examine the data for potential variables of interest and relationships among variables, forming a posteriori hypotheses; as such, exploratory research can be considered hypothesis generating research."[23]*

One way to describe the distinction is that exploratory research is directed towards "unknown unknowns." Boguslav et al wrote: *"Research begins with a question. It progresses through accumulating knowledge such that a previously unexplored subject (an unknown unknown) becomes an active research area exploring the questions (known unknowns), until a body of established facts emerges (known knowns)." [57]*From a risk perspective, Derbyshire et al. describe unknown unknowns as *"…elements of knowledge that would be of importance to assessing the focal risk if they were known but which are presently unknown to anyone including those tasked with making the risk assessment, who, furthermore, lack awareness of not knowing them."[58]* Only when something is "known," can it be subject to rigorous, controlled hypothesis testing or considered for utility in applied or translational research.

From the perspective of reproducibility and replicability, exploratory research may yield observations that are, at least in part, irreproducible or irreplicable since it is impossible to control for unknown unknowns. In fact, failure to replicate observations in exploratory research can be useful in that it may expose the presence of unknown factors and prompt further exploratory studies aimed at their characterization. **We caution that arbitrary standards focused on reproducibility or replicability could be inherently ineffective if applied to exploratory research could compromise the process of exploration and create impediments to progress.**

We endorse efforts to improve the rigor of confirmatory research aimed at testing discrete hypotheses with potential applications in healthcare or industrial development.

We propose the following:

- **NIH should increase its funding for education in research methodologies**, particularly at the graduate level;
- **NIH should assure that investigators have adequate funding for their proposed research** and do not feel pressured to "cut corners" to satisfy budget constraints;
- **Free dissemination and critique of ideas without political interference or consequences is central to our communal responsibility to conduct rigorous research**;
- **Federal health agencies need to set an exemplary standard** in promulgating only applications of research that has been replicated, distinguishing early-stage findings that are only exploratory, and calling out information that is merely observational or conjecture.

Data, Software, and Model Sharing. We agree that "sharing scientific data and tools accelerates biomedical research discovery" and urge the NIH to continue efforts to make data sharing a

normative practice. We believe the NIH has long set a high standard for making data widely available for scientific research and applications. The sharing of publicly funded research, data collections, analytical tools, and even is increasingly normative. We would emphasize the following:

- The **confidentiality of personal, clinical data must remain an overriding principle** without compromise;
- **Data and research tools made available by the federal government must set a high standard and must represent a complete and accurate representation of data that is collected, or research results generated with public funds. These shared collections cannot be subject to ideological modification or censoring**. We note that these collections must be complete datasets and are likely to include content that is not uniformly considered to be accurate or useful. Only information that is formally retracted after scientific critique should be eliminated.

Training and Mentorship. We applaud NIH's continued commitment to training a professional and technical workforce. We call on the NIH to ensure adequate, continuous funding for these programs.

Collaboration. We applaud the NIH's commitment to collaboration. We recommend that the NIH consider collaborations beyond the traditional disciplines of medicine, biology, biochemistry, psychology, informatics, analytics, and physics and promote collaborations also between scientists and individuals expert in management, economics, finance, and public policy. Such collaborations could significantly help bridge the gap between laboratory science and applications in medicine.

Entrepreneurship and Translation. While most discussions of entrepreneurship and the transition from basic to applied or translational science focus on issues of finance**, we believe a critical, overlooked aspects of entrepreneurship and translation is technology readiness.**

> Evidence in engineering suggests that the maturation of technology has predictive value for subsequent development performance including both technical risk, cost, and timelines. The GAO, for example, finds that **entering product development with immature technologies leads to greater costs and schedule delays and have higher development costs than those based on mature technologies.** This has led agencies including DOD and NASA to incorporate technology readiness assessments in their determination of whether novel technologies are sufficiently mature to proceed into development and production. Our research suggests that pharmaceutical development is similarly dependent on the maturation of the underlying basic science, that few, if any targeted therapeutics are successfully developed until this science passes a passes a quantitatively-defined threshold of maturation, and that the timelines of clinical development are significantly longer if clinical development commences before this threshold is reached.[6-9, 22, 59] Our work further suggests that innovation can stall when private capital is invested in immature technologies and is, therefore, dissuaded from subsequent investments in the space as it matures. **Given the high risk, limited availability, high cost of investment capital for early-stage development, greater focus on characterizing the readiness of basic science for development could radically reshape the landscape of innovation and promote more rapid translation of the most promising technologies.**

Foundational Scientific Exploration Our research suggests that the primary contribution of NIH funding to pharmaceutical innovation is its support of basic science. **Basic research conducted with federal funding has an essential role in the innovation ecosystem as the primary driver of discovery and development and a source of economic stimulus.**

Basic science is defined as *"…experimental or theoretical work undertaken primarily to acquire knowledge….without any particular application or use in view*" [60], recognizing that NIH spending is inherently "*use-inspired*" [61]. Our work further suggests that virtually all of this work is performed in public institutions (as opposed to industry) and as noted above, the maturation of this body of research may be a critical determinant of product development success, timelines, and costs. [6-9, 22, 59] Initiating applied, translational, or development work based on an immature body of basic research increases the risk, timelines, and costs to industry.

We would argue that initiatives focused on specific diseases or conditions can only succeed if there is a commitment to establishing a mature body of basic research before considering translation or development. We have studied innovation following passage of the National Cancer Act of 1972. This Act was long considered to have been a failure due to the absence of new therapies or substantial improvement in outcomes for decades after the Act was passed. Our analysis suggest that the Act was, in fact, highly successful. The War on Cancer was launched at the outset of an era that saw the emergence of molecular biology, genomics, and biotechnology and the Act was instrumental in funding much of this foundational work. Our analysis shows that it was only when the foundational, basic research in these areas reached a threshold of maturation that new product began to appear. The last 20 years have seen an explosion of new therapies for cancer and dramatic advances in both treatments and outcomes. [22] Similarly, many early failures of candidate therapies for Alzheimer's involved candidate products that entered development before research on Amyloid was mature while the recent successes uniformly entered development only after that body of research was established. [62]

We would also call attention to the economic efficiencies created by public support for basic science. As described below, the timeline between basic research on drug targets and first approval of a drug associated with that target can be as much as 25 years. [21, 63, 64] This long timeline, coupled with the high cost of capital in industry (10.5%) makes investment in basic science untenable for industry. It is possible to estimate the cost savings provided to industry by NIH funding for basic science that is then transferred to industry through the public domain, workforce training or licensing. Industry typically calculates drug development costs as the sum of spending on the approved drug, an estimate of spending on failed candidate products, and a 10.5% cost of capital. Applying the same calculation to assess the value provided to industry by public funding of basic research, we estimate that the average cost saving to industry is as much as $2.9 billion, an amount roughly equivalent to reported development costs. [20, 21, 65]

Public funding for basic science also creates economic efficiencies through spillovers. Studies suggest that an average of three novel therapeutics are developed for each biological target. [19, 66] This is evident, for example, by the observation that most NIH-funded projects related to at least one drug approval are typically associated with multiple approved drugs. This means that the public investment in basic science is ultimately distributed across multiple approvals, reducing the effective public investment/drug and multiplying the returns from product development.

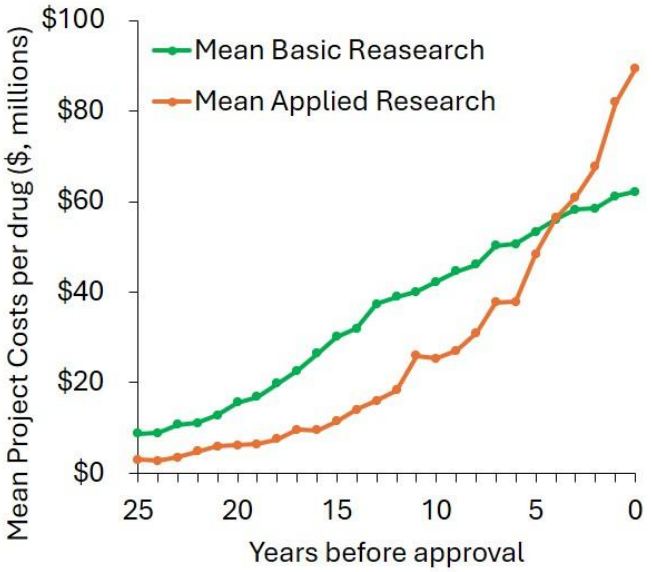
We believe that a **continued government commitment to funding basic science is essential for the future success of pharmaceutical innovation and commercialization. Initiatives that draw resources away from basic science toward applied or translational research in any specific therapeutic or disease area, no matter how well intentioned, represent a threat to future progress.**

Public Impact. NIH seeks approaches for assessing and recognizing the broader public impact of biomedical research, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit.

Supporting research

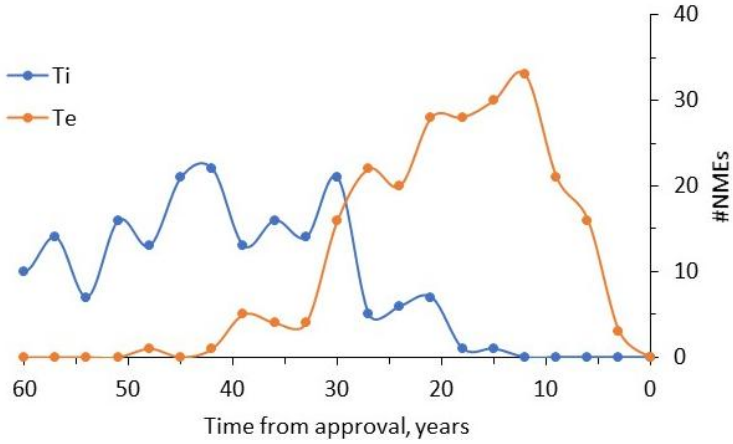
Characterizing the NIH contribution to drug approvals

Recent criticisms of the National Institutes of Health (NIH) argue that NIH spending is overly focused on basic rather than applied or translational research and structured around investigator-initiated research rather than mission-driven strategies [67-69] to "enhance health, lengthen life, and reduce illness and disability" [37]. Ideological concerns aside, these arguments build on longstanding questions about the effectiveness of NIH's reliance on investigator-initiated research and an uncertain alignment between NIH research spending and the US burden of disease [41-46, 70-72]. **While we endorse a process of continuous assessment and evidence-based improvement of the scientific enterprise [73, 74], we believe recent criticisms of the NIH are unfounded.**



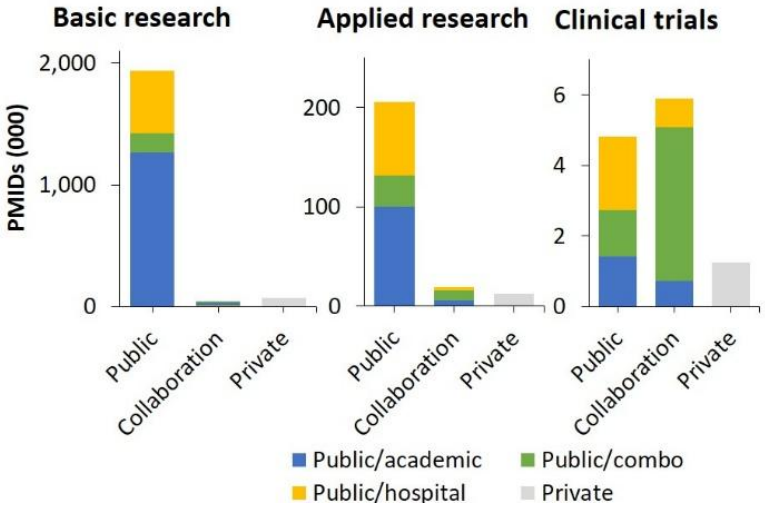
In a series of studies,[vi] we have assessed the NIH contribution to new drug approvals from 2010-2024 [9, 18, 19, 38, 75, 76]. While the biopharmaceutical industry is primarily responsible for discovery, development, and commercialization of novel medicines, we found that the NIH funded basic or applied research related to 99.2% (614/619) of the drugs approved from 2010-2024 before their first FDA approval.[vii] This research involved 386 thousand project years of funding with NIH costs of $254.8 billion including $208.0 billion (81.6%) for basic research and $46.8 billion (18.4%) for applied research. [38] In other studies, we have estimated that ~3-4% of this NIH funding contributes to clinical development [76] and that <1% leads to patents that provide market exclusivity. [75] **Overall, the average cost of NIH funded research associated with each approval has been estimated to be ~$1.5 billion/drug approval, an amount comparable to reported industry spending**. [19-21] **Calculated with a social discount rate of 3% (corresponding to the average cost of borrowing) [73, 77] this represent a public investment cost of $1.7 billion/drug approval.**

The role of NIH funded basic research



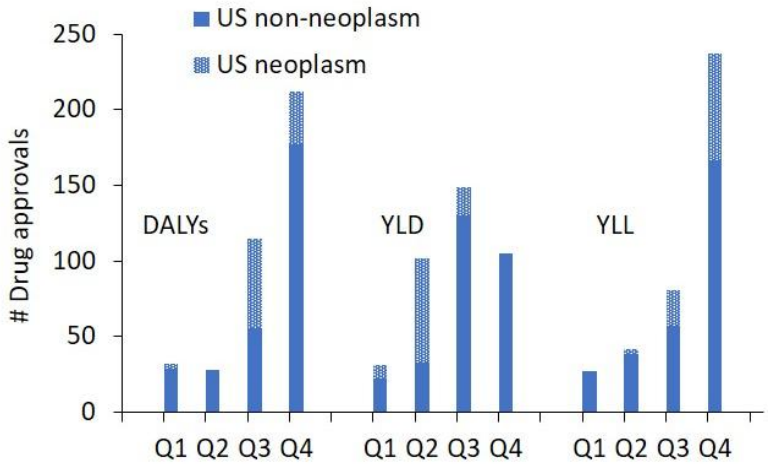
Federally funded basic research plays an essential role in pharmaceutical innovation. Our analyses demonstrate that few if any novel medicines are successfully developed until there is a mature body of basic research on the drug's target. [7-9, 22] Basic research is defined by as *"…experimental or theoretical work undertaken primarily to acquire knowledge….without any particular application or use in view*" [60], recognizing that NIH spending is inherently "*use-inspired*" [61] by the mission of improving health. Importantly, this includes not only salient research milestones, but also studies necessary to replicate, refute, or refine earlier research and establish the body of reliable evidence required for drug development and regulatory approval [7, 8, 18, 23]. In our studies, we identify publications describing basic research by searching PubMed for both the newly approved drug and its biological target. Publications (PMID) and selecting those with NIH funding identified in NIH RePORTER. PMID and the projects that provided funding are categorized as applied research if they were identified in a search for the drug. PMIDs and projects are categorized as applied if they are identified only in a search for the drug target.

Our studies also enabled an analysis of the timeline between public funding of basic and applied science and new drug approvals. These studies suggest that NIH funding supporting basic science on the drug target may support much as 25 years before first approval of a drug associated with that target. [38] This pattern is consistent with the observations of others. [7-9, 78-81]. In contrast we observed a sharp increase in applied science on specific drugs 5-10 years prior to first approval, consistent with timelines of preclinical and clinical development. [21, 63, 64] **The recognized lags between federal funding for basic**



or applied research and drug approvals need to be incorporated in any understanding of the timelines and economics of pharmaceutical innovation

We analyze the maturation of basic science using the analytical TIME model,[6, 7] which models the accumulation of publications as an S-curve analogous to the functions used to model the advance of technologies in other fields (engineering). [6, 7, 9] We then calculate a numerically defined point of "initiation" (Ti) and an "established point" (Te) as the points of maximum acceleration and deceleration respectively. The adjacent figure shows the timeline between the Ti and Te points for 356 drugs approved 2010-2019. For most drugs, basic research on the drug target was initiated >25 years before drug approval and that this body of research had passed this established threshold, indicative of a mature body of basic science, before each successful drug approval. [9]



The large majority of basic research associated with drug approvals is conducted in academic centers with little involvement from industry. These studies identify the institutional affiliations of authors of publications describing basic or applied (including clinical) research related to 387 drugs approved from 2010-2019. Affiliations were designated as public (academic, hospital, or both) or private (for profit corporation). Publications could involve entirely public authors, private authors, or be a collaboration with both public and private authorship. These data show that virtually all basic research was published by academic institutions or public hospitals, a small increase in collaborative applied research, and broad collaboration in clinical development. [82] Recognizing that industry may be less likely to publish basic research, these data provide no evidence to support any significant industry contribution to the advance of basic science.

The effectiveness of investigator-initiated funding mechanisms

A large majority of the NIH funding related to drug approvals was awarded through investigator-initiated, rather than mission-driven, funding mechanisms. Excluding intramural research, 86.4% of project years and 77.5% of NIH costs were associated with funding opportunities that typically solicit investigator-initiated research proposals. This included a preponderance of funding awarded through investigator-initiated R (research) grants or P (Program Project and Center) grants. Mission-driven mechanisms including U (Collaborative Program) grants and institutional P grants provided the majority of funding for clinical trials, but only a small fraction of the total NIH funding associated with drug approvals. This analysis further showed that **investigator-initiated mechanisms were significantly more likely to support research projects that were associated with drug approvals than program-driven mechanisms.**

While program-driven funding mechanisms may be preferred for directing resources toward specified, short-term public needs, investigator-initiated, scientifically driven mechanisms are preferred for advancing long term innovation. These observations are consistent with theoretical arguments that central, strategic planning in science, as in a market economy, is inherently less efficient. Polanyi, for example, argues that neither scientists nor policymakers can reliably predict which lines of inquiry will produce commercially valuable discoveries. In contrast. Polanyi argues that scientific progress depends on the decentralized decisions of scientists who "freely [make] their own choice of problems." [83]. He argues that decentralized systems allow researchers to investigate problems that appear soluble and scientifically important, pursuing varied avenues of investigation, and continuously apply newly emerging knowledge to improve their direction or pursue opportunities with greater promise. **We call on the NIH to resist initiatives to reform the process of investigator-driven research at the NIH or to promote program driven initiatives over scientifically driven investigations.**

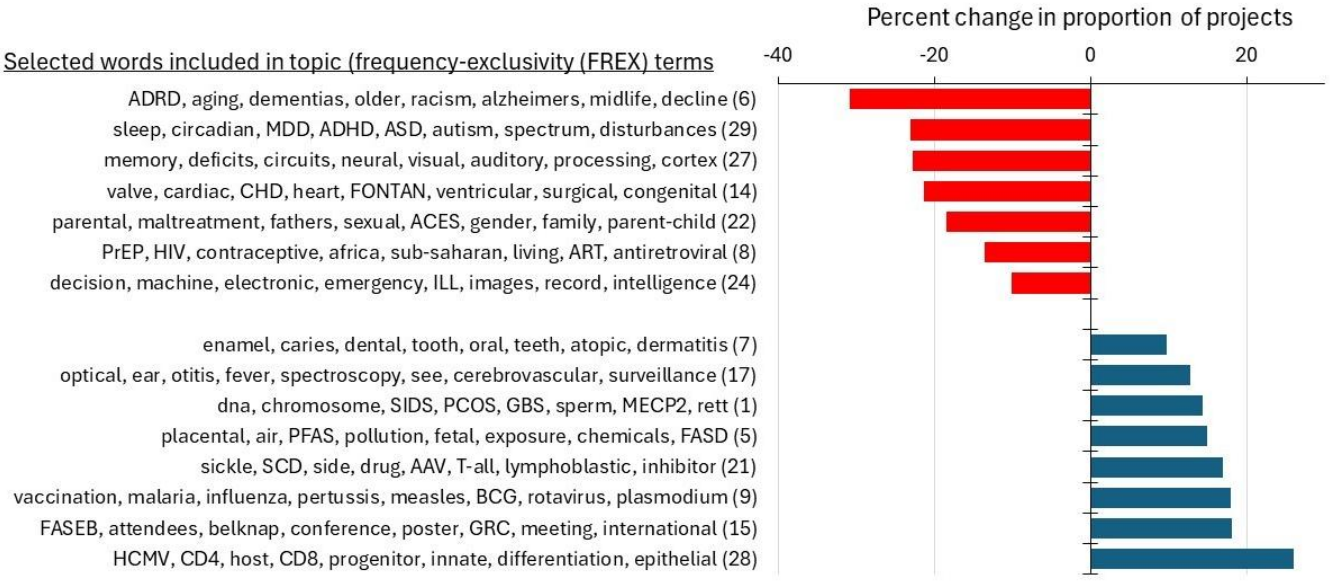
One criticism of investigator-driven mechanisms for research funding has been that there is an uncertain association between NIH funding and the US disease burden [41-46]. Our analysis of the NIH funding associated with drug approvals shows wide, highly asymmetrical variation in the level of NIH spending associated with individual drug approvals. Thus, while t**he number new drug approvals has been shown to be associated with the US burden of disease [47, 48]** this association may not be reflected in an association between NIH spending and disease burden. This suggests that meaningful assessment of the alignment between NIH funding and health priorities must be based on specific outputs from NIH funded research rather than simply levels of NIH spending. **These findings suggest that considerable caution must be exercised in assessing the relationship between NIH funding and the burden of disease in the United States and that any meaningful assessment should be based on health-related outputs rather than the number of grants or amount of funding awarded.**

Effectiveness of the NIH in directing research funding to productive outputs

Our studies have also estimated the fraction of all NIH research spending that is productively employed forward drug approvals.[viii] These studies suggest that 59.7% (range 53.7 to 63.6%) of reported NIH spending for basic research from 2010-2024, 20.5% (range 18.5% to 22.6%) of reported NIH spending for applied research, and 40.9% (range: 36.8% to 43.9%) of all NIH research spending was productively employed toward drug approvals.

Extensive evidence demonstrates that new drug approvals are significantly associated with increased life expectancy and reduced mortality, disability, and functional limitations [49-56]. In this context the observation that a substantial fraction of NIH funding is being productively employed towards outputs that directly contribute to the mission of advancing healthcare and health outcomes. We notes that these totals describe only NIH funding for research prior to first FDA approval and does not include NIH spending for research related to product line extensions, follow-on indications, comparative- or cost-effectiveness studies, or evidence-based guidelines that could influence the impact of these drugs on health. These totals also may not fully capture NIH contributions to candidate products that failed in clinical trials or were abandoned by industry for commercial reasons [21] and do not addres other outputs from NIH funded research that would be expected to have positive impacts on health such as novel devices, diagnostics, materials, instrumentation, or improvements in surgery, nursing, patient safety, nutrition, health equity, wellness management, and healthcare delivery. 78]

In sum, the evidence suggests that the NIH is highly effective in directing research funding to projects with the potential for positively impact the healthcare and health of Americans. These analyses do not support the need for a broad overhaul of NIH's operational model.



There is extensive evidence that federal funding for biomedical research stimulates private investment in innovation. Several criticisms of the Economic studies demonstrate that the stock of public basic research is significantly associated with increases in drug approvals [79] and that growth of disease specific research is significantly associated with the number of drugs entering clinical trials [84] and the number of private sector patents [85]. NIH funding has also been shown to stimulate private investment, with each dollar of public basic biomedical research stimulating $8.38 private spending after eight years and each dollar of public clinical research stimulating $2.35 private spending after three years. [81] There is little evidence for the assertion that federal funding for biomedical research "crowds out" private investment.

Sensitivity of NIH research portfolio to censoring

In a preliminary study we have examined NIH funding for pediatric research projects from 2020-2026 identified in NIH RePORTER. [40] As part of this analysis we performed statistical topic modeling that identifies latent topics (i.e., groups of words that co-occur) across the Public Health Relevance narratives of !15,000 funded research projects involving children or newborns and examined the share of each narrative devoted to each topic (word group). Through this analysis, the topical composition of funded projects can be measured and compared across years without manual coding. We then looked at the frequency of the 30 topics using terms that were commonly found within each topic and relatively exclusive to each topic and compared the prevalence of these terms in projects funded FY2020-FY2024 and those funded FY2025– FY2026.

The results illustrate substantial reductions in topics associated with terms that appeared in the 2025 NIH guidance on awards "…not aligned with the NIH's priorities."[39] For example, "racism" appeared among

FREX terms within a topic also characterized by the terms “Alzheimer’s” and “aging.” Similarly, “gender” appeared within a topic also characterized by “fathers” and “parent-child.” These findings show the broader scientific context in which words subject to the 2025 NIH guidance occur (i.e., flagged terms sit within topics that also contain vocabulary not governed by this guidance. This suggests that administrative screening based on individual terms could cause collateral damage to areas of research that continue to have high priority. The NIH needs to be attentive to collateral damage that can arise from any efforts to selectively restrict funding on specific topics based on simple text analysis.

Endnotes

[i] Dr. Ledley is a physician, scientist, entrepreneur, and researcher who is currently professor of Natural & Applied Science and Management at Bentley University and the founding director of the Center for Integration of Science and Industry (www.bentley.edu/sciindustry). He has an MD from Georgetown University, conducted graduate research as a part-time employee of the NIH (NIDDK), trained in pediatrics and genetics at the Boston Children's Hospital, and was an ACS post-doctoral fellow with Dr. David Baltimore at the Massachusetts Institute of Technology. He has served on the faculties of the Howard Hughes Medical Institute, Baylor College of Medicine, Texas Children's Hospital and Bentley University and was the founder of several biotechnology companies including GeneMedicine, Inc. (NASDAQ:GMED) and Variagenics, Inc (NASDAQ:VGEN). He has published >250 papers on topics ranging from medicine, human molecular genetics, and biotechnology to pharmaceutical development, corporate finance, bioethics, and public policy and is the inventor on 11 issued US patents. He has served on the Board of Directors of the Massachusetts Biotechnology Council and as an Advisor to Boston Children's Hospital and as a consultant to industry and government.

Dr. Ledley has received funding for research and training projects at the Baylor College of Medicine and Texas Children's Hospital and SBIR grants at GeneMedicine and Variagenics.

Dr. Ledley reports no conflicts of interest.

[iv] NIH funding related to new drug approvals from 2010-2024 was identified using a modification of previously described methods 9. Cleary, E., M.J. Jackson, and F. Ledley, *Government as the First Investor in Biopharmaceutical Innovation: Evidence From New Drug Approvals 2010–2019.* Institute for New Economic Thinking Working Paper Series, 2020(133), 18. Cleary, E.G., et al., *Contribution of NIH funding to new drug approvals 2010–2016.* Proceedings of the National Academy of Sciences, 2018. **115**(10): p. 2329-2334, 19. Cleary, E., et al., *Comparison of Research Spending on New Drug Approvals by the National Institutes of Health vs the Pharmaceutical Industry, 2010-2019.* JAMA Health Forum, 2023. **4**(4): p. e230511-e230511.. Details are described in the supplement to Cleary et al, 2023 19. Ibid.. PMID related to the drug or its target are identified through PubMed search. Those identified through a drug search are categorized as applied research. Those identified through target search (but not drug search) are categorized as basic research. NIH funded projects providing funding for these PMID are identified in NIH Reporter and one year of project funding (project year) is assigned for each PMID-PROJECT pair corresponding to the: (i) PMID publication year; (ii) project end year for PMID published 1-4 years after project end: or (iii) year of FDA approval for PMID published 1-4 years after first approval. Project years and costs are described after eliminating duplicates arising from PMID associated with multiple projects or projects producing multiple PMID.

[v] Our research assessed the total health value created through Medicare Part D payment for the drugs subject to price negotiation in 2024 and 2025. This work uses methods for valuing health impacts of public policy recommended by the Institute of Medicine 27. IOM, *Valuing health for regulatory cost-effectiveness analysis: Edited by Wilhelmine Miller, Lisa A. Robinson and Robert S. Lawrence.* . 2007, National Academy of Medicine., Office of Management and Budget 28. OMB, *Circular A-4, Regulatory Analysis*. 2023: Office of Management and Budget. and others 29.EPA, *Guidelines for Preparing Economic Analyses, 3rd Edition*. 2024, Environmental Protection Agency, 30. Hutubessy, R., D. Chisholm, and T.T. Edejer, *Generalized cost-effectiveness analysis for national-level priority-setting in the health sector.* Cost Eff Resour Alloc, 2003. **1**(1): p. 8.. These methods determine the "Health Benefit" created measured in QALYs; the assessed value of that benefit ("Health Value") based on survey data of American's "Willingness to Pay (WTP)" for one QALY of health ("WTP/QALY"), and the Residual Health Value (net Health Value) calculated as the Total Health Value minus the (gross) Medicare Part D Costs.31. Zhou, E.W., et al., *Considering Returns on Federal Investment in the Negotiated'Maximum Fair Price'of Drugs Under the Inflation Reduction Act: an Analysis.* Institute for New Economic Thinking Working Paper Series, 2024(219), 32. Chaves da Silva, P.G. and F. Ledley, *Forget the Posturing – The Inflation Reduction Act May Work Better Than Many Expected*. 2024, Institute for New Economic Thinking Institute for New Economic Thinking, 33. Chaves da Silva, P., R.M. Conti, and F.D. Ledley, *Social and private value created through commercialization of Gilead Sciences' innovative medicines for Hepatitis C and HIV: a cross-sectional analysis.* medRxiv, 2025: p. 2025.06. 11.25329435. These methods apply conventional accounting methods for assessing value, though there are also meaningful analogies to cost-effectiveness analysis or pharmacoeconomic studies 34. Garrison Jr, L.P., et al., *Estimating the allocation of the economic value generated by utilization of all-oral direct-acting antivirals for hepatitis C in the United States, 2015 to 2019.* Value in Health, 2024. **27**(8): p. 1021-1029, 35. [viii] Total NIH spending from 2010-2024 contributing to drug approvals was estimated as the sum of spending related to new approvals over this period and inferred costs for a range of projected approvals after 2024. Spending related to future drug approvals was inferred from 2010-2024 (i) projected annual approvals and approvals associated with novel targets; (ii) observed time course of basic or applied research spending 25 years before approvals prior through 2024; (iii) average number of duplicated project years; (iv) mean, annual project costs with adjustment for COVID spending after 2020. Detailed methods are described in 38. Zhou, E.W. and F.D. Ledley, *Fraction of National Institutes of Health research spending 2010-2024 productively employed toward new drug approvals.* (submitted).

283. Silent Spring Institute

I am responding: On behalf of an organization

Name: Dr. Jennifer Liss Ohayon

Name of Organization: Silent Spring Institute

Type of Organization: Non-Profit Research Organization

Role: Investigator/Researcher

Date Submitted: 8/19/2026

1. Rigor and Reproducibility: While incentives and infrastructure are important for supporting the reproduction and replication of existing findings in certain key areas, this cannot detract from funding novel research and new techniques. One way to increase the level of confidence in existing studies is through implementing rigorous quality assurance/quality control (QA/QC) in all funded studies. Many studies do not adequately describe or interpret quality control (QC) data in publications, which decreases the ability of readers to evaluate data quality and appropriate uses of the data (such as valid comparison to other health studies or application to regulatory decision-making). Silent Spring Institute has published guidance on how to implement quality assurance/quality control (QA/QC) in environmental exposure measurement projects (including emphasizing the importance of incorporating QC samples in study design) and draw conclusions about data validity. NIH can strongly emphasize the importance of rigorous plans for data management, quality control, and quality assurance for all funded projects. These plans should pertain to all stages of the project, including collection, storage, shipment, and analysis of biological samples). Moreover, NIH can require adequate descriptions of QA/QC processes in publications resulting from funded research so that other researchers and government officials are able to assess the quality of the research.

2. Data, Software, and Model Sharing: We support efforts to share scientific data and tools. For example, as part of the Women Workers Biomonitoring Collaborative (WWBC), Silent Spring Institute collaborated with other scientists and impacted workers to develop the first women workers' biospecimen bank. This archive of biological samples is available to other researchers who are studying occupational exposures, including those that support the advancement of non-targeted biomonitoring approaches and those studying associations between exposures and upstream biomarkers of effect with potential relevance to cancer. NIH can fund research that invests in innovative sample archives that other studies can benefit from, including encouraging researchers to establish infrastructure as part of their funded projects. Moreover, NIH can allocate supplemental grants to maintaining infrastructure and catalyzing new collaborations based on existing sample archives or datasets.

Moreover, for funded NIH projects, researchers can be encouraged to publish scientific data and code in public repositories. Code that is archived in repositories such as GitHub, can be assigned DOIs allowing researchers to track its subsequent use, citation counts, and overall impact; these metrics can be shared with NIH. Initial data sharing plans can include trackable metrics for datasets.

3. Training and Mentorship: We propose the following indicators for assessing and quantifying the impact of training and mentorship:
• Number of one-on-one contact opportunities that a trainee has with their mentor.
• Mentor investment in the quality of trainee products, including acceptance of trainee authored articles in high-impact journals.
• Trainee evaluations of mentors.
• Tracking non-traditional outputs from trainees, including media coverage, community presentations, and engagement with K-12 schools.

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: We are encouraged by NIH efforts to issue guidance on aggregate-level report-back, and we call on NIH to promptly formalize requirements for both aggregate- and individual-level sharing of research results in all funded research. Research on report-back in environmental exposure assessment and biomonitoring research has indicated that participants, including those from different socioeconomic backgrounds, overwhelmingly want to know their personal exposure results if given the choice and report-back can motivate participants to consider both personal and collective strategies to reduce toxics in their environment. Moreover, reporting back to individuals can allow new research questions to emerge based on consulting with participants, for example on outlier results.

NIH can also require lay summaries of all research results and require researchers to include in grant reports any activities they undertook to reach larger audiences such as publishing op-eds and giving media interviews, translating research results in social
media posts, and giving presentations to non-academic audiences (e.g., water and wastewater professionals, clinicians, and state public health officials). As an example of ensuring research reaches broader audiences, Silent Spring Institute created the PFAS Exchange, an online resource center about PFAS contaminant in drinking water, to help impacted communities, water utilities, and clinicians understand exposures and take action to protect health (pfas-exchange.org). The website includes a resource hub with fact sheets about PFAS and medical screening guidance for both impacted communities and clinicians, a map of sites across the U.S. with known or suspected contamination, and an exposure tool to help individuals interpret their water or blood results. As other examples, Silent Spring collaborated with social media influencers to communicate research findings regarding endocrine disrupting chemicals to a broader public and created a consumer app, Detox Me, to share evidence-based tips for exposure reduction. We also created a digital tool, DERBI, to facilitate reporting back of individual research results. NIH can require researchers to report on these types of non-traditional outreach and products and also allocate more research funding to researchers to incorporate these types of activities into funded studies.
Finally, funding opportunities can encourage researchers to pick impactful questions that people care about by funding more researcher-community collaborations.
Thank you for your consideration of our comments. We would be happy to schedule a time to discuss any of them further.

8. Other Areas: N/A

Re: Request for Information on Measuring and Rewarding Scientific Impact, NOT-OD-26-087

We thank you for the opportunity to comment on NIH's Request for Information on Measuring and Rewarding Scientific Impact. Silent Spring Institute is an independent research organization that investigates links between the environment and women's health. Silent Spring has defined the set of chemicals that are expected to increase breast cancer risk based on their activity in human and toxicological studies, and our Mammary Carcinogens Review Database was featured in Science as "The Breast Cancer List." Silent Spring continues to update the list of breast cancer-relevant chemicals to include those that alter development of the mammary gland, act as endocrine disruptors and promote tumor growth, or have epidemiological evidence. Silent Spring's research program also includes numerous biomonitoring studies to understand personal exposures to endocrine disrupting chemicals (EDCs) and carcinogens, as well as studies of chemical exposures from consumer products, indoor and outdoor air, and house dust. Our Household Exposure Study was described by Environmental Science & Technology as the "most comprehensive analysis" of exposures in homes. We are leaders in developing best methods and tools for reporting back individual-level research results and have contributed to over two dozen publications evaluating impacts of report-back.

Below we respond to the following topics that NIH is soliciting input on.

Rigor and Reproducibility.

While incentives and infrastructure are important for supporting the reproduction and replication of existing findings in certain key areas, this cannot detract from funding novel research and new techniques. One way to increase the level of confidence in existing studies is through implementing rigorous quality assurance/quality control (QA/QC) in all funded studies. Many studies do not adequately describe or interpret quality control (QC) data in publications, which decreases the ability of readers to evaluate data quality and appropriate uses of the data (such as valid comparison to other health studies or application to regulatory decision-making). Silent Spring Institute has published guidance on how to implement quality assurance/quality control (QA/QC) in environmental exposure measurement projects (including emphasizing the importance of incorporating QC samples in study design) and draw conclusions about data validity.[1] NIH can strongly emphasize the importance of rigorous plans for data management, quality control, and quality assurance for all funded projects. These plans should pertain to all stages of the project, including collection, storage, shipment, and analysis of biological samples). Moreover, NIH can require adequate descriptions of QA/QC processes in publications resulting from funded research so that other researchers and government officials are able to assess the quality of the research.

Data, Software, and Model Sharing

We support efforts to share scientific data and tools. For example, as part of the Women Workers Biomonitoring Collaborative (WWBC), Silent Spring Institute collaborated with other scientists and impacted workers to develop the first women workers' biospecimen bank. This archive of biological samples is available to other researchers who are studying occupational exposures, including those that support the advancement of non-targeted biomonitoring approaches and those studying associations between exposures and upstream biomarkers of effect with potential relevance to cancer.[2] NIH can fund research that invests in innovative sample archives that other studies can benefit from, including encouraging researchers to establish infrastructure as part of their funded projects. Moreover, NIH can allocate supplemental grants to maintaining infrastructure and catalyzing new collaborations based on existing sample archives or datasets.

Moreover, for funded NIH projects, researchers can be encouraged to publish scientific data and code in public repositories. Code that is archived in repositories such as GitHub, can be assigned DOIs allowing researchers to track its subsequent use, citation counts, and overall impact; these metrics can be shared with NIH. Initial data sharing plans can include trackable metrics for datasets.

Training and Mentorship.

We propose the following indicators for assessing and quantifying the impact of training and mentorship:

- Number of one-on-one contact opportunities that a trainee has with their mentor.
- Mentor investment in the quality of trainee products, including acceptance of trainee authored articles in high-impact journals.
- Trainee evaluations of mentors.
- Tracking non-traditional outputs from trainees, including media coverage, community presentations, and engagement with K-12 schools.

Public Impact

We are encouraged by NIH efforts to issue guidance on aggregate-level report-back, and we call on NIH to promptly formalize requirements for both aggregate- and individual-level sharing of research results in all funded research. Research on report-back in environmental exposure assessment and biomonitoring research has indicated that participants, including those from different socioeconomic backgrounds, overwhelmingly want to know their personal exposure results if given the choice and report-back can motivate participants to consider both personal and collective strategies to reduce toxics in their environment.[3-7] Moreover, reporting back to individuals can allow new research questions to emerge based on consulting with participants, for example on outlier results.

NIH can also require lay summaries of all research results and require researchers to include in grant reports any activities they undertook to reach larger audiences such as publishing op-eds and giving media interviews, translating research results in social

media posts, and giving presentations to non-academic audiences (e.g., water and wastewater professionals, clinicians, and state public health officials). As an example of ensuring research reaches broader audiences, Silent Spring Institute created the PFAS Exchange, an online resource center about PFAS contaminant in drinking water, to help impacted communities, water utilities, and clinicians understand exposures and take action to protect health (*pfas-exchange.org*). The website includes a resource hub with fact sheets about PFAS and medical screening guidance for both impacted communities and clinicians, a map of sites across the U.S. with known or suspected contamination, and an exposure tool to help individuals interpret their water or blood results. As other examples, Silent Spring collaborated with social media influencers to communicate research findings regarding endocrine disrupting chemicals to a broader public[8] and created a consumer app, Detox Me, to share evidence-based tips for exposure reduction. We also created a digital tool, DERBI, to facilitate reporting back of individual research results.[9] NIH can require researchers to report on these types of non-traditional outreach and products and also allocate more research funding to researchers to incorporate these types of activities into funded studies.

Finally, funding opportunities can encourage researchers to pick impactful questions that people care about by funding more researcher-community collaborations.

Thank you for your consideration of our comments. We would be happy to schedule a time to discuss any of them further.

Mark H. Histed, PhD, commenting in personal capacity and not on behalf of any organization

"NIH seeks public input on the defining features of modern 21st-century science that should be measured, recognized, and incentivized. "

Executive summary: Quantitative measurements of science, and other creative fields, inherently reduce innovation and limit big ideas. New metrics and measurement can in some cases add information, but NIH should strive to de-emphasize metrics in any evaluation or incentive structures in science. Instead of attempting to reduce the process of science to inherently limited data and measurement, NIH should rely on the gold-standard procedure of evaluating science that has been used to great success in the US for decades: peer review from the scientific community. This peer review should be applied to materials and research papers developed as a product of the creative and intellectual work of scientists.

Committees of scientists that read papers will do better at assessing the value of new ideas than any quantitative measure or metric, which will always be backward-looking..

*** The science ecosystem is a complex and nonlinear system impossible to characterize fully with data and measurement
Science is a highly complex social system which relies on frontier thinking from tens of thousands of scientists. Any empirical model or data will have difficulty assessing the quality of a complex system like science, because empirical models are backward-looking --- data themselves are observations of past events. Thus, quantitative evaluation will never be a complete way to capture the complex system that is science. NIH should therefore be incredibly cautious of bringing new metrics to bear to evaluate innovation.

To illustrate how empirical models alone are limited for understanding the world, without the accompanying development of theoretical models and a back-and-forth process that adjust models (or metrics) as new observations arrive, let me give an example. Neuroscience, my field, shows how data and quantitative measurements are useful — but are not a full description of a complex system. In the cerebral cortex, excitatory and inhibitory neural networks are tightly coupled to each other. This produces a phenomenon called the balanced state mode of network operation, which increases sensitivity to input, and decouples the activity of nearby neurons to maximize the ability to read out information carried by their responses. Cortical networks in the balanced state have coupled local excitation, and thus exhibit the inhibition-stabilized network (ISN) property. That is a property in which self-amplified activity that can boost certain input patterns is tracked and kept stable by local inhibition.

I give this background to note that ISN property would likely never have been found by pure experimental measurement or data collection. In 1987, Misha Tsodyks and a group of American and international collaborators (https://pubmed.ncbi.nlm.nih.gov/9151754/) showed that ISNs produce 'paradoxical responses,' where boosting inhibition unexpectedly causes excitatory cells to increase, not decrease, their activity. In a two-variable continuous-time model they demonstrated that linear perturbations in the model phase space produce unintuitive effects, curved paths in the phase space that change direction from the marginal or initial incremental direction. Many years later, focused experiments to test this nonlinear model by the Miller, Ferster, and my own group, amongst others, showed this property holds in the cortex.

The ISN model is merely a two-variable system and yet produces complex dynamics. And most empirical measurements --- applying regressions to large-scale data, for example --- measure only the initial marginal effect and missed these curved paths in the state space. Even adding nonlinear terms to a regression does not do a good job inferring curved/non-marginal dynamics, not least because more complex non-linearities become increasingly data-hungry to estimate. That is, most measurements that can be collected in finite time rely on a local linearization of a bigger complex system.

To quantitatively describe real-world complex systems, whether brain networks or the incredibly complex sociological system that is a science and innovation economy, we must not just develop metrics based on data. We must move beyond that to apply the simple models imposed by data to the construction of mathematical models that capture important nonlinear phenomena. This is difficult and

takes a long time. We see this in other fields too -- the dynamic general static equilibrium (DGSE) models of the macroeconomy have been built on many, many economics studies, and are still not perfect predictors of our economic future. Developing metrics to evaluate science, for all these reasons, is likely to fail. At best it will distort science and constrain genuinely new ideas. If metrics are applied in a backward-looking way to evaluate which ideas are good -- well, we already have measures of success in science, that involve persuading the scientific community and the public, or assessing commercial or medical impact. And adding new metrics that will necessarily be simplifications of what we want to measure merely creates a temptation to game the metrics.

*** Measurements and metrics will be gamed by humans, and thus support the status quo and suppress innovation

Perhaps the most dangerous feature of new metrics is described by Goodhart's Law, coined by British economist Charles Goodhart in 1975: "When a measure becomes a target, it ceases to be a good measure." Metrics go bad because humans react to incentives and find ways to target and game metrics. Andrew Likierman wrote an article called "The Five Traps of Performance Metrics" in the Harvard Business Review (https://hbr.org/2009/10/the-five-traps-of-performance-measurement). One of Likierman's traps is "Gaming your Metrics." He suggests using a diversity of metrics and changing them frequently so they cannot be gamed. But any metric created by NIH is likely to not change fast enough --- given the many stakeholders and democratic accountability of NIH, including to Congress --- to satisfy Likierman's advice. Science requires more nimbleness, requires investigators empowered to quickly follow the data where it leads.

Moreover, metrics tend to support the status quo. To avoid gaming, metrics must change over time. But that means that any metric is a trailing measure of important factors in a complex system. These factors cut against innovation.

It should also be noted that wealthy interests invested in the status quo have often funded quantitative work in social systems, and those efforts have benefited the wealthy by reinforcing the status quo. One example is the "Law and Economics" effort in the law. That moved antitrust law in a direction that benefited entrenched and powerful interests. (See e.g. Heyer K, /Consumer Welfare and the Legacy of Robert Bork/, 2015, the Journal of Law and Economics: "Bork's antitrust analysis drew largely on basic microeconomic theory"... Khan, L /Amazon's Antitrust Paradox/, "unequipped to capture the architecture of market power in the modern economy...").

Aspects of the quantitative-first "Metascience" effort show signs of this capture by wealthy interests. While the vast majority of metascience researchers are engaged in a good-faith pursuit of truth, several thinktanks that support this work are funded by libertarian billionaires or have leadership or board members with libertarian training or current ties. We should be careful that metascience is not used as a way to dull American public innovation — to benefit a few wealthy donors — by reinforcing the status quo.

*** Peer review of qualitative written and oral materials prepared by creative scientists is the gold standard for evaluating science

If metrics are not the way forward to evaluate science, what is? We have decades of experience in the

United States of gold-standard methods for evaluating science, and that relies on qualitative peer review, where rotating panels of experts think carefully about past and proposed work and evaluate it.
The most obvious example of peer review of funding is the NIH extramural grant review system. Peer review panel membership changes over time, which limits the possibility of capture by a few. When peer review is working well, twenty to thirty percent of applications are funded, and reviewers read proposals carefully. The proposals are developed by scientists with significant investment of time, and again in an ideal situation scientists write no more than one grant application every year or two.

But review by peers is also the way that scientific impact is evaluated. Persuading members of the scientific community that ideas are good, to create scientific consensus, is the way impact has been successfully measured.

Two other examples of successful peer review come from the NIH intramural review process and the related HHMI review process. In both cases the scientific research programs to be reviewed are described by the principal investigator in written documents and then the expert panel convened for review hears an oral presentation by the scientist. It can be an advantage to do this kind of investigator, not project-based, review --- which can weight past track record heavily and trust the investigator to do future high-risk work. NIH might consider more widespread evaluation of scientific impact via expert panels of that sort.

There are multiple options for ways to conduct peer review and NIH should experiment with different approaches. However, the feature at the core of each of these methods is that the scientific judgement of many experts is harnessed.

Reducing scientific evaluation to metrics is a recipe for disaster. We should have humility about what it is possible to capture in a complex system like science with quantitative measures alone. Data and measurement can supplement expert decision-making but should never play a primary or even major role in choice of the best science. Science is a creative, forward-looking process and we should treat it as such.

Comment on RFI on Measuring And Rewarding Scientific Impact

Mark H. Histed, PhD, commenting in personal capacity and not on behalf of any organization

"NIH seeks public input on the defining features of modern 21st-century science that should be measured, recognized, and incentivized. "

Executive summary: Quantitative measurements of science, and other creative fields, inherently reduce innovation and limit big ideas. New metrics and measurement can in some cases add information, but NIH should strive to de-emphasize metrics in any evaluation or incentive structures in science. Instead of attempting to reduce the process of science to inherently limited data and measurement, NIH should rely on the gold-standard procedure of evaluating science that has been used to great success in the US for decades: peer review from the scientific community. This peer review should be applied to materials and research papers developed as a product of the creative and intellectual work of scientists. Committees of scientists that read papers will do better at assessing the value of new ideas than any quantitative measure or metric, which will always be backward-looking..

The science ecosystem is a complex and nonlinear system impossible to characterize fully with data and measurement

Science is a highly complex social system which relies on frontier thinking from tens of thousands of scientists. Any empirical model or data will have difficulty assessing the quality of a complex system like science, because empirical models are backward-looking --- data themselves are observations of past events. Thus, quantitative evaluation will ***never*** be a complete way to capture the complex system that is science. NIH should therefore be incredibly cautious of bringing new metrics to bear to evaluate innovation.

To illustrate how empirical models alone are limited for understanding the world, without the accompanying development of theoretical models and a back-and-forth process that adjust models (or metrics) as new observations arrive, let me give an example. Neuroscience, my field, shows how data and quantitative measurements are useful — but are not a full description of a complex system. In the cerebral cortex, excitatory and inhibitory neural networks are tightly coupled to each other. This produces a phenomenon called the balanced state mode of network operation, which increases sensitivity to input, and decouples the activity of nearby neurons to maximize the ability to read out information carried by their responses. Cortical networks in the balanced state have coupled local excitation, and thus exhibit the inhibition-stabilized network (ISN) property. That is a property in which self-amplified activity that can boost certain input patterns is tracked and kept stable by local inhibition.

I give this background to note that ISN property would likely never have been found by pure experimental measurement or data collection. In 1987, Misha Tsodyks and a group of American and international collaborators (https://pubmed.ncbi.nlm.nih.gov/9151754/) showed that ISNs produce

'paradoxical responses,' where boosting inhibition unexpectedly causes excitatory cells to increase, not decrease, their activity. In a two-variable continuous-time model they demonstrated that linear perturbations in the model phase space produce unintuitive effects, curved paths in the phase space that change direction from the marginal or initial incremental direction. Many years later, focused experiments to test this nonlinear model by the Miller, Ferster, and my own group, amongst others, showed this property holds in the cortex.

The ISN model is merely a two-variable system and yet produces complex dynamics. And most empirical measurements --- applying regressions to large-scale data, for example --- measure only the initial marginal effect and missed these curved paths in the state space. Even adding nonlinear terms to a regression does not do a good job inferring curved/non-marginal dynamics, not least because more complex non-linearities become increasingly data-hungry to estimate. That is, most measurements that can be collected in finite time rely on a local linearization of a bigger complex system.

To quantitatively describe real-world complex systems, whether brain networks or the incredibly complex sociological system that is a science and innovation economy, we must not just develop metrics based on data. We must move beyond that to apply the simple models imposed by data to the construction of mathematical models that capture important nonlinear phenomena. This is difficult and takes a long time. We see this in other fields too -- the dynamic general static equilibrium (DGSE) models of the macroeconomy have been built on many, many economics studies, and are still not perfect predictors of our economic future. Developing metrics to evaluate science, for all these reasons, is likely to fail. At best it will distort science and constrain genuinely new ideas. If metrics are applied in a backward-looking way to evaluate which ideas are good -- well, we already have measures of success in science, that involve persuading the scientific community and the public, or assessing commercial or medical impact. And adding new metrics that will necessarily be simplifications of what we want to measure merely creates a temptation to game the metrics.

Measurements and metrics will be gamed by humans, and thus support the status quo and suppress innovation

Perhaps the most dangerous feature of new metrics is described by Goodhart's Law, coined by British economist Charles Goodhart in 1975: "When a measure becomes a target, it ceases to be a good measure." Metrics go bad because humans react to incentives and find ways to target and game metrics. Andrew Likierman wrote an article called "The Five Traps of Performance Metrics" in the Harvard Business Review (https://hbr.org/2009/10/the-five-traps-of-performance-measurement). One of Likierman's traps is "Gaming your Metrics." He suggests using a diversity of metrics and changing them frequently so they cannot be gamed. But any metric created by NIH is likely to not change fast enough --- given the many stakeholders and democratic accountability of NIH, including to Congress --- to satisfy Likierman’s advice. Science requires more nimbleness, requires investigators empowered to quickly follow the data where it leads.

Moreover, metrics tend to support the status quo. To avoid gaming, metrics must change over time. But that means that any metric is a trailing measure of important factors in a complex system. These factors cut against innovation.

It should also be noted that wealthy interests invested in the status quo have often funded quantitative work in social systems, and those efforts have benefited the wealthy by reinforcing the status quo. One example is the "Law and Economics" effort in the law. That moved antitrust law in a direction that benefited entrenched and powerful interests. (See e.g. Heyer K, /Consumer Welfare and the Legacy of Robert Bork/, 2015, the Journal of Law and Economics: “Bork’s antitrust analysis drew largely on basic microeconomic theory”... Khan, L /Amazon’s Antitrust Paradox/, “unequipped to capture the architecture of market power in the modern economy...”).

Aspects of the quantitative-first "Metascience" effort show signs of this capture by wealthy interests. While the vast majority of metascience researchers are engaged in a good-faith pursuit of truth, several thinktanks that support this work are funded by libertarian billionaires or have leadership or board members with libertarian training or current ties. We should be careful that metascience is not used as a way to dull American public innovation — to benefit a few wealthy donors — by reinforcing the status quo.

Peer review of qualitative written and oral materials prepared by creative scientists is the gold standard for evaluating science

If metrics are not the way forward to evaluate science, what is? We have decades of experience in the United States of gold-standard methods for evaluating science, and that relies on qualitative peer review, where rotating panels of experts think carefully about past and proposed work and evaluate it.

The most obvious example of peer review of funding is the NIH extramural grant review system. Peer review panel membership changes over time, which limits the possibility of capture by a few. When peer review is working well, twenty to thirty percent of applications are funded, and reviewers read proposals carefully. The proposals are developed by scientists with significant investment of time, and again in an ideal situation scientists write no more than one grant application every year or two.

But review by peers is also the way that scientific impact is evaluated. Persuading members of the scientific community that ideas are good, to create scientific consensus, is the way impact has been successfully measured.

Two other examples of successful peer review come from the NIH intramural review process and the related HHMI review process. In both cases the scientific research programs to be reviewed are described by the principal investigator in written documents and then the expert panel convened for review hears an oral presentation by the scientist. It can be an advantage to do this kind of investigator, not project-based, review --- which can weight past track record heavily and trust the investigator to do

future high-risk work. NIH might consider more widespread evaluation of scientific impact via expert panels of that sort.

There are multiple options for ways to conduct peer review and NIH should experiment with different approaches. However, the feature at the core of each of these methods is that the scientific judgement of many experts is harnessed.

Reducing scientific evaluation to metrics is a recipe for disaster. We should have humility about what it is possible to capture in a complex system like science with quantitative measures alone. Data and measurement can supplement expert decision-making but should never play a primary or even major role in choice of the best science. Science is a creative, forward-looking process and we should treat it as such.

1. Rigor and Reproducibility: NIH should emphasize that sharing data, software, and computational models, specifically in such a way that an outside researcher can understand and reuse them, is required for rigorous and reproducible science. NIH should provide incentives for and clear guidance on best sharing practices.

As biomedical research increasingly creates and depends on “big data” and computational methods, rigor and reproducibility in this field increasingly depend on researchers adequately sharing and describing all of the data, software, and computational models used in their studies. We found that reproducibility often fails not necessarily due to the underlying science, but due to data, analysis details, or other aspects not being shared or sufficiently described.

In our proof-of-concept exercise, the most common roadblocks to reproducibility that we encountered were:
- Data and/or code not shared
- Code shared, but with insufficient documentation for installation or use
- Data shared, but without a data dictionary or other field-level description
- Raw data shared, but without sufficient description of processing and analysis methods used to generate the published results

We suggest that NIH emphasize sharing that enables reproducibility. If outside researchers do not have enough information to be able to use shared data or code to reproduce findings, this is not sufficient sharing. NIH should therefore incentivize and provide guidance on sharing data, software, and computational models in such a way that enables others to easily reuse these materials.

Indicators NIH could consider in this area include:
- Whether all data needed to evaluate the main findings of a publication are deposited in a repository with the desirable characteristics laid out by NIH (e.g., assigning unique persistent identifiers, requiring metadata, etc.)
- Whether said data is shared with relevant metadata and/or data dictionaries
- Whether relevant code is deposited in public repositories with version control
- Whether said code is shared with sufficient documentation for another researcher to install and successfully use the code

- Whether sufficient detail of preprocessing steps is provided to move from raw data to analytic datasets
- Whether workflows are shared in ways that support reuse such as conda packages or containers
- Whether relevant community standards and interoperable formats are used when possible
- Whether persistent identifiers are assigned to datasets, software, models, and other research outputs

One implementation approach would be for NIH to require that funded studies deposit the minimum set of materials (i.e. data, code, computational workflows, etc.) needed to reproduce key published findings in appropriate repositories, except where legal or privacy constraints prevent full public release. NIH should provide clear expectations for adequate sharing for computational reproducibility, such as minimum standards for data and workflow descriptions. These expectations would need to be coupled with NIH funding to support training and related efforts such as curation, annotation, and repository maintenance to ensure the requirements are not overly burdensome.

2. Data, Software, and Model Sharing: NIH should emphasize that sharing data, software, and computational models, specifically in such a way that an outside researcher can understand and reuse them, is required for rigorous and reproducible science. NIH should provide incentives for and clear guidance on best sharing practices.

As biomedical research increasingly creates and depends on “big data” and computational methods, rigor and reproducibility in this field increasingly depend on researchers adequately sharing and describing all of the data, software, and computational models used in their studies. We found that reproducibility often fails not necessarily due to the underlying science, but due to data, analysis details, or other aspects not being shared or sufficiently described.

In our proof-of-concept exercise, the most common roadblocks to reproducibility that we encountered were:
- Data and/or code not shared
- Code shared, but with insufficient documentation for installation or use
- Data shared, but without a data dictionary or other field-level description
- Raw data shared, but without sufficient description of processing and analysis methods used to generate the published results

We suggest that NIH emphasize sharing that enables reproducibility. If outside researchers do not have enough information to be able to use shared data or code to reproduce findings, this is not sufficient sharing. NIH should therefore incentivize and provide guidance on sharing data, software, and computational models in such a way that enables others to easily reuse these materials.

Indicators NIH could consider in this area include:
- Whether all data needed to evaluate the main findings of a publication are deposited in a repository with the desirable characteristics laid out by NIH (e.g., assigning unique persistent identifiers, requiring metadata, etc.)
- Whether said data is shared with relevant metadata and/or data dictionaries
- Whether relevant code is deposited in public repositories with version control
- Whether said code is shared with sufficient documentation for another researcher to install and successfully use the code

- Whether sufficient detail of preprocessing steps is provided to move from raw data to analytic datasets
- Whether workflows are shared in ways that support reuse such as conda packages or containers
- Whether relevant community standards and interoperable formats are used when possible
- Whether persistent identifiers are assigned to datasets, software, models, and other research outputs

One implementation approach would be for NIH to require that funded studies deposit the minimum set of materials (i.e. data, code, computational workflows, etc.) needed to reproduce key published findings in appropriate repositories, except where legal or privacy constraints prevent full public release. NIH should provide clear expectations for adequate sharing for computational reproducibility, such as minimum standards for data and workflow descriptions. These expectations would need to be coupled with NIH funding to support training and related efforts such as curation, annotation, and repository maintenance to ensure the requirements are not overly burdensome.

3. Training and Mentorship: NIH training programs should include education and mentorship in FAIR principles and reproducibility best practices.
At the end of the day, any science being performed will only be as good and as rigorous as the scientists performing it. For this reason, any efforts to strengthen rigor and reproducibility in biomedical research should emphasize initiatives to train researchers in data management and sharing best practices. This would likely address many of the barriers to reproducibility we encountered in our exercise.
We therefore recommend that NIH prioritize training and mentorship efforts that instill in upcoming and current researchers the best practices for ensuring reproducibility. Potential indicators NIH could consider in this area include:
- Training programs that cover data management, metadata creation and curation, code sharing, and workflow documentation
- Requiring FAIR principles and other reproducibility practices be incorporated in trainee education programs across specialties

4. Collaboration: NIH should expand policies to assess and recognize collaborative contributions to science, beyond first and senior authorship.
We appreciate that NIH acknowledges science is increasingly team-based and is seeking input on how best to recognize such collaborative contributions. From our perspective as data scientists, we recognize that teams with computational and data-sharing expertise are often better positioned to produce transparent and reproducible research outputs.
Potential metrics for NIH to consider for assessing and recognizing contributions to team-based science include:
- Contributions to data curation, software development, and software/workflow maintenance
- Use of shared standards, repositories, and workflows
- Development of resources (data repositories, software tools, etc.) that enable reuse by others
NIH should encourage more explicit documentation of team roles and recognize contributions beyond first or senior authorship through the development of better metrics to track data and software sharing (for example, the S-index), events focused on highlighting exceptional examples of reproducible science, or other avenues.

Request for Information on Measuring and Rewarding Scientific Impact

Response to: NIH Guide Notice NOT-OD-26-087

Prepared by:

Rachel Waymack and members of the NIAID Office of Data Science and Emerging Technologies: Reed Shabman, Sydney Foote, Meghan Hartwick, Lisa Mayer, Dasha Pokutnaya.

Disclaimer: The response below represents perspectives and points to consider from NIAID subject matter experts on this topic and does not necessarily reflect the official NIAID position. As such, the response uses 'we' in reference to the contributors of this document, not 'NIAID'

A. Executive Summary

The NIAID Office of Data Science and Emerging Technologies (ODSET) includes a diverse group of data scientists. ODSET partners with NIAID Divisions and the extramural community to advance data science and computational modeling in infectious, allergic, and immunological diseases. ODSET supports methods and approaches that enable biomedical data, computational methods, and software tools to be findable, accessible, interoperable, and reusable (FAIR). We appreciate NIH's efforts to best measure and reward scientific impact and believe these efforts should be grounded in the FAIR principles.

Recently, ODSET conducted a proof-of concept exercise in which we sampled a limited number of NIH-funded publications and attempted to reproduce select figures or findings using the data and methods made available by the authors. In most cases we were unable to do so, often due to data or code not being shared or shared with inadequate documentation. While not a systematic study, this small exercise reinforced the point that reproducibility depends not just on sharing data or code, but on sharing in ways that make them usable by others.

From this perspective, the main points to consider in support of rigorous and reproducible science are:

1. NIH should incentivize and structurally support sharing research data ***and corresponding methods (e.g. computational workflows)*** in such a way that an outside researcher can understand and use them (expanded upon in section B.1).
2. NIH training programs should include education and mentorship in FAIR principles and reproducibility best practices (expanded upon in section B.2).
3. NIH should expand policies to assess and recognize collaborative contributions to science, beyond first and senior authorship, including but not limited to data managers, computational modelers, and software developers (expanded upon in section B.3).

We welcome further discussion with NIH colleagues, such as the Office of Research Innovation, Validation, and Application, and can be contacted at datascience@niaid.nih.gov or rachel.waymack@nih.gov.

We offer additional detailed comments below, which are broken down by category and numbered in alignment with the main points above:

B. Detailed response

B.1. Adequate sharing of data and computational workflows fosters rigor and reproducibility.

Response to sections: Rigor and Reproducibility; Data, Software, and Model Sharing

NIH should emphasize that sharing data, software, and computational models, specifically in such a way that an outside researcher can understand and reuse them, is required for rigorous and reproducible science. NIH should provide incentives for and clear guidance on best sharing practices.

As biomedical research increasingly creates and depends on "big data" and computational methods, rigor and reproducibility in this field increasingly depend on researchers adequately sharing and describing all of the data, software, and computational models used in their studies. We found that reproducibility often fails not necessarily due to the underlying science, but due to data, analysis details, or other aspects not being shared or sufficiently described.

In our proof-of-concept exercise, the most common roadblocks to reproducibility that we encountered were:

- Data and/or code not shared

- Code shared, but with insufficient documentation for installation or use
- Data shared, but without a data dictionary or other field-level description
- Raw data shared, but without sufficient description of processing and analysis methods used to generate the published results

We suggest that NIH emphasize sharing that enables reproducibility. If outside researchers do not have enough information to be able to use shared data or code to reproduce findings, this is not sufficient sharing. NIH should therefore incentivize and provide guidance on sharing data, software, and computational models in such a way that enables others to easily reuse these materials.

Indicators NIH could consider in this area include:

- Whether all data needed to evaluate the main findings of a publication are deposited in a repository with the desirable characteristics laid out by NIH (e.g., assigning unique persistent identifiers, requiring metadata, etc.)
- Whether said data is shared with relevant metadata and/or data dictionaries
- Whether relevant code is deposited in public repositories with version control
- Whether said code is shared with sufficient documentation for another researcher to install and successfully use the code
- Whether sufficient detail of preprocessing steps is provided to move from raw data to analytic datasets
- Whether workflows are shared in ways that support reuse such as conda packages or containers
- Whether relevant community standards and interoperable formats are used when possible
- Whether persistent identifiers are assigned to datasets, software, models, and other research outputs

One implementation approach would be for NIH to require that funded studies deposit the minimum set of materials (i.e. data, code, computational workflows, etc.) needed to reproduce key published findings in appropriate repositories, except where legal or privacy constraints prevent full public release. NIH should provide clear expectations for adequate sharing for computational reproducibility, such as minimum standards for data and workflow descriptions. These expectations would need to be coupled with NIH funding to support training and related efforts such as curation, annotation, and repository maintenance to ensure the requirements are not overly burdensome.

B.2. NIH training programs should include education and mentorship in FAIR principles and reproducibility best practices.

Response to section: Training and Mentorship

NIH training programs should include education and mentorship in FAIR principles and reproducibility best practices.

At the end of the day, any science being performed will only be as good and as rigorous as the scientists performing it. For this reason, any efforts to strengthen rigor and reproducibility in biomedical research should emphasize initiatives to train researchers in data management and sharing best practices. This would likely address many of the barriers to reproducibility we encountered in our exercise.

We therefore recommend that NIH prioritize training and mentorship efforts that instill in upcoming and current researchers the best practices for ensuring reproducibility. Potential indicators NIH could consider in this area include:

- Training programs that cover data management, metadata creation and curation, code sharing, and workflow documentation
- Requiring FAIR principles and other reproducibility practices be incorporated in trainee education programs across specialties

B.3. NIH should expand policies to assess and recognize collaborative contributions to science.

Response to section: Collaboration

NIH should expand policies to assess and recognize collaborative contributions to science, beyond first and senior authorship.

We appreciate that NIH acknowledges science is increasingly team-based and is seeking input on how best to recognize such collaborative contributions. From our perspective as data scientists, we recognize that teams with computational and data-sharing expertise are often better positioned to produce transparent and reproducible research outputs.

Potential metrics for NIH to consider for assessing and recognizing contributions to team-based science include:

- Contributions to data curation, software development, and software/workflow maintenance
- Use of shared standards, repositories, and workflows

- Development of resources (data repositories, software tools, etc.) that enable reuse by others

NIH should encourage more explicit documentation of team roles and recognize contributions beyond first or senior authorship through the development of better metrics to track data and software sharing (for example, the S-index), events focused on highlighting exceptional examples of reproducible science, or other avenues.

I am responding: On behalf of an organization

Name: Mark Stoner

Name of Organization: BioCrowd, Inc.

Type of Organization: Commercial Entity (Biotech/Device/Pharmaceutical Company/Small Business)

Role: Other

Role - Other: We're building BioCrowd, a capital deployment platform for clinical research, beginning with space biology. Microgravity accelerates biological changes associated with aging—including muscle loss, immune dysfunction, neuroinflammation, and cardiovascular decline—making space a powerful environment for studying age-related disease affecting longevity. BioCrowd helps universities and research institutions fund these programs and translate their scientific milestones into investable opportunities. https://www.biocrowd.com/

Date Submitted: 8/20/2026

1. Rigor and Reproducibility: Measurable indicators. Preregistration or registered analysis plans; availability of protocols, materials, code, and statistical specifications; validation of key resources; reporting of sample-size logic and sensitivity analyses; documented deviations; reporting of null or negative findings; independent reproduction or replication attempts; and whether later evidence strengthens, narrows, or refutes the original claim. For causal research, records should identify the causal question, estimand, assumptions, identification strategy, comparator, prespecified falsification or sensitivity tests, and limits on generalizability.

Potential incentives. Dedicated replication awards, administrative supplements, bridge funding for confirmatory work, recognition in progress reviews and subsequent applications, and formal credit for high-quality negative or inconclusive results.

Safeguard. Do not reward a positive replication rate. Reward transparent, rigorous execution and complete reporting regardless of result; otherwise, the system may encourage selective targets or suppression of discordant findings.

2. Data, Software, and Model Sharing: Measurable indicators. Persistent identifiers; metadata completeness; community standards and common data elements; time from primary result to availability; documented access conditions; FAIR characteristics; versioned and citable software or models; executable environments, tests, model cards, and provenance; maintenance status; and evidence of responsible reuse.

Potential incentives. Treat datasets, software, models, protocols, and curation as first-class research products in biosketches and review; fund stewardship and maintenance; and provide supplemental support when reuse demonstrates unusual public value.

Safeguard. Downloads alone are not impact, and unrestricted release is not always appropriate. Metrics should not penalize privacy-preserving controlled access, community governance, licensing obligations, cybersecurity, biosecurity, or legitimate protections needed for translation.

3. Training and Mentorship: Measurable indicators. Documented mentoring plans; protected mentoring time; trainee-defined goals; completion of rigor, quantitative, data, and responsible-conduct training; verified trainee contributions; career progression across academic, clinical, government, nonprofit, and industry pathways; and confidential mentorship-quality feedback.

Potential incentives. Recognize substantive mentoring in grant review and progress reporting, support mentor development, protect salary effort for mentoring, and reward teams that produce durable skills and career development across diverse pathways.

Safeguard. Raw trainee counts and prestige of placements can disadvantage small laboratories and nontraditional careers. Evaluate quality, opportunity, and value added relative to context rather than pedigree.

4. Collaboration: Measurable indicators. Verified contributorship; cross-disciplinary and cross-institutional roles; timely execution of data-use, material-transfer, and reliance agreements; shared protocol and data standards; patient and community participation where relevant; resolution of documented bottlenecks; and continuity of shared resources after the initial award.

Potential incentives. Permit structured team-science contribution statements, give reviewers explicit guidance to credit enabling roles, recognize shared research operations, and support modest coordination supplements tied to transparent deliverables.

Safeguard. Counting collaborators, institutions, or disciplines rewards superficial network size. Assess necessity, contribution quality, governance, conflict management, and delivered value.

DeSci. BioCrowd is building decentralized science (DeSci) into our long-term platform engagement models between R1, R1 institutions and individual scientists. This DeSci can be very helpful for accelerating science and reducing silos internal to institutions, between institutions in the US but internationally also. Yet still be able to protect developed intellectual property (IP) rights for investors and the universities that support them. DeSci can be very helpful for biodefense, pandemic response or rapid deployment research needs. This Ethereum website details how DeSci works and the benefits. https://ethereum.org/desci/

5. Entrepreneurship and Translation: Measurable indicators. Completion of need validation; reproducibility and technical-readiness evidence; invention disclosures and patents where appropriate; regulatory, manufacturing, reimbursement, implementation, or clinical-development milestones; licenses, responsible startups, sponsored research, and follow-on capital; time to the next decision-quality milestone; and evidence of accessibility, adoption, or patient benefit.

Potential incentives. Translation supplements, milestone-based awards, leave or mobility mechanisms, entrepreneur-in-residence access, regulatory and commercialization assistance, and recognition of validated handoffs to capable partners.

Safeguard. Company formation, valuation, patents, and dollars raised are incomplete proxies. NIH should reward credible de-risking and public value, require conflict disclosure, and keep public or charitable research decisions separate from private investment decisions.

6. Foundational Scientific Exploration: Measurable indicators. Clarity and testability of the question; novelty relative to the field; potential to create a new method, dataset, instrument, model, or conceptual framework; informative value of failure; challenge to an important assumption; future option value; and retrospective evidence that the work opened productive lines of inquiry.

Potential incentives. Staged high-risk awards with light initial burden, opportunities to continue or pivot based on learning, dedicated support for early-career and overlooked investigators, and portfolio-level evaluation that accepts well-designed failures in exchange for rare breakthroughs.
Safeguard. Rigid milestones can prematurely narrow exploratory work. Milestones should emphasize learning, methods, evidence quality, and explicit go, pivot, or stop decisions - not predetermined favorable findings.

7. Public Impact: Measurable indicators. Links to clinical trials, guidelines, standards, public-health programs, diagnostics, therapeutics, devices, implementation studies, and policy; changes in practice; reach to intended populations; time to access; health outcomes where attribution is supportable; reduction in burden or cost; domestic capability and workforce; public trust; and distribution of benefits across regions and populations.

Potential incentives. Follow-on implementation and dissemination awards, recognition for contributions to guidelines and standards, longitudinal linkage between awards and downstream records, and public-impact narratives supported by verifiable evidence.
Safeguard. Health impact often occurs years later and usually has multiple causes. Use contribution analysis and uncertainty ranges, avoid claims of sole attribution, and prevent near-term outcomes from crowding out basic science and rare-disease research.

8. Other Areas: 5.3 Incentive Design Lessons from the World Intellectual Property Organization (WIPO)

WIPO's 2024 guide on incentives in technology transfer offers a useful framework for an NIH DeSci pilot. It groups incentives into non-financial recognition, career advancement, and financial support; emphasizes clear, transparent and achievable criteria; recommends tailoring incentives to people, institutions and stages; and warns that a program can hit a target, such as producing more patents, while missing the underlying goal of durable economic or societal value. WIPO also advises rewarding technology-transfer effort and enabling contributions, not only downstream outcomes, and monitoring programs for unintended effects. [7]
For NIH, this supports a layered incentive portfolio in which DeSci infrastructure supplies verifiable evidence of contribution but does not determine scientific merit. The portfolio should recognize investigators, technology-transfer professionals, research software engineers, data stewards, regulatory staff, technicians, trainees, patients, and community partners according to their actual roles.
• Non-financial recognition: verified contributor records, public acknowledgment, reusable-output badges, leadership recognition, and visibility for rigorous negative, null, replication, stewardship, and translation work.

• Career advancement: structured credit in biosketches, progress reports, promotion dossiers, and team-science statements for reproducibility, data and software stewardship, mentorship, regulatory execution, and technology-transfer enabling work.
• Financial and resource support: administrative supplements, proof-of-concept or translational funds, protected staff time, training, conference support, and small fixed-dollar awards for bounded deliverables.
• Stage-appropriate timing: use near-term recognition and resources at protocol, evidence, validation, and handoff milestones rather than relying only on distant licensing income or commercialization events.
• Goal-aligned measurement: pair quantitative indicators with qualitative evidence and test whether incentives advance trustworthy knowledge and public benefit, not merely counts of patents, companies, publications, or transactions.
• Safeguards: preserve the right to publish subject to limited confidentiality and IP-protection review; protect foundational research; provide choice where feasible; and regularly audit for gaming, inequity, administrative burden, and displacement of intrinsic motivation.

Response to NIH RFI: Measuring and Rewarding Scientific Impact

Submitted by: SciClin LLC

SciClin is a patient-centered translational science consultancy

About This Response

SciClin works with academic research teams and institutions to build translational strategy into biomedical research at the design stage before data collection, not after. Our perspective on this RFI is shaped by direct, applied experience: we regularly observe where studies with strong internal validity nonetheless fail to reproduce cleanly or translate into clinical practice, and the root cause is almost always the same: the research question was never anchored to the patient population or clinical context it was ultimately meant to serve. In preparation for this response, we conducted a pilot qualitative study comprising six semi-structured, de-identified interviews with basic researchers and clinicians across multiple disease areas in the translational pipeline. We draw on that dataset throughout this response as applied evidence, alongside our broader workshop and advisory experience, and would welcome the opportunity to share the full coded dataset directly with NIH staff. Our team and professional network span institutions including Virginia Commonwealth University, University of Southern California, Indiana University, University of Rochester, and Longwood University. We have also previously discussed related priorities directly with NIH program staff.

Framing Comment

Current metrics of scientific success: publication counts, citation indices, and grant dollars largely measure activity within a single stage of the research pipeline. They do not capture whether a finding was ever positioned to survive contact with the patients, clinicians, and health systems it was meant to serve. The NIH's Replication and Reproducibility Initiative is an important corrective. Still, we would encourage the agency to resist measuring"rigor" and "impact" as sequential checkpoints independent of each other: rigor at the bench, impact at the bedside. In our work advising research teams on translational design, we consistently find that studies which reproduce reliably and translate successfully share a common feature: patient and clinical context was built into the research question and study design from the outset,

not retrofitted after results were generated. Reproducibility, in other words, is not only a property of a mechanistic finding in isolation, but it is also a property of how well that finding was designed to hold up as it moves toward real-world application. We believe any indicator framework should measure both dimensions together, and reward research designs that account for the second at the moment the first is being planned, rather than treating translational relevance as something assessed only once a discovery is already mature.

This has a direct bearing on how NIH defines "causal research," which the RFI specifically raises. A causal claim generated from a model system with undocumented relevance to the target patient population is, in practice, a claim about that model system alone; its causal status in the intended clinical context remains untested. We would encourage NIH to treat clinical/population context documentation as a prerequisite for evaluating the strength of a causal claim, not a separate translational concern.

On Rigor and Reproducibility

We recommend NIH consider indicators that assess reproducibility readiness at the design stage, not only replication outcomes after the fact. Concretely, this could take the form of a scorable field in grant applications and progress reports assessing whether a study's model system, patient-derived materials, or clinical endpoints are documented with enough context: disease stage, population characteristics, comorbidities, and care setting that a downstream investigator or clinical partner could evaluate the finding's applicability without needing to contact the original authors.

In our applied work with research teams, this single gap in the absence of patient/clinical context in method reporting is one of the most common and correctable barriers we encounter to both replication and translation. It is also, notably, inexpensive to fix relative to most rigor interventions: it requires no new wet-lab infrastructure, no additional data collection, and no extension of study timelines, only a documentation habit built into protocol design. A simple present/partial/absent scoring rubric could be piloted within existing progress-report or Research Performance Progress Report (RPPR) structures at low administrative cost, and could be validated retrospectively against existing replication failure data before being formally adopted. We would also note that this indicator is measurable by a third party

without requiring the original investigator's self-assessment, which addresses a common critique of rigor metrics that they rely on investigators grading their own work.

This pattern was directly reflected in our pilot interviews: each study participant (across both basic-research and clinical roles) independently raised structural or institutional barriers to integrating patient/clinical context into their work, and the same group named funding and career-incentive structures as compounding factors. Participants also drew a sharp, consistent line between patient/provider input that was merely "acknowledged" after the fact and input incorporated early enough to actually change experimental design, endpoints, or population definitions; the latter was the only version participants could point to that changed a real research decision. This maps directly onto NIH's reproducibility question where design-stage context improves rigor by ensuring relevance remains at the center of scientific discovery. We are positioned to make this dataset available to NIH staff for review.

On Data, Software, and Model Sharing

We would encourage NIH to extend its sharing indicators beyond raw data and code to include the *contextual metadata* that makes shared data usable for translational purposes, specifically, structured documentation of the population, clinical setting, and stage of disease represented in shared datasets and model systems. A dataset or cell line shared without this context can still be technically "open" while remaining functionally unusable to a downstream team trying to assess its relevance to a specific patient population. We would suggest NIH consider a minimum contextual-metadata standard as a condition of data/model sharing credit, similar in spirit to existing FAIR data principles, but specifically oriented toward translational reuse rather than technical reproducibility alone.

On Training and Mentorship

We would encourage NIH to recognize and fund training that builds translational design literacy directly into graduate and postdoctoral training, not as a supplemental commercialization or entrepreneurship elective late in a trainee's career, but as a core research-design skill taught alongside statistics and experimental design. In our own workshop-based work with research teams, we have found that translational thinking is most effective, and most durable, when it is taught as part of how a hypothesis is

framed, rather than added afterward as a business or dissemination skill. An indicator here might track institutional investment in this kind of design-stage training (distinct from tech-transfer or startup-formation training) as a component of training grant (T32, etc.) review. We are currently developing asynchronous self-paced e-learning courses for research faculty and learners to understand how to build strategic partnerships and design translational research to improve translation from bench to bedside.

Current grant pipelines reward mechanistic breakthroughs and do not fund the necessary activities (strategic partnership building, regulator readiness, industry-academic collaboration, community advisory board, provider/patient input) that bolster translational research. Thus, many scientific discoveries halt at publication and never evolve to therapeutic innovation in clinical practice. Also, translational research is much more time-intensive than curiosity-driven research. For impact to occur sustainably, there needs to be funding available distinct from the traditional R01 grant system for bench researchers who seek to identify mechanisms at the bench and translate these ideas into impact for patients.

On Collaboration

Cross-disciplinary collaboration is often assessed by counting co-authorship across departments or institutions, which can reward administrative breadth without capturing whether a collaboration meaningfully improved a study's design. We would suggest NIH consider indicators that specifically credit collaborations bridging basic science and clinical/patient-facing expertise; for example, whether a clinician, patient advocate, or clinical operations expert was involved during protocol design (not only during a later clinical trial phase). This is a narrower, more targeted version of team science credit that maps directly onto the translational goals this RFI is oriented around. Having the principal investigator list both a provider/clinician and a community advisory stakeholder as part of the research program in grant review will significantly bolster impact. We have worked with researchers who successfully translated scientific discovery into human applications, and of not was through early partnerships with providers and community partners early in the design process. This helped in research approaches, clinically relevant models, and findings that more broadly applied to various populations. Also, having an expert who is well-versed in regulatory compliance, especially for protocol development regarding toxicity in humans as part of the research program early on in the experimental design, was a significant positive indicator for

rewarding scientific impact. When we worked with bench scientists to understand the fundamental principles of scientific impact and translational practices, researchers were able to significantly improve the bridge between curiosity-driven research and therapeutic innovation. Lastly, to see the fruits of thoughtful collaboration toward impact, researchers must be incentivized to do so through the promotional structure or the grant funding; otherwise, there is no protection or guarantee that their efforts to promote scientific impact for patients will be able to sustain long-term.

On Foundational Scientific Exploration

We want to name a risk directly that we also flag later in this response: translational or reproducibility-readiness indicators, applied indiscriminately, could pressure investigators doing foundational, high-risk basic research to justify translational relevance prematurely or artificially. We do not believe that is NIH's intent, and we would recommend the agency state so explicitly, for example, by scoping any new translational-fidelity indicator to mechanisms and award types where translational or clinical intent is already a stated goal (translational R01s, U-series awards, SBIR/STTR), and explicitly exempting R01s, R21s, and other awards designated as basic/exploratory from that scoring. Foundational science should continue to be evaluated on its own terms: novelty, technical rigor, and paradigm-shifting potential without being asked to retroactively demonstrate a translational pathway it was never designed to have. Protecting this distinction is, in our view, what allows translational indicators elsewhere in the portfolio to be adopted with less resistance from the research community, since investigators will trust that the new measures are targeted rather than universal.

On Entrepreneurship and Translation

We would encourage NIH to fund and recognize translational design capacity-building training, workshops, and advisory support that help research teams build translational thinking into a study before data collection begins as distinct from, and complementary to, downstream commercialization support (tech transfer, licensing, startup formation), which is where most current "translation" incentives are concentrated. The two interventions address different points of failure: commercialization support helps a mature discovery reach the market; design-stage translational support helps ensure the discovery was

shaped to be relevant to patients in the first place. Both are necessary, and we would caution against measuring "translation" activity in a way that only captures the former.

Our own consultancy's proprietary frameworks (including our Patient-Centered Discovery Framework™) were built specifically to address this earlier, design-stage gap, and we have applied them directly with academic research teams. Bench researchers with high preclinical expertise note a lack of education in clinical research when framing their preclinical work to patients or in the context of translating their work into humans. Our pilot interviews reinforce why this gap persists: researchers described independently discovering they needed regulatory, IP, or manufacturing expertise, then separately locating who could provide it, then separately finding a way to fund it three sequential, avoidable delays for every team that encountered them. Participants also directly named the absence of translational milestones in tenure and promotion review as a structural disincentive, independent of any individual investigator's intent. We would welcome the opportunity to share implementation data and lessons learned with NIH staff as the agency refines its approach to this indicator category.

On Public Impact

We recommend a composite indicator that pairs a measure of scientific rigor with a measure of translational fidelity: the degree to which a study's design anticipated the population, setting, and constraints of its eventual real-world application. Public impact, in our experience, is best predicted not at the point of publication but at the point of study design: research designed with translational fidelity from the outset is disproportionately more likely to eventually demonstrate real-world health, clinical, or economic impact, simply because it was built to be usable by the systems meant to adopt it.

We have developed and piloted one such composite measure internally (our Patient-Centered Translation Index™, or PCTI); we mention it here as evidence that operational, scorable versions of this kind of indicator are feasible today, not merely aspirational, and are glad to discuss our methodology and findings with NIH directly outside this public comment process.

Our pilot interviews also surfaced a public-impact risk that current metrics do not capture at all: participants across both research and clinical roles described cases where an efficacious, translationally

sound finding still failed to reach patients not for scientific reasons, but because an industry partner judged it insufficiently profitable to manufacture, or because contract and IP terms left the originating academic or clinical team without downstream control. A public-impact indicator built only around whether research could translate, without accounting for whether the surrounding funding and contracting structures allow it to actually reach patients, will systematically overstate impact potential relative to realized impact. We would encourage NIH to consider this distinction explicitly in how "public impact" is defined and measured.

We would also note that SciClin occupies a distinct position relative to other organizations NIH is likely to hear from in response to RFI CTSA hubs, AAMC, and institutional tech-transfer offices, among others. Those entities are largely oriented toward institutional infrastructure and downstream commercialization. Our focus is narrower and earlier: design-stage translational thinking, delivered directly to research teams through workshops, translational audits, and applied consulting, independent of any single institution's infrastructure. We see this as complementary to, not competitive with, the institutional layer, and would welcome the chance to discuss how independent, cross-institutional translational support of this kind could factor into NIH's broader strategy.

Applied Evidence and a Proposed Pilot

The pilot dataset referenced throughout this response, with basic researchers and clinicians across multiple disease areas, thematically coded into seven primary barrier categories with ten linked recommendations, was produced independent of NIH funding, using our own methodology. We reference it here not as a completed study but as a proof of concept: a design-stage translational-fidelity indicator, and a reproducibility-readiness rubric of the kind described above, can be piloted quickly and inexpensively using qualitative and document-review methods already validated in this dataset.

We would welcome the opportunity to propose a small-scale pilot to NIH's Office of Science Policy directly, for example, applying a reproducibility-readiness rubric to a defined set of active R01 or translational-mechanism protocols across a handful of partner institutions, and reporting de-identified, aggregate findings back to OSP within a defined window as a concrete next step ahead of any broader

adoption decision. Alternatively, we are positioned to provide in-person workshops and share our online educational resources centered on translational readiness.

Feasibility and Unintended Consequences

Any new indicator in this space should be piloted with investigator and reviewer burden explicitly in mind; an additional checklist or index item is only useful if it takes minutes, not hours, to complete, and if it is scored by someone other than the original investigator to avoid self-assessment bias. Where possible, new indicators should be layered onto existing reporting mechanisms (RPPRs, progress reports, renewal applications) rather than introduced as standalone instruments requiring new infrastructure or review burden.

We would also flag two risks worth naming directly:

1. **Without care, "translation-readiness" metrics could inadvertently penalize foundational, high-risk basic research that has no near-term clinical application by design.**
    a. We would recommend any composite scoring approach apply only where translational intent is already claimed by the investigator (e.g., in R01s or U-series translational mechanisms), rather than universally across all NIH-funded science. If to be applied to all science for impact, the agency would best benefit from requiring more discussion on how the experimental design was derived from clinical observation or may lead to the betterment of patients, not as a background premise of study but as the backbone for experimental design accounting for sex differences, biological diversity, disease burden, technical replication, etc.
2. **Metrics tied to funding decisions create strong incentives to game documentation rather than genuinely improve design.**
    a. We would recommend the NIH pilot any new indicator as a reported and tracked metric before tying it directly to funding or renewal decisions, so that its validity can be assessed against downstream reproducibility and impact outcomes first.

Disclosure of AI use

In preparing this response, AI-based tools (Anthropic's Claude) were used to support two aspects of our work: (1) drafting and editorial assistance, including organizing and refining language for clarity and conciseness, and (2) analytical support in coding and synthesizing qualitative data from our pilot thematic analysis of patient/clinical integration barriers in translational science. All AI-assisted outputs were reviewed, verified, and edited by the author(s), who take full responsibility for the accuracy, interpretation, and conclusions presented in this response. The underlying research design. Interview conduct, thematic framework development, and substantive recommendations reflect the professional judgment and expertise of the author(s); AI tools served as a productivity aid rather than a substitute for that judgment.

SciClin LLC would welcome further engagement with NIH's Office of Science Policy on any of the above, including a walkthrough of our applied frameworks and full pilot dataset, and stands ready to scope the reproducibility-readiness pilot proposed above, outside of this public comment record.

Patients to Science. Science to Patients.

288. Angela Sy

I am responding: On behalf of myself

Name: Angela Sy

Name of Organization: University of Hawaii

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/20/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: • Indicators of network, organizational and investigator capacity building, such as
o Development of investigators and clinician fellows
o Improved access to scientific research infrastructure
o Subsequent submission of HRPs after completing the RPP'
o Subsequent submission of peer-reviewed grant proposals (for example, K-awards, RPGs)
o Subsequent external independent funding obtained by participants in the program
o Subsequent implementation of research findings across the organization, partners, or the state to inform evidence-based practices and policy.

4. Collaboration: • Indicators of research or research network development and collaboration, such as:
o Number and characteristics of partner organizations
o Resources shared among partner organizations
o Research collaborations established across lead organizations and with other IDeA organizations (CTR-D) or network organizations and with non-network IDeA organizations (CTR-N)
o Engagement with PBRNs or community clinics to expand resources, expertise, and funding opportunities
o Number of HRP submissions by PBRN or community clinic investigators

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: • Indicators of scientific productivity and impact among program or network organizations, such as:
o Peer-reviewed research publications and citations
o Conference presentations
o A number of clinical trials and complex observational studies conducted
o Utilization of the I-CRRC:
- Tracking the number of Clinical Trial participation and the number of participants in the Clinical Research Coordinator Certificate(s)

- Real-World Data-enabled activities attributable to IDeA Clinical Research Resource Center (I-CRRC) engagement, such as relevant grant submissions, funded awards, and dissemination efforts

7. Public Impact: Funding for 5 year NIH grants, especially in the first cycle are not able to evaluate broader public impacts. Furthermore broader impacts are the contribution of many initiatives. This level of impact evaluation requires a separate initiative that specifically assesses the long term impacts, which only result from multiple initiatives working together. NIH could have NOFO specifically on impact evaluation or some type of supplemental funding for existing projects to conduct this resource intensive evaluation.;

8. Other Areas: NIH funded research centers—CTSA, U54—have been considering and have even identified common metrics addressing many of the areas in this RFI. More importantly in addition to identifying measures, a concerted planned effort is required to ensure that measures are feasible and have utility (https://www.eval.org/About/Competencies-Standards/Program-Evaluation-Standards). Some NIH funded research center consortia have discussed and implemented common metrics in the evaluation of it research impacts. The administration and implementation of common metrics requires a NIH wide strategy so that measures that have been identified (as a result of this and other efforts) have a clear purpose on how it will be used. For example CTSA outlines its purpose for common metrics: "The Common Metrics Initiative was designed to assess and optimize the CTSA Program's overall impact on the nation's health. Establishing a set of standard evaluation measures across CTSA Program institutions helps to focus program activities, streamline data collection, and demonstrate measurable progress toward program goals, including improvements in research translation and workforce development." (https://ncats.nih.gov/research/research-activities/ctsa/projects-and-initiatives). The NIMHD U54 Research Centers in Minority Institutions recommends identifying common metrics that allow for valid consortium-wide evaluations and that these metrics are used to facilitate research impacts for the community (https://www.mdpi.com/1660-4601/17/22/8373). The NHGRI U54 Centers for Genomic Research prospectively developed a Consortium evaluation plan based on common metrics across the funded centers to facilitate the ongoing evaluation, reporting, and adjustment of research centers to increase the genomics workforce
(https://www.sciencedirect.com/science/article/pii/S0002929725001016).
Efforts within the NIH community to identify common metrics for the research enterprise exist, and this initiative including the RFI process should work in alignment so as not to "reinvent the wheel." Common metrics sound like a good idea; its implementation and strategies to make such initiative useful and feasible require careful and thoughtful planning (references).
The next step is to have a clear agenda on the purpose of the common metrics, how it will be used, and the extent it will be collected, and how (by NIH). For example to what extent will the common metrics be aggregated, and if so, how will the aggregated results be used?
I would like to participate in future efforts regarding measuring scientific impact. Thank you for the opportunity to comment Angela Sy, DrPH sya@hawaii.edu

Stuart A. Gansky, DrPH, Alex C. Cheng, PhD, Dinesh Mendhe, MS, Aryanna Chavez, MPH, Hsin-Chieh Yeh, PhD, Kathy Lanier, MPH, William Brown III, DrPH, PhD , Derek E. Hersch, MPH, Elbert S. Huang, MD, Felicity T. Enders, PhD, MPH, and Sean M. Phelan, PhD, MPH

ABOUT THE AUTHORS

Stuart A. Gansky, Kathy Lanier, and William Brown III are with the Research Coordinating Center to Reduce Disparities in Multiple Chronic Diseases, University of California, San Francisco, CA. Alex C. Cheng is with the Southeast Collaborative for Innovative and Equitable Solutions to Chronic Disease Disparities, Vanderbilt University Medical Center, Nashville, TN. Dinesh Mendhe is with the Rutgers–New York University Center for Asian Health Promotion and Equity, Institute for Health, Health Care Policy and Aging Research, Rutgers University, New Brunswick, NJ. Aryanna Chavez is with the University of California, Los Angeles–University of California, Irvine Center for Eliminating Cardio-Metabolic Disparities in Multi-Ethnic Populations, University of California - Irvine, Irvine, CA. Hsin-Chieh Yeh is with the Mid-Atlantic Center for Cardiometabolic Health Equity, Johns Hopkins University, Baltimore, MD. Derek E. Hersch, Felicity T. Enders, and Sean M. Phelan are with the Center for Chronic Disease Reduction and Equity Promotion Across Minnesota; DEH is at the University of Minnesota, Minneapolis, MN; FTE and SMP are with Mayo Clinic, Rochester, MN. Elbert S. Huang is with the Chicago Chronic Condition Equity Network, University of Chicago, Chicago, IL.

In the 1989 film *Field of Dreams*, a voice states, "If you build it, they will come." But if you build a common data element data warehouse, will they (community research participants) come?

Common data elements (CDEs)—having the same wording and response options for questionnaire items across studies—are important to advance health equity research because they provide standardized data that can be systematically collected, shared, and analyzed across different studies. Adopting uniform measures as CDEs enables researchers to pool data from diverse populations, thereby enhancing power and generalizability of research findings. This is particularly crucial for health equity research, which aims to identify and address disparities in health outcomes among different, often underrepresented demographic groups. CDEs ensure that key social determinants, or drivers, of health (SDOH) and comorbidities are consistently captured, facilitating cross-study comparisons and meta-analyses that are critical for understanding health inequities on a larger scale. Most publications report using researchers and experts for developing CDEs.[1,6]

The National Institutes of Health (NIH) and other funding agencies have recognized CDEs' importance, have implemented policies to promote their use, and have required their use in some recently established cross-cutting initiatives, specifically to foster synergistic evidence building supporting health equity. The NIH Scientific Data Council established a working group to recommend "a minimum core set of CDEs" for "NIH clinical research/trials" and sought public comment (https://bit.ly/43bhUpl). A systematic scoping review of 22 CDEs of SDOH development studies found that 73% included only research experts.[7] Such top-down approaches can lead to suboptimal results, but community-based approaches can be more successful.[8] We describe the process used to develop de-identified CDEs in the community-engaged research of the Health Equity Action Network (HEAN), discuss lessons learned, and make recommendations for future consortia.

However, developing and implementing CDEs require careful consideration to avoid potential drawbacks that could undermine their effectiveness in promoting health equity. Without active community involvement, particularly from marginalized and underrepresented populations, CDEs may lack cultural relevance or fail to address community-specific needs. Reduced participation, incomplete responses, and distrust in the research process can result. For example, inadequately

AJPH Supplement 2, 2025, Vol. 115, No. S2

tested or culturally insensitive items may alienate potential participants, compromising data quality and the overall research validity. To mitigate these risks, study investigators must collaborate with community partners early in CDE development. Thus, researchers can ensure that measures are contextually appropriate and ethically sound, increasing their acceptance and likelihood of meaningful engagement. Moreover, community collaboration enhances research credibility, fosters trust, and strengthens findings' applicability to populations with the most health disparities. This participatory approach not only improves data relevance and quality but also helps fulfill the broader goal of advancing health equity through inclusive and community-centered research practices.

HEALTH EQUITY ACTION NETWORK'S COMMON DATA ELEMENTS PROCESS

NIH's National Institute of Minority Health and Health Disparities (NIMHD) issued joint requests for applications as funding opportunity announcements for both the P50 regional research centers and the research coordinating center (RCC) for a new initiative. NIMHD required P50s to work closely with community partners and for the RCC to collect the CDEs of SDOH from P50 main research components in a de-identified data warehouse. However, NIMHD did not detail which CDEs would be mandatory. The NIH strongly encouraged using existing CDE registries, such as the 52-item PhenX Toolkit SDOH Collections (core, individual, and structural along with prerequisites) to "facilitate downstream harmonization and meta-analysis"[9(p258)] and "[foster] a new era of cooperation and collaboration and facilitating cross-study, transdisciplinary, and translational research."[9(p259),10] The RCC proposed including comorbidities and quality of life measures because the initiative focused on multiple chronic diseases with various health outcome measures.

The RCC evaluated the CDEs of SDOH using screening tools tabulated by the Social Interventions Research and Evaluation Network,[11,12] including the 26-item Centers for Medicaid and Medicare Services Accountable Health Communities Health-Related Social Needs Screener,[13] the 83-item All of Us SDOH module,[14,15] and the 32-item Kaiser Permanente Your Current Life Situation questionnaire.[16] The RCC evaluated resources (e.g., screeners, toolkits, and modules) using clinical and translational social and environmental nomenclature,[17] seeking to include at least one item from each domain, while keeping the overall list parsimonious. Using that nomenclature, 16 ectome (external or outside the body) domains are composed of five environmental (aerome: air, hydrome: water, terrome: soil, nutriome: consumed food, and biome: flora, fauna, and microbiota), seven social (philome: family and social support network, allolome: people not in the philome, legome: educational achievement and opportunities, econome: economic circumstances, ethnome: culture including race/ethnicity, actome: physical activity, and home: living environment and neighborhood), and four health care (iatrome: personal health care experience, therapome: therapeutic care, preventome: preventive care, and pharmacome: pharmaceuticals) factors. Ectome domains and CDEs of the HEAN items are depicted mapped onto the NIMHD research framework in Figure 1).[18]

Consortium options for CDEs were to adopt an existing resource (screener, toolkit, or module), entirely or partially, to map and collapse items from P50 projects' planned instruments, or to adapt existing resources and harmonize across P50 projects. Adoption had the advantage of selecting reliable and validated instruments, but it lacked HEAN community partner engagement. Map and collapse had the advantage of using measures P50s adopted with extensive community engagement, but initial measure reviews showed items mappable in limited domains and only after extensive collapsing, resulting in significant loss of information. Thus, we selected the last—adapt and harmonize—as a pragmatic middle ground balancing the pros and cons by parsimoniously including all domains and harmonizing across projects, while also including dialogue with community partners.

To facilitate harmonizing, the RCC included plans to use natural language processing but pivoted to large language models such as ChatGPT (OpenAI, San Francisco, CA) to increase efficiency. Certified translators translated the CDEs of the HEAN into Spanish and Vietnamese, as multiple P50s planned to conduct research with communities who spoke those languages. P50s translated CDEs into other center-specific languages (e.g. Chinese, Korean, and Somali).

Centers, research projects, and some community partners (including those from faith-based organizations, health care systems, community-based organizations, educational institutions, and community gathering places) evaluated the proposed 50-item CDE list of SDOH. There was notable friction between the P50s and the RCC regarding the scope and plans for the CDEs of SDOH; specifically, objections related to

FIGURE 1— Domains and Items Mapped Onto the National Institute of Minority Health and Health Disparities (NIMHD) Research Framework (a) Clinical and Translational Nomenclature Domains, and (b) Health Equity Action Network (HEAN) Common Data Element Items

CDEs considered not central to individual study hypotheses, changes needed in pragmatic designs using extant data, some specific CDEs on safety-related or sensitive topics, increased participant burden, and lack of planned cross-center analyses. The RCC suggested some cross-center analyses; however, the requests for applications required creating a data warehouse. Some consortium members noted that if no local or study resources were available to address a SDOH need, then the screening item was potentially unethical. Negative affect and depressive symptom

assessment was debatable depending on local resources available. Others note that CDEs specific to adults should be excluded for studies focused on children. During discussions, other consortium members requested that data that could be self-incriminating or have legal implications be excluded.

Thus, the RCC removed the following items based on consortium community feedback: country of origin, recreational or illegal drug use, and physical or financial abuse. Also based on consortium input, a disability item was added. Qualitative research projects were strongly encouraged to add the CDEs of SDOH to permit mixed methods research. Two projects that did not obtain informed consent of any individuals—one implementation science study with process measures and one evaluation study using only aggregate data from an honest broker—were exempted from collecting any CDEs. Three studies focused on children were granted exceptions for specific CDEs focused on adults.

Census-based geolocation enables more precise and equitable SDOH and health outcome analyses compared with zip codes or zip code tabulation areas. Unlike zip codes, which are designed primarily for mail delivery and often cover large, heterogeneous areas, census-based geolocation offers finer granularity with defining specific geographic boundaries (i.e., census tracts and blocks). Using zip codes (or zip code tabulation areas) in health research presents several limitations. Zip code boundaries can encompass highly diverse populations, including both high and low levels in important variables such as socioeconomic status, health care access, and environmental factors. Relying on zip code as geolocation may result in misleading conclusions, such as masked significant health disparities. By contrast, census-based geolocation enables researchers to better pinpoint specific areas of need and tailor interventions to better address inequities, potentially enhancing targeted, data-driven health equity initiatives.

To reduce response burden on individual participants, we are obtaining neighborhood-level data based on each participant's geocoded residential address. However, because the pooled consortium CDE data will be completely de-identified, we will coarsen linked neighborhood characteristics and retain them for the data warehouse, but we will remove actual geolocation information (e.g., Census tract and address including zip code) before transferring to the RCC.

The final 42 CDEs of SDOH—plus one of two comorbidity CDE versions and one quality of life CDE, along with 12 high-value optional CDEs of SDOH, summarized in a codebook and REDCap (Research Electronic Data Capture, Vanderbilt University, Nashville, TN)[19] data dictionary, along with a data use agreement template—are publicly available on the consortium Web site (https://health-equity-action.org).

PROGRESS AND ACHIEVEMENTS TO DATE

Of the 28 nonexempt initial R01-level projects, 100% are collecting CDEs. Across those projects, the mean percentage of required CDEs being collected is 98%; 27 of 28 nonexempt projects are collecting at least 90% of the required CDEs. All codebooks for the 28 nonexempt projects have been received. Most (85%) data use agreements from institutions requiring them to provide data to the University of California, San Francisco as the recipient institution have been fully executed, and four are in progress. To date, 20 R01-level projects have transferred CDE data to the RCC.

LESSONS LEARNED AND RECOMMENDATIONS FOR THE FUTURE

Although developing and implementing CDEs in HEAN was successful, we learned many lessons throughout the process, which we offer here as suggestions for similar future endeavors. Initially, start the CDE selection process as early as possible in the project life cycle. One key element of successful CDEs of the HEAN collection was the requests for applications that included the expectation and requirement for CDEs, which allowed individual center and study primary investigators to plan for CDE collection from the beginning. Beginning the CDE selection process before funding participating centers or projects has three important benefits. First, providing candidate CDE measures to study primary investigators at the outset of their studies enables them to conduct meaningful engagement with the community members and their partner organizations to review items, discuss rationale for CDEs, and provide recommendations and feedback to refine and improve the process. For example, community partners may identify items that create discomfort or difficulty for people in their communities to answer and suggest alternatives that might lead to better quality data. Involving communities early in the process also shows respect for their active participation in study design, consistent with the values that underlie community-engaged research. Second, early study primary investigator and team

involvement in CDE development helps primary investigators develop their own survey instruments, as they will know which data elements will be required and can avoid redesigning surveys to accommodate new measures. Third, beginning the process early helps ensure that study primary investigators have time to discuss and negotiate exemptions that might be necessary to accommodate study designs that make CDE collection difficult or impossible.

Another recommendation for successful CDE implementation is to clearly and frequently communicate with center and study primary investigators about the importance of CDE collection and planned future data uses. Communicating, as specifically as possible, the ways data will be reused (e.g., a cross-center meta-analysis of a common intervention type) provides two important benefits. First, understanding the effort's purpose is likely to improve buy-in and effort from researchers if the planned outcomes are consistent with their goals and values. Second, communicating plans allows primary investigators and other study leaders, including community partners, to contribute their own ideas for novel data reuse, allowing more opportunities for engagement in the work of achieving those goals, benefiting the end results, and encouraging shared responsibility for efforts and benefits (e.g., authorship).

PRINCIPLES FOR THE FUTURE

Tensions between bottom-up grassroots and top-down funder-driven CDE development approaches present a critical challenge in community-engaged data collection. Grassroots efforts, based on the specific needs and contexts of local communities, ensure relevance and community empowerment but often lack the standardization and comprehensiveness necessary for broader data comparison. Conversely, top-down approaches prioritize uniformity and scalability but may impose external priorities that do not fully align with each unique community's needs. To resolve this, a balanced approach is recommended—one that is community centered yet allows local adaptation to extract meaningful SDOH information in standardized frameworks. Achieving this balance requires working collaboratively with community partners and advisory boards from project initiation and CDE development inception and is characterized by genuine dialogue and cocreation. This approach ultimately would combine the strengths of both methods and thus allow scientific research questions to be investigated rigorously while being deeply responsive to community contexts.

Based on our experiences with multiple efforts to develop CDEs in previous consortia across multiple awards funded at different institutions,[20,21] we recommend that sponsors build in three or four months in the first year for CDE development and pretesting across projects in the consortium. No matter how much a set of CDEs has been developed and tested with other community partners, each implementation with new communities or new community members needs to include ample time for their involvement as equals to modify proposed CDEs to foster developing and maintaining authentic partnerships in community-engaged research. Thus, funder-mandated, required CDEs developed without engaging the specific communities in these studies are likely to reduce enrollment as well as data completeness, validity, or both. Skipping community engagement with expert-developed CDEs may seem expeditious, but it almost always involves delays from backtracking to involve communities after the fact, which is less ideal and can take just as long or longer. AJPH

CONTRIBUTORS

S. A. Gansky conceptualized the study and developed the methodology. S. A. Gansky, A. C. Cheng, D. Mendhe, A. Chavez, H. C. Yeh, and D. E. Hersch wrote the original draft of the article. S. A. Gansky, A. C. Cheng, D. Mendhe, A. Chavez, H.-C. Yeh, D. E. Hersch, E. S. Huang, F. T. Enders, and S. M. Phelan contributed to writing and editing the article. K. Lanier and W. Brown III contributed to developing the methodology. F. T. Enders visualized the

figure. All authors reviewed and approved the final version of the article.

ACKNOWLEDGMENTS

Research reported in this article was supported by the National Institute on Minority Health and Health Disparities, National Institutes of Health (NIH; awards U24MD017250, P50MD017319, P50MD017338, P50MD017341, P50MD017342, P50MD017344, P50MD017347, P50MD017348, P50MD017349, P50MD017351, P50MD017356, and P50MD017366).

The authors are part of the Health Equity Action Network's Common Data Element and Data Harmonization Working Group. Other members include Juan Espinoza, Payal Shah, Katherine Crew, Jeanine Genkinger, Rita Kukafka, John Jackson, Lisa Lanza, Aparna Kalbag, James Selig, Ruofei Du, Dina Jones, April Agne, April Carson, Emily Mire, Tapan Mehta, Ivan Azarov, Alejandra Casillas, Monica Ayala-Rivera, Krystal Griffith, Natalie Robles, Megan Huisingh-Scheetz, Brad Appelhans, Tongtan Chantarat, Julia Stantoznik, Isaac Schlotterbeck, Robert Brook, Michael Twiner, Jackie Parker, and Brian Reed.

Note. The content of this article is solely the responsibility of the authors and does not necessarily represent the official views of the NIH.

CONFLICTS OF INTEREST

The authors have no conflicts of interest to disclose.
