1. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Other

Type of Organization - Other: National laboratory

Role: Institutional Review Oversight Committee Member

Date Submitted: 6/18/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

8. Other Areas: Overarching Recommendation
NIH should avoid reliance on any single metric (such as publication count, journal impact factor, or citation totals). Instead, a balanced scorecard approach combining scientific rigor, collaboration, impact, mentorship, openness, innovation, and research culture would better reflect the collaborative, rigorous, and mission-driven nature of modern biomedical science. Metrics should be normalized for career stage, discipline, project type, and institutional context to ensure fairness and minimize unintended incentives.

2. Shu Joy Jiang

I am responding: On behalf of myself

Name: Shu Joy Jiang

Name of Organization: Washginton university in st. louis

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/18/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: Current incentive structures reward publishing about tools more than building and sharing them. A researcher who builds validated, deployable software used by 50 institutions has more real-world impact than one who publishes 10 papers about methods nobody implements.
Specific indicators:

-Number of institutions actively using shared tools
-Download and deployment metrics
-Validation studies by independent groups
-Infrastructure built on shared foundations

3. Training and Mentorship: Students who go on to build companies, get regulatory clearances, or lead policy changes are invisible in current mentorship metrics. We count publications from trainees. We should count:

-Startups founded by trainees
-Regulatory submissions by trainees
-Policy positions held by trainees
-Industry roles that translate research

4. Collaboration: Multi-site federated research is completely invisible in current metrics. Leading a 10-site consortium is infinitely harder than single-site research — yet authorship conventions and grant metrics don't capture this.
Specific indicators:

-Number of institutions in collaborative networks
-Cross-disciplinary team composition
-Data sharing agreements established
-Infrastructure coordination role vs. passive participation

5. Entrepreneurship and Translation: Current metrics completely miss translational impact. FDA regulatory clearance should be a measurable indicator equivalent to a high-impact publication. A Breakthrough Device Designation represents peer review by the most rigorous regulatory body in the world — yet it appears nowhere in academic promotion criteria. Similarly, industry acquisition of research tools, licensing agreements, and startup formation from academic research should be formally tracked and weighted in grant renewal and promotion decisions.Specific measurable indicators:

Regulatory submissions and clearances (FDA, Health Canada, EMA)
-Industry partnerships with dollar value
-Startup formation and funding raised
-Technology licensing agreements
-Time from research to clinical deployment

6. Foundational Scientific Exploration: N/A

7. Public Impact: Media coverage, policy citations, and clinical guideline inclusion are real measures of public impact that current NIH metrics ignore entirely. A research finding covered by NYT reaching millions is more impactful than a paper cited 50 times within academia.
Specific indicators:

-Media coverage reach
-Clinical guideline citations
-Policy document citations
-Patient advocacy engagement
-Health economic impact estimates

8. Other Areas: N/A

3. Camelia Kantor

I am responding: On behalf of myself

Name: Camelia Kantor

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/18/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: With the future of science being increasingly AI-assisted, the differentiator will likely not be technical expertise gained but mastery of human specific capabilities.
- Human skills development index to be created as a strong measure of success (e.g., a lab producing a technically excellent but dysfunctional scientist from a society engagement, emotional intelligence, resilience, acceptance of critique, and empathy perspective).

Network creation index - trainee-initiated/led engagements (collaborations, cross-disciplines, institutions, etc.)

Team science readiness score (Do trainees manage smaller projects with interdisciplinary teams? Do they communicate across disciplines?)

4. Collaboration: Team science contribution to receive high credit. More specifically, recognition of the "translators" between disciplines, sectors, institutions, methodologies who bring significant value but tend to be less cited or only in support roles, not senior PI/co-PIs roles. Those who make "convergence" possible. Examples include: research development professionals, synthesis leaders, center/institute directors, strategic initiatives leaders, etc.

Rewards for institutions and projects that integrate multiple disciplines, encouraging diversity of expertise (previously disconnected but complementary disciplines) and novel combination of methods, cross-field citations.

Recognition and rewards for investigators who create or leverage shared resources.

Evaluation of collective intelligence.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: Reward intellectual novelty - ideas that have not/have rarely been connected before.

Institution-level evaluation of risk-taking portfolio (fund more those who have some high risk/high impact transformative research in their portfolio)

Projects that present lessons learned from failures that help refine theories, address certain gaps, and disprove hypotheses (well-documented failure that advances understanding, not any kind of failure).

7. Public Impact: Reward visible changes in nearby communities (geography matters) before solving problems elsewhere (e.g., actual local schools' nutrition not just public health recommendations).

8. Other Areas: N/A

4. Luigi Ferrucci

I am responding: On behalf of myself

Name: Luigi Ferrucci

Name of Organization: IRP/NIA

Type of Organization: Not Applicable

Role: Government Official

Date Submitted: 6/18/2026

1. Rigor and Reproducibility: The reliability of scientific findings is as important as their novelty. Indicators of rigor might include:

Data and code sharing.
Development and dissemination of protocols and methods.
Replication and validation studies.
Transparent reporting practices.
Correction of errors when identified.

2. Data, Software, and Model Sharing: Some of the most influential scientific contributions involve the creation of resources that support decades of discovery. Examples include longitudinal cohorts, biobanks, databases, software platforms, and shared methodological tools.

Potential indicators include:

Utilization of shared resources by the scientific community.
Scientific outputs enabled by those resources.
Long-term sustainability and accessibility.

This is particularly important in fields where scientific progress depends on sustained investments over many years. There should be way or rewarding those who produce data that are then used extensively by the scientific community. These key investigators have often difficulty to generate may paper because they focus on data generation.

3. Training and Mentorship: Possible indicators include:

Trainee development and career progression.
Evidence of effective mentoring practices.
Contributions to training programs.
Development of diverse and interdisciplinary scientific talent.

Assessment should emphasize quality and effectiveness rather than simple counts of trainees.

4. Collaboration: Possible indicators include:

Trainee development and career progression.
Evidence of effective mentoring practices.
Contributions to training programs.
Development of diverse and interdisciplinary scientific talent.

Assessment should emphasize quality and effectiveness rather than simple counts of trainees.

5. Entrepreneurship and Translation: Examples include:

Contributions to clinical guidelines.
Influence on public health policy.
Development of diagnostics, therapeutics, or technologies.
Demonstrated improvements in health outcomes.

6. Foundational Scientific Exploration: This aspect of science is critical for the NIH mission. Basic science medical and biophysics discovery produce the found for translation science that has the potentials for translational applications. There two problem that this unique to NIH: 1. Is expensive and there is high risk or failure. 2. Even when successful, the translation to practical applications may occur may years (decades sometime) later. For this reason, this type of research is not done by the private sector.

The practical assessment of what will be important in the future and what will not is complex and requires personal judgment, and should be assessed over time.

7. Public Impact: Very difficult to measure, and requires long time.
Some possible suggestions:

Adoption of findings into clinical guidelines
Demonstrated improvements in patient outcomes
Contributions to public health programs
Development of widely used datasets, methods, or tools
Regulatory approvals influenced by the research
Evidence of reducing disparities or improving access
Educational and public engagement activities with measurable reach

8. Other Areas: The objective should not be to replace traditional scholarly metrics but to develop a more comprehensive framework that evaluates both the generation of scientific knowledge and the contributions that enable scientific progress. Such a framework should recognize discovery, rigor, collaboration, mentorship, infrastructure development, and translation of knowledge into practice.

5. Clifford Saper

I am responding: On behalf of myself

Name: Clifford Saper

Name of Organization: Beth Israel Deaconess Medical Center/ Harvard Medical School

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/18/2026

1. Rigor and Reproducibility: While rigor in scientific design is important, rigidity of thinking about that design can still lead to erroneous results. The beauty of science is that it is self-cleaning. Even rigorous work that is barking up the wrong tree is eventually corrected, when new ideas and new approaches become available. The true test of the reproducibility and value of the work is best reflected in its long term citation. Many newsy papers are a flash in the pan, while work that is still cited 5, 10 or 20 years later after it has been tested, re-tested, and challenged, has the greatest value. So, I would propose that the 5 year citation rate be a standard for estimating the value of work across time.

2. Data, Software, and Model Sharing: NIH says it values sharing, but does little or nothing to foster it. Perhaps the NIH should have a program that would support the time and effort it takes to share resources: to put them in a form that makes them available, provide a forum for a standard way to communicate that, and help pay for the costs of distribution.

3. Training and Mentorship: NIH takes way too long to support training. Students and postdocs can have to submit, resubmit, and sometimes submit again to obtain support. Their graduate school or postdoc research time is generally 3 or 4 years, so a support grant that takes 3 cycles (read: three years!) to achieve is almost worthless. There should be a special short form for application and short cycle for funding for training.

4. Collaboration: Perhaps this could be recognized by the products, not the grant proposals (which are easily gamed). Look at the publications by investigators, and their collaborations, to assess the extent to which this is happening, and perhaps reward for that (for example, extend the payline by 5 percentile points for projects with investigators who have a history of collaboration).

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: Basic research is alive and well in academia, but it is under attack from the current NIH priority statements. This is particularly true for organismal problems, such as brain function (which frequently requires an intact brain for example to measure cognition, anxiety, attention, wake-sleep, etc). The recent NIH priority statements advertise the priority of almost everything else above this critical work, which is the only to take air-fairy concepts from reduced preparations (cell lines, organoids, organs on a chip), which lack validation for whole animals, and test them for their applicability to the real world.

7. Public Impact: Look at new diagnostics and treatments, and follow the idea back in time to its basic science roots. Society has to be educated that the origin of almost every single advance in medicine and biotech in the last 50 years has been due to NIH support for basic science.

8. Other Areas: N/A

6. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/18/2026

1. Rigor and Reproducibility: While rigor and reproducibility are essential pillars of scientific progress, the current peer-review system has significant limitations in ensuring research integrity. Reviewers are generally unpaid volunteers who must evaluate a large volume of manuscripts and grant proposals under substantial time constraints. As a result, reviews often focus on scientific novelty and technical merit rather than a thorough assessment of data integrity, reproducibility, or potential misconduct.

Furthermore, allegations of research misconduct are frequently difficult to investigate and may be dismissed as errors, oversight, or poor research practices rather than being subjected to rigorous scrutiny. This can allow problematic findings to remain in the scientific literature and continue influencing future research and funding decisions.

To strengthen rigor and reproducibility, additional review mechanisms should be established that specifically focus on research integrity. Dedicated reviewers or independent integrity panels could evaluate data transparency, methodological rigor, statistical validity, image and data manipulation, and reproducibility considerations for both grant applications and manuscripts. Creating incentives, infrastructure, and accountability mechanisms for replication studies would further improve the reliability of the scientific record and enhance public trust in biomedical research.

2. Data, Software, and Model Sharing: While data, software, and model sharing are important for transparency and reproducibility, sharing alone does not ensure research quality or integrity. Researchers can share datasets that contain errors, biases, or even fabricated results. The larger challenge is creating incentives that reward rigorous, reproducible, and trustworthy science rather than primarily rewarding publication counts, novelty, citation metrics, or funding success. Policies that recognize replication studies, data validation efforts, negative results, and long-term reproducibility may have a greater impact on scientific reliability than data-sharing requirements

3. Training and Mentorship: NIH has invested substantially in training programs and protected research time, but additional measures are needed to evaluate the long-term effectiveness of these investments. Current metrics often emphasize grant acquisition, publication counts, and career advancement rather than the quality, rigor, reproducibility, and scientific impact of the resulting research. In some cases, investigators with established funding records continue to receive substantial support despite limited assessment of whether previous awards produced robust, reproducible, and influential findings. NIH should consider incorporating stronger outcome-based evaluations of prior funding, including research

quality, data transparency, reproducibility, mentorship outcomes, and long-term scientific impact. Such measures would help ensure that funding decisions reward excellence and stewardship rather than primarily prior funding success

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: NIH should expand support for early-career investigators and high-risk, high-reward research through dedicated funding mechanisms that are less influenced by traditional peer-review biases. While NIH recognizes the importance of bold and innovative science, the current review system often favors established investigators, well-known institutions, and projects with extensive preliminary data, creating barriers for transformative ideas and researchers from smaller universities.

Many high-risk proposals are judged by panels that are inherently risk-averse, despite programs being specifically intended to support innovative research. In addition, investigators at smaller or less research-intensive institutions may face disadvantages due to institutional reputation, available resources, or reviewer perceptions rather than the scientific merit of the proposal itself.

NIH should explore review models that reduce institutional and investigator bias, including greater use of partially anonymized review processes, dedicated panels trained to evaluate high-risk research, and funding mechanisms that place greater emphasis on innovation and potential impact rather than prior funding history. Expanding opportunities for early-career investigators and researchers outside major research-intensive institutions would broaden participation, diversify scientific perspectives, and increase the likelihood of paradigm-shifting discoveries.

7. Public Impact: N/A

8. Other Areas: N/A

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: In the clinical space, make training awards more fairly applicable across types of scientists so that trainee success can be more clearly understood. For example, NIH trainee award salary caps are too low to matter for MD applicants but the new rule where trainees must be funded at their current pay rate disincentivizes PhD postdocs (who always make under the pay cap) from applying, and thus it may appear MD trainees are applying for, and being awarded more early career awards. New rules around pay rate only affect those scientists who make under the NIH cap- who are also the scientists more like to be PhDs, to come from smaller institutions, or come from states not as heavily funded by NIH and thus understanding impact is skewed. Additionally, delays from the NIH in making awards or erroneously canceling awards should be factored into trainee success rates and other measures of impact, as these months of delay significantly impact trainee productivity and career progression.

4. Collaboration: N/A

5. Entrepreneurship and Translation: Take into account when the NIH delays awards or shuts down programs as it quantifies the successful grant cycles, such as the STTR and SBIR programs

6. Foundational Scientific Exploration: N/A

7. Public Impact: NIH should make their award process fully transparent (e.g., what exactly happens between council and funding and who is involved? Who exactly decides which proposals that are "competitive but not discussed" move forward and which do not, and by what exact criteria are proposals placed in this new category? This should be 100% public information!) and take political appointees completely out of award decisions (e.g., do not implement the current proposed executive order to allow non-scientists to make scientific funding decisions). Only then can the public and the scientific community actually trust that the awards being funded are truly based on merit.

8. Other Areas: N/A

8. Anonymous

I am responding: On behalf of myself

Name: Anonymous

Name of Organization: Tier 1 University

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/20/2026

1. Rigor and Reproducibility: More then replicating randomly identified efforts, the emphasis should be on practices that support rigor in the first place. Incentives should be present for solid design - with sufficient power, sufficient control conditions, and milestones to decision making. NIH currently doesn't offer any incentive for reproducibility of findings (the emphasis is on innovation). Providing RFAs that support replication perhaps would incentivize replication efforts.

2. Data, Software, and Model Sharing: These activities require resources. The primary obstacle to utilizing or contributing to such efforts is lack of resources. As such if NIH is interested in incentivizing such activity it needs to offer financial supplements that make the hiring of staff with skillsets to support data/software/model sharing. It is impossible for each lab to maintain such expertise, which then leads to inequality whereby large centers are the only ones who can do this work. Alternatively NIH can create a team that will provide that service to researchers, or reduce the barriers (usually of high overhead burden).

3. Training and Mentorship: The emphasis should not be on numbers (of trainees or workshop attendees) but on products. What do these trainees produce? Do they produce papers, do they produce a collaboration, do they produce a new diagnostic effort.

4. Collaboration: Unfortunately the recent proposal to cap #of RPGs per investigator (https://rfi.grants.nih.gov/?s=6a1f200c6e0a7544e30b3f12) and also the OMB provision that limits international collaborations (§200.220, https://www.federalregister.gov/documents/2026/05/29/2026-10817/regulation-for-federal-financial-assistance) is in direct opposition to collaboration. So perhaps a first step would be to oppose these efforts. Team based science requires both multiple RPGs per investigator and international investigators.

Rewarding MPI efforts would be the right way forward but this is in direct conflict with the proposals above. Either we do team science and hold multiple grants (so that we can work together and combine expertise) or we work in isolation so that more people can get RPGs. This conflict is deeply problematic and prohibits a recommendation to this question.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: The R21 mechanism is supposed to support high-risk initiatives but it is a total of $250,000 over 2 years. This covers about the salary+benefits of 1 individual (staff

member) for 2 years. If the desire is to support high-risk initiatives then there should be RFAs with significantly more funding dedicated to them!

7. Public Impact: Then this should be built into RFAs as a required product and outcome.

8. Other Areas: N/A

9. CC

I am responding: On behalf of myself

Name: CC

Name of Organization: Prefer not to Share

Type of Organization: Non-Profit Research Organization

Role: Investigator/Researcher

Date Submitted: 6/21/2026

1. Rigor and Reproducibility: Staff scientists and postdoctoral fellows are mature scientists who play a seminal role in advancing science in many NIH funded labs. They are well suited to independently report reproducibility as they are funded by non profit agencies and taxpayers via grants, not by the PI or university. Leveraging that existing wealth of granular expertise without additional cost to the PI or the university, while serving the greater cause of publicly funded science, could be practically implemented at virtually no cost via a web portal similar to FDAs famous side effect reporting site. AI agents could summarize or pinpoint recurring areas of concern to a human examiner. Inadvertently, such a forward looking practice also frees these talented colleagues from the fear of negative consequences, similar to culture surveys granting agencies have put in place to deter or identify habitual harassers. Most scientists are scrupulously honest and hopefully would support their postdocs and staff scientists ability to report.

2. Data, Software, and Model Sharing: Reviewers could be asked to rate an additional component on how impactful a method or tool or big data paper has been for those kinds of grants by assessing how widely the tool or data is being used. This metric feeds also links the quality of big data and its reproducibility to general applicability for large grants. This has worked quite well for the Human Genome project and epigenetics consortia.

3. Training and Mentorship: Definitely need a hotline to report harassers that is independent of the Professors chain of command and the university or institute training office--as internal processes such as these are loth to investigate and have vested interest in the outcomes. A preferable method is an independent agency or appointed council who can neutrally evaluate claims made in accordance with laws or policies. Currently trainees are advised to move on and not shake the tree --allowing the very small fraction of serial harassers and fraudsters to keep climbing the tree. For taxpayer funded work, integrity should extend to every component of the product and process.

4. Collaboration: This is much harder as some collaborations are truly impactful while some are merely form letters to get important names on a paper.
Something like the Manhattan project for a given intractable disease is sorely needed to focus efforts towards specific 5-10 year needs with measurable outcomes, preferably under the leadership of visionary broad minded scientist with a reputation for excellence in science and global impact.

5. Entrepreneurship and Translation: Same principle as above would apply

6. Foundational Scientific Exploration: You need leadership that can identify bold and creative scientists vs. those who are merely sloppy scientists but excellent snake oil salespeople. Non trivial endeavor requiring astute leadership that can parse that difference.

7. Public Impact: Having patient representatives on Grant panels can help. Non profits already do this.

Date Submitted: 6/22/2026

1. Rigor and Reproducibility: Scientific findings that have real impact within a given research field are always examined critically and tested by other scientists within the relevant field. This process may not happen instantaneously, but it happens inevitably. To make it happen more quickly, the NIH could consider funding projects with explicit goals of testing the reproducibility of important results from other labs. The NIH should also encourage investigators to include full details of their experimental protocols, calculations, and data analyses in all publications. Review panels could be asked to examine whether these details have been included.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: Entrepreneurship by scientists is already strongly encouraged by universities, the venture capital community, and state governments. The desire for personal wealth is also a strong motivation for some individual scientists. Additional incentives from NIH seem unnecessary.

6. Foundational Scientific Exploration: There is definitely too much emphasis on publications in "high-impact" journals. The NIH should explicitly discourage review panels and program officers from using the "impact factor" of journals or other simple-minded metrics in their decisions. Instead, decisions should be based on careful reading of publications, proposals, and other information by true experts. This is a laborious process, but it is necessary.

7. Public Impact: N/A

12. Western Michigan University Homer Stryker MD School of Medicine

I am responding: On behalf of an organization

Name: Robert G. Sawyer

Name of Organization: Western Michigan University Homer Stryker MD School of Medicine

Type of Organization: Not Applicable

Role: Organizational Official

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: Foundational/basic research: Issue a strong message to study sections that applications that seek funding to reproduce previously generated data (even on a smaller scale) either by the original investigator or others as the first step to an extension of research is not just acceptable but desired.

Clinical research: Actively fund research that reproduces clinical trial results either in a key subgroup or uses the experimental arm intervention as the control in a subsequent trial.

Health services research: Require all funded studies in large health services data sets to perform the same analysis in a similar but separate data set, either domestic or international.

2. Data, Software, and Model Sharing: Foundational/basic research: Construct a central, national repository for data generated by NIH-funded research (and perhaps non-NIH-funded researchers) that is accessible to other legitimate researchers. This repository should be searchable and include detailed methods and results.

Clinical research: Work immediately to define standards to make patient data acceptably anonymous to encourage clinical data set sharing between institutions. A central repository would be ideal, but this first step will allow easier sharing without resorting to one-by-one data use agreements.

Health services research: Fund projects that seek to devel tools that allow for easier bridging of health services data sets, for example, between COSMOS and HCUP/NIS.

3. Training and Mentorship: No matter how you cut it, the most important indicators need to be intermediate to long term (5+ years) after training stops. Measuring output (publications, etc.) during training is slightly helpful, but very dependent on the mentor. The best measure would be likelihood of trainees from a specific program staying in academics at the 5 and 10-year post-training mark. To have a trainee be very productive during training but not pursue an academic career is a fairly wasteful result, since an alternate trainee that was less productive during training but had a prolific academic career afterwards would be a far better outcome.

4. Collaboration: There needs to be some recognition in funding mechanisms that PIs in multi-PI efforts all contribute a great deal, and not that their salary support is just a division of the traditional 20% salary

support for a PI. For example, if an award historically might have a single PI at 20% effort, it does not mean that research in the same area with four PIs as part of a multi-PI project should result in 5% effort for each PI. One way to work toward this is to have a smaller number of awards but increase support for legitimate work done by each PI in a multi-PI grant.

5. Entrepreneurship and Translation: Take away the required business partnership in SBIR/STTR applications IMMEDIATELY. There are thousands of excellent ideas in the device space that could easily be prototyped in an academic/university setting with the goal being to sell the IP to a commercial entity. Currently, the hardest part in device development is not developing the device, but having to establish a company, find a company as a partner, or spin a company out of a university before applying for NIH or NSF funding!

6. Foundational Scientific Exploration: Be very, very careful when constructing review panels for funding applications that are meant to lead to new "bold and innovative research directions." If the reviewers all represent mainline, historically successful institutions, the panel will fund mainline, historically accepted ideas. Representation from non-traditional and newer organizations would help a great deal.

7. Public Impact: Fund more prospective, multicenter trials with reasonable reimbursement. The New England Journal of Medicine, Lancet, and JAMA are filled with high-quality trials from Canada, Europe, Australia, and Asia and very few from the US and even fewer NIH-funded trials. This is especially true for studies that do not include novel therapeutic agents. Trial data from North America are, far and away, the most influential in terms of clinical practice and public trust.

8. Other Areas: N/A

13. Alice Berger

I am responding: On behalf of myself

Name: Alice Berger

Name of Organization: Fred Hutchinson Cancer Center

Type of Organization: Non-Profit Research Organization

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: In my view, there is a natural selector for rigor and reproducibility in our scientific system, and explicit reproducibility studies are not needed. For truly impactful research (think of CRISPR), the field quickly moves to replicate and extend the finding. The citation index of the individual paper that reported the advance therefore provides a reasonable indicator over time of how impactful and reproducible the work was. Alternative methods for quantifying the degree to which the finding was externally validated or extended could be considered, but I think citation index is reasonable.

2. Data, Software, and Model Sharing: the pros of data, software, and model sharing is that we can ensure usefulness of these products after their production. The con is that this takes time and money. If these data sources, software, or models, are not broadly useful, then the resources needed to share these products are not worth the cost. I think a great success is the GEO database, which makes it reasonably easy for investigators to share data. Continued investment in GEO is recommended.

3. Training and Mentorship: Training and mentorship is very important, but there seems to be a great emphasis on "training" in biomedical science than in other career paths such as tech. Sometimes I wonder why we treat 35 year old post-docs as "trainees" rather than full individual scientists. I think this is worth discussing. At what point does training end and doing science begin?

4. Collaboration: A collaboration metric could be developed to quantify how much of a person's research portfolio is collaborative. This would allow tracking and analysis to understand how collaboration impacts scientific productivity.

5. Entrepreneurship and Translation: N/A

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: The best indicator of rigor and reproducibility in research, is when other laboratories independently confirm your findings and successfully apply your methodologies to their programs. Publication in the highest impact journals doesn't necessarily convey rigor or assure reproducibility. In fact, too often, high impact journals - in their rush to publish articles they deem will serve as the highest click bait - are obliged to offer retractions. Research that stands the test of time, and significantly moves one or more fields forward, is the best reflection of rigor and reproducibility.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: I actually think the problem is you are often funding the same intervention over and over that has no real-world value. Focus on real world value. Who cares if it is reproducible if it has no real world value.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: Right now it feels like it is K award or bust for an ESI. You also give most of your ESI grants to the same people, doing

4. Collaboration: Have team science based grants. That will solve your problem. Right now, you make Multiple PI proposals more burdensome, instead of facilitating or rewarding them.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: You need to fund more innovative digital health (extended reality, AI, etc.) That is the future. Most of what you fund is too dated. Stop funding dated research. That will require getting new people in the study section who value real innovation.

7. Public Impact: N/A

8. Other Areas: Stop funding the same JTAI and text messaging studies. Stop just funding elite researchers who have no real connection to real-world problems or needs. Stop funding useless DEI research. Start funding stuff with more real world application. Your study sections are too biased for certain research approaches that carry very little real-world impact. Start funding for the future: extended reality, AI, digital health. Most people outside of academia would be shocked by the silly stuff that NIH funds and confused by the more practical things it doesn't fund. Also, stop funding research that is just about giving people free stuff. That is not practical in the real world, yet you keep on funding it.

16. Timothy Robinson

I am responding: On behalf of myself

Name: Timothy Robinson

Name of Organization: Yale University

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: early phase studies in humans (phase 0/1) could provide less artifactual study findings that arise due to nuances of in vitro artificial systems.

2. Data, Software, and Model Sharing: Novel methods should be judged on whether other people actually use them.

3. Training and Mentorship: There is little to no reward these days for being a good mentor or being a good teacher - in fact quite the opposite. Training grants that provide some mentor support would be a great idea.

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: In oncology, there are too many preclinical studies being performed with models that do not reflect human physiology and immune systems. These can be helpful, but there needs to be a dramatic shift towards emphasizing early phase 1 / phase 0 trials that are directly exploring actual human physiology and cancer. This can be done through non-invasive, low-risk imaging and other correlative approaches. These have tremendous potential to directly learn about REAL human cancers. Some animal models have been studied for decades and then when they are attempted to be translated into humans - they don't work. Preclinical science is critically important, but early phase 0/1 trials are EQUALLY critical for understanding tumor biology - not just for trying a new drug.

8. Other Areas: N/A

17. Colin Reardon

I am responding: On behalf of myself

Name: Colin Reardon

Name of Organization:

Type of Organization: Not Applicable

Role: Member of the Public

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: Although I am an academic scientist at a public university, I write today as a concerned private citizen. Rigor and Reproducibility has always been part of science in this country. It has fueled incredible growth, prosperity and provided new advances in health care. These continued efforts and a "gold standard science" agenda seem to suggest that we haven't followed a mantra of ensuring our results are correct, and that we in the scientific community do not seem to care if our conclusions are correct. This would seem to be opposite to the stated goals of reassuring the public. There is indeed a disconnect in our country when those who deny the value of vaccines, or suggest that new technologies that have evolved over 20 years of careful peer reviewed science are not safe, but that colloidal silver or Ivermectin will cure many conditions. This administration and the leadership at HHS is destroying our standing in the world, and handing over our future to geopolitical rivals.

2. Data, Software, and Model Sharing: Increasing the amount of meta data as part of data sets would be welcome. too often one finds samples labeled in a simple manner that do not allow reconstruction of analysis. The efforts to data have been good though. improvements could look to simplified viewing of data such as in cellxgene for scseq to more rapidly determine if the data set is useful.

3. Training and Mentorship: N/A

4. Collaboration: The limitations on the number of applications per cycle have curtailed our ability to collaborate. the administration seems intent to cherry pick some small number of investigators and punish the rest of the community. You are having the exact opposite effect of your stated goal.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: Again the limits on submission for these applications means that I will no longer apply for R21 or other types of these applications. you are incentivizing the community to submit only safe applcaiton for standard competitions.

7. Public Impact: It is truly amazing how this country can lead the work in number of therapies developed, operation warp speed, and to see this question asked. if you think the public distrusts experts, the administration could start by not demonizing public servants that dedicate their lives to the American people.

8. Other Areas: N/A

18. Francis O Walker, MD

I am responding: On behalf of myself

Name: Francis O Walker, MD

Name of Organization: Wake Forest School of Medicine

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: 1) Reproducibility: At the time of funding, studies should be divided into those that can be replicated cost-effectively and those in which rigor can be cost-effectively assessed. For example, many biomarker studies can be easily replicated, as can drug trials in animal models. A replication RFP should be put out for a percentage of such studies, which would simultaneously fund another lab to replicate the study, ideally before the results of the initial study is funded; obviously confidentiality and shared resources would be required. The knowledge that a study is likely to be undergoing a replication effort would help ensure rigor as well as accuracy, and the process would be instructive for reviewers.
2) Rigor: Using the above criteria, put out an RFP for key aspects of a study amenable to testing of rigor. A biomarker could be tested for reliability, and/or metabolites from an animals blood stream or urine might be able to validate drug/placebo dosing. Studies producing a new antibody, compound, or proposing a new technique might be amenable to having one or two aspects of the study validated in a second laboratory. Again, confidentiality and shared resources would need to be required. The knowledge that some aspects of a study's rigor were undergoing validation would help ensure reproducibility of findings.

2. Data, Software, and Model Sharing: no suggestions

3. Training and Mentorship: no comment

4. Collaboration: no comment

5. Entrepreneurship and Translation: no comment

6. Foundational Scientific Exploration: no comment

7. Public Impact: This needs some exploratory work. If one looks at citations, it reflects what academicians are reading and using. One needs to survey practicing physicians to see what new technology has significantly changed their practice and the care of their patients. Experience designing and interpreting such surveys will take a few years, but in the long run will probably be the most informative way to sort this out.

8. Other Areas: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

8. Other Areas: Is it possible to use AI to do these evaluations? In principle, if human evaluation data are generated for a significant number of cases (need to ensure the data is fair and no biase), they can be used to train AI to do the work. It should be better than relying solely on pub #, citation #, and grant amount.

21. Dmitry terentyev

I am responding: On behalf of myself

Name: Dmitry terentyev

Name of Organization: The Ohio State University

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: In my opinion, one of the biggest problem with reproducibility and rigor is that follow-up studies are not encouraged and not funded. The race for innovation makes it impossible for the researcher to spend time an invest financially to test whether study published earlier can withstand a challenge with refined/novel experimental approaches/tools. Furthermore, more meticulous experimentalists are getting punished in the environment with shortened grant cycles and overall attitude favoring fresh, exiting, and borderline scandalous stories vs boring tedious data collection. There is a massive internal conflict between fast and rigorous, between exciting and meticulous, between deep diving into the problem and jumping between research fields. So, if my research withstands scrutiny and repetition for almost 30 years, I do not think it's a good idea to punish me for being "boring".
Indicators: High quality publications in journals with rigorous review process is the strongest indicator of researcher's scientific "value". Sure, they might not be cited a lot, but review process must be rigorous. For example, it is hard to publish both in Circulation (IF40) and Journal of Physiology London (IF4). The review process in Journal of Physiology is more rigorous than in Circulation whose impact factor is an order higher.
Publications cannot be discounted as a measure of researcher's productivity. I see more and more scientists who do not publish at all and spend all their time writing grants. In recent years these grant-writers became significantly better funded than researchers that regularly publish their findings. If you publish something - it is not novel-exiting anymore. So you cannot finish this line of research because you will not get funds already distributed to people who intend to hold their finding unpublished for decades.

2. Data, Software, and Model Sharing: It is questionable how much data sharing can help validation of the results. The parallel independent studies of the same problem can have much better outcome for correct solution for a specific problem. There is no doubt that collaboration is good. However, grant reviewers often see too many Co-Is as a major weakness. Furthermore, collaborators need to get paid, which is not feasible with current acceptable grant budget limits.

3. Training and Mentorship: N/A

4. Collaboration: Increase in PPG grant funding could be a good solution

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: High-risk high reward research still have to be balanced with improving our understanding of fundamentals.

7. Public Impact: N/A

8. Other Areas: N/A

Description: Several opinions

22. Daniel Herschlag

I am responding: On behalf of myself

Name: Daniel Herschlag

Name of Organization: State Farm

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: The emphasis is wrong. We are wasting much time and effort trying to reproduce 'old' results instead of ensuring that results lead to models and that THOSE models get tested --that's the most effective way to test the validity of prior results while moving science forward.
And the best ways to do this are to remove the reward structure for publishing in Science/Cell/Nature and to fund (much) more research so that scientists can explore their ideas of interest and are not incentivized to come up with 'big' results that are often (typically) marketing exercises that do not move a field forward as much as oft-derided 'incremental' advances do.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: Hard or impossible to have one assessment for this --but limiting lab sizes (say <=12) is generally a good idea.

4. Collaboration: You should fund it (at NIGMS) instead of expecting MIRA awardees to collaborate with no funds to work with --this is unrealistic and a disincentive. Removing program project grants several years ago while stating that collaborations are important was, at best, a mixed message. Change happens through funding, which there's not enough of and too much is targeted rather than the fundamental or exploratory, which will fuel science decades into the future.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: They don't have to bold to be of value. They do have to be well grounded and creative.

7. Public Impact: It is good when we know more.

8. Other Areas: N/A

23. Paul O'Connor

I am responding: On behalf of myself

Name: Paul O'Connor

Name of Organization: Medical college of georgia

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: Peer review does not and cannot examine the quality of data. Institutions need to take more responsibility in verifying researches work.
While reproducing everything is cost prohibitive the main findings where possible should be reproduced. Perhaps basic scientists could pre-register with their institution critical studies for a manuscript (I.e main figure). The institution could then verify best practices were followed and the quality of raw data. Validate no data points were excluded/based on animals entering/raw data /blinded analysis etc. These types of figures would then hold extra weight at publication.

Even replication by other labs is prone to confirmation bias.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: A bar exam for scientists testing principles of experimental design rigor and reproducibility. These concepts are often lost in graduate school and many now are legitimately unaware their research practices are below par - bending the rules makes publication and career advancement easier and (my feeling) is that this has crept into (normalized) in lab training. Fooling ourselves is the easiest thing to do but very few labs emphasize how to avoid in practice anymore. Teaching how to avoid bias needs to be explicit at all graduate schools and is generalizable and easily testable no matter the topic. If they don't have already, NIH should develop a training module similar to others (university of Glasgow) and test knowledge of people applying for funding. There will still be people bending the rules and producing less rigorous science but they could not claim they are unaware and more likely to be called out by others with training.

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: There is nothing inherently wrong with animal research. Most drugs that work in humans do the same thing in animals. The problem underlying translation (IMO) is 1. It never worked (even in animals) due to bias/fraud 2. The animal model does not fit the disease.

7. Public Impact: N/A

8. Other Areas: N/A

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: Each grant currently must provide resource and data management sharing plans, but adherence to these is not reported in a way that can be tracked over time. Incentivization can include "scoring" the extent of sharing to common NIH-supported repositories that require specific formatting to facilitate secondary use, with that score being associated lifelong to an investigator. This could serve as an internal metric that can influence funding decisions.

Team science can be encouraged, with reviewers recognizing synergistic studies that would encourage data and resource sharing as a part of the review process.

3. Training and Mentorship: Reports of training is currently under-reported in progress reports. Similar to training grant applications, a table of training opportunities and successes could be integrated into grant administrative review, with scores rather than Yes/No as an output.

4. Collaboration: Equal contribution publications are currently not tracked or equally recognized in promotion and tenure considerations. Finding a way to highlight or quantify this would be a start in the right direction.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: The majority of grants and papers revolve around "proving" the proposed hypothesis. Explicit discussion of the scientific merit of supporting or refuting a given hypothesis can be an enforced expectation as part of experimental design and alternative outcomes in grant applications and publications.

7. Public Impact: Current public information about funded grants is found in RePORTER, which only states what is EXPECTED to result from a given grant application. An additional section in RePORTER could be what was successfully accomplished from this grant that could be readily searched and highlighted in the media.

Additionally, RePORTER is difficult to absorb as a member of the general public. Adding an AI link to RePORTER that provided an overall summary of the studies (and/or resulting publications) for a given search, with outcomes that support or refute a particular subject, would be a helpful resource.

1. Rigor and Reproducibility: When one is fostering trust, my first comment is that I was reluctant to put my name down and just skip this -The culture of fear has now landed and even responding here evokes concern. That said, I would offer the reproducibility and replicability in research are part of the scientific method, but mandate it within a grant rather than via independent replication is a tainted approach. It doesn't focus on others being able to replicate the work, but is asking the researcher to validate themselves. Certainly there are times when this is appropriate within studies, but so many NIH studies are underpower (in reality) because of funding limitations, the power to even detect lack of reproducibility or replication is interpreted as success. No one can really argue this is bad as a principle, but as a mandate it makes little sense - it is a goal; it should occur; but one size fits all is often the solution by NIH which creates misapplication of resources that could be directed at more realistic effect sizes.

2. Data, Software, and Model Sharing: The simplicity of the idea is not matched by the complexity of data and data management. There are many decisions that are made to perform an analysis, but the demands and ability to achieve appropriate documentation is diminished by a lack of funding. It is getting increasingly worse as more and more researchers use RedCap for their data management. It is a wonderful tool, but creating a dataset that can be used to elicit replication of someone's results is simply not paid for by NIH. FDA addressed this problem to a degree by mandate CDISC file creation. An excellent concept, but the cost of which can be borne by industry is simply not affordable within academic settings. There may be ways to make it affordable, but just making a CDISC file in industry can cost over 250k.

One potential for high value research projects is to provide funding to faciliate this as a last step when it is determined that a dataset is high value.

Another aspect of deterrence sharing is that when investigators are contacted to provide data, IRBs have to weigh in and approach even though the data are already in the public domain. One potential solution would be to exempt all data that has been made public from local IRB oversight.

3. Training and Mentorship: The simultaneous push to limit the number of RPGs per investigator isgoing to diminish this mentorship rather than enhance it. The funding formula would allow for more time for a PI and less for CO-Is, but as restrictions are placed on the 10% of grants that exceed 2 RPGs and replaces them with other investigators, the support for mentoring will be diluted. Mandating mentors on grants

ends up assigning or "rewarding" grants that include these linkages, but what is the probability that true mentoring exists - meetings might occur, but there is much more to mentoring that mandating the illusion of a mentor.

4. Collaboration: Collaboration and collaborators are generally easy to recognize. Rather than try to create assessments, using H-indices, multi-authored papers with varying position in the authorship as well as appearance on grants and contracts can easily be quantified. Using existing data of course favors older researchers because they tend to be better known and accessible than younger individuals. This interconnectedness can be measured, but won't this disadvantage younger investigators? Further does this enhance recognition for teams, but at the expense of potentially the quality of the isolated work horse.

5. Entrepreneurship and Translation: Science moves at varying paces depending on the disease or topic - Many institutions put too much burden for commercialization on the investigator, thus incentivizing this aspect of translation is a balance between the risk aversion of the institution, the way rewards are shared and an understanding that many developments are way ahead of their time. We wouldn't want to focus on short term gains or translation at the expense of the value of the unknown, but new or innovative.

6. Foundational Scientific Exploration: NIH has been called the institute of logistics which inhibits foundational scientific exploration trading ideas for implementation details. This is going to have to be large efforts at the reviewer level. Too much of reviews are focused not on the long term, but is the biosketch the right version, did they address the data monitoring and all the other mandates that allow for concrete criticisms, but maybe miss the downstream implications.

7. Public Impact: This is a two edge sword in this hyper partisan environment. Old methods of distribution of knowledge are fragmented and picked apart as to a point that enriching public impact is going to take enormous efforts at educating the public. They need to understand several key factors of research - failure is an option and it often more important than succeeding as it leads to better understanding. The media hype of major advances when the impacts are incremental and often small needs more visibility. NIH is so large and houses so many thousands of research results, it will be hard to make the general public realize the balance of success and failute.

26. yin chen

I am responding: On behalf of myself

Name: yin chen

Name of Organization: University of Arizona

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: NIH could create a dedicated grant mechanism, or periodic RFAs, to support independent replication and verification of key biomedical findings identified by NIH program officers, advisory groups, review panels, or the original investigators themselves as highly influential, clinically important, or central to future NIH investment. This would be especially valuable for findings from human clinical and translational studies, which are often difficult to replicate because they depend on unique patient cohorts, limited biospecimens, specialized clinical data, or complex analytical pipelines.

The original investigators could participate in or even initiate such replication applications by providing protocols, reagents, datasets, biospecimen access, or scientific context, while NIH-supported independent examiners, validation cores, or third-party replication teams would provide objective verification, similar in concept to independent monitoring or adjudication in clinical trials. Such a mechanism would not be intended to criticize original investigators, but to strengthen confidence in high-impact findings before they are used to guide clinical trials, therapeutic development, diagnostic decisions, or major follow-up investments.

2. Data, Software, and Model Sharing: NIH could strengthen incentives and infrastructure for data, software, and model-system sharing by designating a set of NIH-approved, searchable repositories for raw data, analysis code, software tools, protocols, and model-system information. Many tools and repositories already exist, but they remain fragmented, inconsistently used, and difficult to search across. NIH could build or designate a PubMed-like discovery framework for research outputs beyond publications, in which datasets, code, computational pipelines, animal or cell models, reagents, and protocols receive persistent identifiers and are linked to grants, publications, and investigators.

3. Training and Mentorship: No Comment

4. Collaboration: NIH could leverage the recent removal of the prior-approval requirement for applications requesting $500,000 or more in direct costs to encourage more ambitious team-based science. Large interdisciplinary projects often require multiple investigators, shared infrastructure, and complementary expertise, but current metrics still emphasize individual productivity. NIH could use this policy change to reward well-justified collaborative team science.

5. Entrepreneurship and Translation: no comment

6. Foundational Scientific Exploration: NIH may create additional mechanisms to reward groundbreaking foundational science, while distinguishing bold, evidence-informed exploration from unsupported speculation. The current “no preliminary data required” concept can be confusing. High-risk research needs to be innovative and paradigm-shifting, but still built up on prior observations, conceptual plausibility, or limited supporting data. Because review of groundbreaking ideas depends heavily on human judgment, NIH could consider partial anonymization, broader reviewer pools, and inclusion of international experts when appropriate. These approaches could help NIH support unconventional but achievable science more fairly and rigorously.

7. Public Impact: no comment

8. Other Areas: NIH may also consider grant review reform as part of measuring and rewarding scientific impact. For example, NIH could consider a mechanism for applicants to respond to factual errors or clearly unsupported critiques before final scoring.

27. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: Areas ripe for replication and reproducibility efforts can best be determined by active researchers. Congress rightfully assigns funding to broad areas of biomedical research and application, but funding decisions about specific areas must be made by experts in these areas. NIH's peer review system is well suited for the task.

2. Data, Software, and Model Sharing: Large data sets allow investigation of complex processes, but the use of data collected by other teams cannot excel in rigor and reproducibility. Small scale studies with full control of relevant variables are needed. Funding must be provided to both approaches.

3. Training and Mentorship: Usually, the better the training, the better the results. But trainees are not all equal, and more qualified trainees can achieve more by receiving better training. If the goal is to train the best biomedical personnel, success can be measured by measuring the later achievements of the trainees.

4. Collaboration: Some questions require collaborative research groups, but other questions are better addressed through small groups. Success should not be measured by the extent of contribution to team-based science.

5. Entrepreneurship and Translation: Entrepreneurship is valuable, but basic research is essential. There is plenty of snake oil in the biomedical marketplace. The current balance between basic research and translation in the NIH and NSF is appropriate. This is not an area that needs change.

6. Foundational Scientific Exploration: Yes, innovation is a cornerstone of biomedical research. The current peer review system at NIH includes two main components: Significance/innovation and Rigor/feasibility. Scores for the first component are considered fundamental and can only be made worse by scores for the second component. Thus, high-risk high-reward initiatives are already being emphasized in the review of grant applications.

7. Public Impact: Because clinical practice involves much more than the direct application of scientific knowledge, it is difficult to evaluate the true public impact of biomedical research even many years down the road. Rigorous clinical trials are extremely helpful, even if applicable only to a few situations.

8. Other Areas: No comments

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: Independent reproducible data generation is an excellent approach. Getting others to confirm one's findings during this phase will be most useful and democratic.

2. Data, Software, and Model Sharing: Sharing of data generated saves duplication of effort and dollars spent for the same data.
Sharing also exposes the PI to others. A very important step in sharing knowledge for the greater good.

3. Training and Mentorship: This should also be done for SBIR/STTR funded projects. This way scientists/entrepreneurs can be developed in today's fast paced AI world. The world is now accessible to everyone and that has increased the pace and reach.

4. Collaboration: A team based approach to investigation will yield faster and authentic results. This will enable meeting the objectives of NIH and use the taxpayer funds effectively.

5. Entrepreneurship and Translation: With AI this has to be the area to focus and fund. This technology is making every global potential participants. With internet and video calls etc the number of researchers who can and will participate has exploded. We must take that into account or loose the initiative in new ideas to others who are just waiting . WE MUST CHANGE OUR PRIORITIES .

6. Foundational Scientific Exploration: Universities will always lead this early theoretically based investigations but data sharing will reduce the waste of time and money.
New ideas will mushroom faster and with gl9bal access this has the potential to transform the way we livea and enjoy our environment.

7. Public Impact: There has to be someway to relate or quantify dollars spent and the outcomes of each research funded. Positive or negative data. Etc.

8. Other Areas: Applying AI to glean and develop models will further enhance the pace of using data in new ways to get new and fast interpretations of the same. There has to be the outcome as the tool to judge effectiveness of dollars being spent.

29. Andrew Belmont

I am responding: On behalf of myself

Name: Andrew Belmont

Name of Organization: University of Illinois, Urbana-Champaign

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: Generally, important discoveries have always been expected to be followed by confirmation by others. In basic science, if results can not be confirmed, then ultimately over time the field will question the discovery and challenge what can not be repeated or what is inconsistent with the older discoveries.

The challenge is more for where there is large investment in translational research or commercial applications and certainly medical trials.

But I am worried about over-reacting to the point that funding that supports new discoveries takes a major hit in order to fund disproportionally replicate studies.

The important point is to support many avenues of research, rather than the field converging on just one view point. What happened in the Alzheimer's field is a good example where funding went excessively to one particular theory of the disease. I would say the problem here was not the lack of replication of the one dominant paper that led to this, but rather the subsequent assumption that all funding should be steered towards one model of the disease.

2. Data, Software, and Model Sharing: I believe this train has left the station. Journals increasingly are asking for deposition of these data sets as a requirement for publication. In genomics, people already recognize the contributions of scientists generating the large data sets and those that focus on analyzing these data sets.

What might be helpful is ensuring more stable long term support for the data repositories. For example, in my laboratory we have placed a great deal of data on the 4D Nucleome Data portal. Right now there is free hosting by Google of much of the data and the data repository is still there. But we are now depositing past data also in GEO in case this data repository goes away due to lack of funding.

Having funding to maintain the life time of the data repositories is a major challenge that should be addressed.

3. Training and Mentorship: I don't think NIH needs efforts for "promoting the growth and stability of the biomedical research workforce". The goal of NIH should be maximizing research output as a function of tax payer dollars- not creating a secure job for scientists. The two are related but not exactly. Job force

stability should be promoted to the degree that it maximizes output but it should not an end in itself.

1. In NIGMS they have pushed the idea of sustaining the maximum number of scientists rather than maximizing the scientific output. They have argued that these are the same based on studies that have tracked output per research dollar.

However, I would ague that their analysis is fundamentally flawed and may be wrong. The argument has been that the number of publications or the total number of citations per research dollar actually declines at high levels of funding. However, the number of publications or total number of citations I would argue is a poor metric of scientific impact.

As Erin O'Shea once said during a NIH study section, "We are not farmers, that should be maximizing yield per acre" - ie number of publications. We should be maximizing new, highly impactful scientific discoveries, which does not scale with number of papers.

More specifically if you compare top University departments with average University departments the number of citations per Professor does not vary that much. Also the h-index of faculty doesn't vary that much. What does vary is the number of HIGHLY CITED papers. This has been shown in publications. Whereas the number of publications or h-index may vary by small amounts (ie ~30%) from the top department to top 30 department, the number of papers cited 100 times or 500 times or 1000 times varies several fold.

Thus there is an important analysis that needs to be done before NIH moves to much in this direction. If you repeat the study about impact per research dollar, how would the results change if you use as a metric the number of highly impactful papers rather than number of papers?

2. It needs efforts for stabilizing overall funding from year to year. The switch to multi-year payouts for new grants from the budget year in which these grants are approved conceptually is a good idea as it will significantly buffer the impact of small changes in funding from year to year.

However, its sudden implementation is on the shorter term absolutely decimating American biomedical science as we make the multi-year transition to the new budget model. Many of us will not survive this transition.

4. Collaboration: Encourage journals to require more paper specific descriptions of each author's contributions to the final research paper. Right now many journals use generic categories- ie "Conceptualization, Funding, Methodology, etc" which provides essentially no real information about each person's contribution.

Much more meaningful would be to describe each author's contribution to each Figure or experiment described in the paper.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: I don't believe NIH actually believes this- at least NIGMS. If they did they would reverse directions in which they have limited investigators to a single grant and even a

single grant application.

The message I am getting from NIGMS to younger investigators is that they can start with a a NIGMS grant as a new investigator, but then to grow their research program in the future they will need to mature by applying for funding through other Institutes for translational work.

It used to be that young investigators with creative and innovative ideas could rapidly grow their research programs by securing a second grant on a different or related direction that would allow them to build rapidly on new advances. Now with the idea of MIRA grants, etc, they are limited in the growth of their research program to incremental growth every 5 years with their MIRA renewal- but no faster.

This is terrible as it doesn't recognize the innovation does not occur steadily but in bursts. The current NIGMS model prevents exploitation of new advances which frequently occurs with new investigators who are more creative and have newer expertise, etc. In the past young investigators could create entirely new fields of research over 5-10 years of establishing their own laboratories. But the NIGMS new funding mechanism prevents that for investigators focused on basic science;.

The hidden message seems to be that basic research is no longer valued relative to translational, disease-oriented research.

7. Public Impact: N/A

8. Other Areas: N/A

30. Iraida Sharina

I am responding: On behalf of myself

Name: Iraida Sharina

Name of Organization: UTHouston McGovern MS

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: Absolutely agree: No science exist without proper statistical analysis and reproducibility.

2. Data, Software, and Model Sharing: It is also necessary to introduce reasonable rules for data reuse—similar to citation or authorship—to create a clear incentive for research groups to share their hard-earned data. Furthermore, commercial data usage must be addressed. Paying a dividend to the original source for using critical information would be fair; if the music industry can implement such a model, the scientific community can too

3. Training and Mentorship: Turnover rates for faculty and, especially, research assistants serve as strong indicators of workplace stability. Currently, retaining supporting research personnel is exceptionally difficult because their salaries rely on extramural grants and are inherently temporary. This instability is highly disruptive to preserving a research group's technical expertise and legacy.

4. Collaboration: Scientific collaboration is vital, but it becomes highly complex when funding, labor distribution, and credit are involved. The NIH could significantly enhance collaborative efforts between research groups by establishing clear guidelines for participation, funding distribution, and authorship within specialized collaborative grants.

5. Entrepreneurship and Translation: I agree that patenting critical data is a powerful incentive for research. However, a major challenge is predicting which data will ultimately lead to a successful end product. In some cases, it might be more effective to reward innovation retroactively—identifying and honoring the pioneering groups that contributed most to a specific technological or medical advancement.

6. Foundational Scientific Exploration: I absolutely agree. However, this must be done in a balanced way, as there is a growing tendency to favor short-term, profitable, applied projects at the expense of fundamental, basic research.

7. Public Impact: The United States has a highly successful history of funding public-interest medical research, as demonstrated by landmark advancements in cancer research and treatment. This targeted funding model should be maintained and scaled to address other critical public health and epidemiological challenges, including cardiovascular disease, healthy aging, maternal health, and neonatal care.

8. Other Areas: It is absolutely vital to insulate science from political influence. Political interference can rapidly dismantle decades of established scientific thought and legacy, ultimately dealing a devastating blow to the training and development of the next generation of scientists.

31. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: Research laboratories are increasingly struggling to maintain the baseline funding required to sustain their programs. This challenge is particularly acute for Select Agent (SA) laboratories and others that must comply with additional layers of biosafety and security requirements, which are both costly and time-intensive. As the regulatory tier increases, so too does the complexity and burden of compliance.

For these laboratories, securing sufficient and stable funding to continue their work—already subject to rigorous oversight—has become progressively more difficult. Yet these facilities are essential for generating rigorous, high-quality, and reproducible data, particularly in the study of novel pathogens and potential pathogens. They possess the specialized infrastructure, technical capabilities, and expertise required for this work, and their core missions often directly support public health, economic resilience, clinical practice, public trust, and broader societal benefit.

Despite their importance, pursuing an academic career in this area is becoming increasingly unattractive. Some PIs also rely on “soft money” support, making it difficult to sustain stable academic positions. In addition, recruiting and retaining qualified trainees and staff and convincing them to build a career in a scientific area with so many restrictions is an ongoing challenge. Without meaningful intervention, academic SA laboratories will decline significantly—or even disappear—within the next 10–20 years, resulting in a substantial loss of critical biosecurity and public health infrastructure in the United States.

A viable solution would be the establishment of stable, long-term base funding mechanisms for these laboratories to maintain their specialized research programs. Such support would not only ensure continuity but also facilitate collaboration with other research groups, industry partners, and public health agencies, enabling rapid, coordinated responses to emerging threats—for example, the identification of a novel toxin serotype or the emergence of a pandemic-capable virus.

Importantly, sustained funding would also strengthen research rigor and reproducibility. It would enable independent validation of critical findings within the field and support collaborative efforts that ensure the use of appropriate and methodologically sound approaches. In doing so, it would reduce the risk of disseminating incomplete or constrained datasets that arise from regulatory limitations, and instead promote robust and reliable science.

In today’s highly competitive funding landscape, there is little capacity or incentive for investigators to prioritize replication, validation, or methodological rigor. Efforts aimed specifically at ensuring reproducibility are rarely funded and carry limited professional reward. Establishing funding mechanisms tied to already demonstrated, rigorous, and responsible research programs would both enable these essential activities and provide appropriate recognition for them.

1. Rigor and Reproducibility: establish a special discussion panel to identify the important results from the PIs that hold multiple grants, either concurrently or in series. The panel officer can then contact the PI for detailed methodology, testing models etc.. The officer can then contract internal or external groups that possess similar expertise to repeat the experiment, and report to the panel the results. If the results are consistently reproducible, the group will be labeled and be subjected to a different criteria of grant award, such as awarding at score of 20% instead of regular 10% score. IF the results are confirmed not reproducible, then a penalty 5% score can be applied to that PI instead of regular 10%.

34. Herbert M Sauro

I am responding: On behalf of myself

Name: Herbert M Sauro

Name of Organization: Univesity of Washington

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: My area of work is supporting the reproducibility of computational models in systems biology through publishing best practices and providing technological solutions in the form of grass-roots driven standards for model exchange and representation. We are also pursuing a similar strategy to develop a grassroots standard for describing computational experiments in a reproducible manner. These standards are designed to allow persistence of both models and reproducibility of experiments over a 20-year time frame.
A comment on terminology: In computational modeling we define repeatability as the ability of a user to repeat their own work and reproducibility as the ability of a third-party to recreate what was done. I assume the technical terms you are using are from the National Academies report. The panel that wrote that report did not have any biologists or molecular biologists, and so the language they use doesn't always match what the biological community, or in fact other disciplines, use in practice.

In order to encourage reproducibility, which is the most important of the two, the best mechanism is to provide incentives. One such incentive is that it has been recently shown that authors who published reproducible models (using our approaches) get cited more often. The simple reason is that reproducible models can be more easily reused. Another more forceful approach would be for the NIH to demand that the computational models be deposited at a central location (such as NLM) and would have to be reproducible in order to get, say, a NLM DOI.

As for rigor, that is served by peer review. However, because of the extra activities scientists have to do today, peer review is given less attention than it should. In addition, journals now require very fast turnaround, which is not consistent with rigorous review. When I was a postdoc and a graduate student, my supervisor would spend up to a week reviewing a single paper. I suspect that rarely happens today.

2. Data, Software, and Model Sharing: Model Sharing: In systems biology, the sharing of models is largely a solved problem, provided researchers use the established open standards such as SBML. It is estimated that over 50% of published models now use this standard, which has resulted in the establishment of large model repositories such as Biomodels. In addition, all genome-scale models use SBML and large repositories of such models now exist. The use of SBML has had a significant impact on both reproducibility and access to published models. In addition, any model in SBML can be more easily reused in future work, preserving the investment made by the NIH and other agencies. The human-readable form of SBML, called Antimony, is also well-suited for AI use, and the most well-established AIs

understand Antimony very well. SBML has one other significant advantage: it stores the biological information alongside the quantitative aspects of the model. Models represented as pure mathematical equations lose the vast majority of the biological information from which they were derived; SBML does not. In practice, SBML compilers exist that convert the SBML into a target execution language such as C/C++ , Python etc.

There are researchers who continue to use executable formats such as MATLAB or other programming languages to publish their models. These models are largely inaccessible, cannot easily be reproduced, and cannot be reused without considerable effort.

While there is an established model-sharing standard for subcellular models, very little effort has been devoted to developing other open standards for larger-scale systems, specifically multicellular, organ, whole-body, and even population models. Part of the problem is that the NIH has never had no funding program to support such activities.

Interestingly, during the pandemic, because infectious models were based on executable formats such as C, Java, etc, none of the models could be easily reduced or even understood by others. Later into the pandemic, some groups successfully used SBML to store infectious models. The episode illustrated the problem in publishing models as executable artifacts rather than in terms of the underlying biological systems.

Software Sharing: Software sharing has been largely solved with sites such as GitHub. Personally, I don't think there is an issue today with sharing software other than the researcher making the effort to make it happen.

Data Sharing: This is by far the hardest to problem to solve because of the huge variety of data types and the fact that new data types keep getting developed because there are new ways and new things to measure. I don't have a good solution to this.

3. Training and Mentorship: N/A

4. Collaboration: Collaboration is best done at the grassroots level, especially between graduate students and postdocs from different research groups. Such collaboration can be fostered by small grants to fund travel and accommodation, the NSF does this very effectively. The NIH instead expects us to go through a full grant proposal to request relatively large amounts of funding that are not necessarily required. Smaller funds ($20K-$20K) at more frequent intervals is far better for encouraging collaboration. Assessment can be done by the group writing *short* reports on what they accomplished, this could be structured in a way that would be easily digestible by LLMs. Over time a record of contributions could be created.

5. Entrepreneurship and Translation: As researchers we are always exposed to translation opportunities. The SBIR and STTR awards are excellent ways to help stimulate initial translation from the lab to the bed side. I hope that the NIH will continue these opportunities.

6. Foundational Scientific Exploration: Foundational research is the bedrock of all innovation and discovery, providing the start of a long pipeline from lab to treatments and technology. It has been one

of the great success stories of the US scientific enterprise of the last 80 years, and for whatever reason, it has not been replicated as successfully in other countries. The key to foundational research is that it should be undirected, meaning we should avoid placing biases on the direction of research because this will result in missed opportunities. The study of other organisms has resulted in a wealth of knowledge that has been translated to human biology and disease. A recent example of this is CRISPR, which started off as a curiosity-driven study of research into unassuming repeat sequences in bacterial DNA. Who would have known it could eventually lead to the potential to cure inherited disease? The development of AlphaFold relied on over 60 years of protein research to access the necessary training data. Foundational research plays the long game; discoveries 20 years ago may only now have an impact on the general population. This is why it is critical to maintain funding for foundational work, a break now will be felt 10 or 20 years into the future.

7. Public Impact: I would encourage researchers at universities and other institutions to make an effort to communicate with the general population on the work they do. Not all work of course will lead to immediate health improvements. However, the public is also receptive to research that is interesting and exciting from a scientific point of view if communicated well. Obviously research that is closer to the bed side will be of more interest but from my experience the general population is also interested in foundational work related to human physiology or how discoveries in other organisms can highlight similar process in humans. The general population also needs to be aware that research takes time, a single grant to study an autoimmune disease won't result in a cure in 3 years, but 100 grants over 15 years may.

Finally, universities in particular need to change their assessment criteria for promotion. When I applied for promotion, outreach was not a factor that was considered. This needs to change. In addition, any outreach mentioned in grant proposals is generally either ignored by panels or considered an weakness. That also needs to change. The more we communicate with the public the better.

8. Other Areas: Lighten the bureaucratic load on researchers. Most of this however comes from the federal and state governments so perhaps little can be done. Given the growth in paper work I estimate that within 100 years almost 100% of our time will be spend on bureaucracy.

35. Olivier Le Saux

I am responding: On behalf of myself

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: Here is my 2 cents. I my view there is more to this than how science is done but more systemic change also need to happen.

1- Data should systematically include larger number than n=3. I still commonly see n=3 and more recently n=2 with p values in a prominent journal !

- Peer-review should be strengthened to include rigor and reproducibility, model validation, etc...
- Faculty evaluation should evolve (perhaps return to the tenure system) to reduce pressure to publish AT ALL COST for continued employment, promotion and for extramural funding.

2- Analysis from cultures or animals shouldn't be divided into 3 or more samples but come multiple independent animals or cultures. Preferable not done at the same time/day/lab.

3- Blind analysis or double blind experiments and analyses whenever possible even in the most mondain basic science experiment.

4- Duplication and validation (of models) in another lab. Whenever appropriate, validate model with human data.

5- Anonymity for submitting authors and PI whether for publication or grants should be considered: see below in collaboration. I understand this would get in the way of the evaluation of the environment and feasibility in grant reviews. But reputation is a major bias in peer-reviews.

I have personally done 3 and 4 with various collaborators whereby we duplicated (whenever possible) each other's experiments during collaboration and obtained human data and/or samples.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: This notion should be expanded and engrained in graduate education.

4. Collaboration: As stated above, collaboration can be used as an essential tool for rigor and reproducibility but the mindset should change with respect to competition and data theft (this comes from experience and I am not alone here). I have published data (from my lab only) that I partially

question the reproducibility of, years later. Not that it wasn't rigorous at the time but subsequent results and exchanges at conferences make me wonder whether the model or the experimental approach was correct. Collaborating on this research would have been beneficial. Recently, an article was published that contradicts some of my published results. Here, I have confident in my data (multiple line of independent data) as it cames from 2 labs, animal models + validating human samples/analyses. This competing lab - despite prominent names on the publication - has a history of sub-par rigor in their publication.

Heavy weights in various fields should NOT receive an easy pass simply because of reputation or a long list of publications.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: perhaps some special NIH NOFO for data reproducibility should be developed and offered.

7. Public Impact: Better education and outreach of the public of what scientific research AND data entails. We, scientists, are sorely lacking on communication.

I found that the public (i.e. friends, social acquaintances) have simply no idea of what I do as a faculty and researcher and how I do it. I have given many talks in patients meetings and I can tell how hard it is from lay people to understand what 15+ years of education and training has taught us. Few lay person understand critical thinking, or that science is not a belief system.

A simple example far from biology: hardly anyone understands that there IS gravity in space, why? Simply because since Apollo, everyone has seen astronauts floating in space and thereby assume there is NO gravity. Appearance can be deceiving.

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: Publishing in peer reviewed journals is critically important for assessing rigor. It is important to have peers review the work. Presenting at national meetings with audience feedback is also helpful. Supporting “science of science” research through CTSAs is also important for knowing what works.

2. Data, Software, and Model Sharing: Central websites where data can be shared would be helpful. Data safety rules are key.

3. Training and Mentorship: Mentoring should be part of academic life. Instead of mentoring grants, how about a small percentage of effort added to grants for incorporating junior faculty as mentees and continuing the pipeline of research.

4. Collaboration: Effort for researchers on grants is key to encouraging collaboration. There should be support for clinician researchers so the health impact isn’t missed.

5. Entrepreneurship and Translation: Competitions with funding could help.

6. Foundational Scientific Exploration: N/A

7. Public Impact: More support for health services research and research on health quality is needed. This type of research can make significant impact. In addition, more support for clinician researchers is needed to make sure there is truly clinical impact.

8. Other Areas: N/A

37. Gregory A. Pesko

I am responding: On behalf of myself

Name: Gregory A. Pesko

Name of Organization: Harvard Medical School/Brigham and Women's Hospital

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: I strongly urge you to read Stephen J. Gould's "The Mismeasure of Man". It may keep you from making the same tragic mistakes that the people who developed the IQ test - and the people who misused it - made. There are two fallacies in your effort: the first is that something as complex and multifaceted as research success is susceptible to accurate qualification. This is called the fallacy of reification. The second is the fallacy of ranking, in which imperfect or inaccurate quantities are ordered and used as the basis for making decisions.

Do not fall into this trap. It is damaging to the United States's scientific enterprise and will lead to important issues of impact and quality being made by bureaucrats instead of by peers.

2. Data, Software, and Model Sharing: Same comment. Stop thinking you can measure what cannot be measured accurately.

3. Training and Mentorship: Same comment. Stop thinking you can measure what cannot be measured accurately.

4. Collaboration: Same comment. Stop thinking you can measure what cannot be measured accurately. Instead of trying to assess this, look for ways to incentivize it, such as promoting collaborations with foreign institutions instead of impeding them. Quality science is an international enterprise.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: These approaches are already embedded in the academic enterprise. The problem is that ham-handed attempts to judge research based on its concordance with the goals of the part in power will never be able to evaluate this kind of science properly. It doesn't have a political aim or even a practical end. It is driven by the curiosity of the individual investigator. It must be protected from political interference and from the mistaken notion that science must serve a practical purpose.

7. Public Impact: Same comment as the first section. You can't properly assess the broader impact quantitatively. It's like Potter Stuart's definition of pornography: you know it when you see it. The best approach is to have these things evaluated qualitatively by other scientists.

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/23/2026

1. Rigor and Reproducibility: To alleviate the pressure for investigators to publish only statistically significant results, NIH should host an electronic publication that allow grant awardees to publish all results, whether statistically significant or not, that were specific aims of funded grants.
For research results that are changing clinical/research practice and having significant impact, NIH should specifically fund studies to replicate the results if they had not be replicated already.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: NIH should develop indices to track translational impact of investigators and discoveries in terms of licensed patents, commercialized products, shared software, and resulting diagnostic and therapeutic procedures and drug prescriptions.

39. Jon A. Krosnick

I am responding: On behalf of myself

Name: Jon A. Krosnick

Name of Organization: Stanford University

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/24/2026

1. Rigor and Reproducibility: I am writing to propose two topics for future research efforts in this arena.

First, the basic problems of reproducibility and replicability of empirical findings are well documented. What is less understood are the causes of such problems. Any efforts to reduce such problems must begin with a rigorous understanding of the psychological, organizational, and cultural factors that cause the problems. And yet, remarkably little scholarship has been devoted to developing hypothesis about those causes and to rigorous testing of those hypotheses.

My colleagues and I proposed a model of the causal processes at work:

https://pubmed.ncbi.nlm.nih.gov/31565236/

Designing interventions to minimize problems of reproducibility and replicability will be significantly advantaged by tests of this model.

Secondly, I'd like to identify an important likely reason for failures to replicate: inattention to the process of sampling participants in studies of human subjects. For nearly a century, survey researchers have known that drawing a random sample of participants from a well-defined population allows for generalization from the sample to the population, even when response rates are considerably below 100%. But a body of accumulating evidence shows that recruiting participants for a study in a non-random way yields results that are routinely notably less accurate and that vary considerably from sample to sample.

Yet during these many years, the field of psychology, the field of medicine, and others have generated thousands of research studies with non-random, haphazard samples of participants. Because a huge body of literature shows moderation of effects by moderator variables (including characteristics of participants), there is a strong theoretical basis to expect that results of studies will vary from study to study if the participants are not randomly sampled from a single population of interest. Such variation can be responsible for the appearance of lack of replication, when in fact, the problem is lack of generalizability of findings across population subgroups.

This problem can be solved by implementing random sampling from well-defined populations for more

studies, even if initial, exploratory investigations employ haphazard samples. It is therefore worthwhile to document how replication rates increase when participant sampling is made more systematic.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

40. Aaron James

I am responding: On behalf of myself

Name: Aaron James

Name of Organization: Johns Hopkins University

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/24/2026

1. Rigor and Reproducibility: I would suggest identifying those researchers who consistently retract published work. This should be considered at council meeting or some other place in secondary review.

2. Data, Software, and Model Sharing: Incentivizing such activity should take the form of specific grants to support these activities.

3. Training and Mentorship: I believe that growth and stability come from stable funding for biomedical research. More than that, expansion of funding to improve funding rates, re-institution of paylines, easing restrictions and fees on H1B visas, and increasing the modular R01 budget would go far to ensuring stability of the biomedical research workforce

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: Agree. R21 funding amounts should be doubled in size and extended to a 3 year period. The current rates do not allow for much science to be conducted.

7. Public Impact: N/A

8. Other Areas: N/A

41. Gordon W. Laurie

I am responding: On behalf of myself

Name: Gordon W. Laurie

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/24/2026

1. Rigor and Reproducibility: Rigor and Reproducibility are themes inherent in the practice of science. Full transparency of data has been well adopted in many journals, but not in all moderate to lower tier ones. A uniform standard could be required/encouraged of all journals. NIH should be wary of introducing investigator burden.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: Themes of Rigor and Reproducibility are seeded in strong training and mentorship. Joint mentorship of trainees can be very healthy. Also helpful is a third mentor from a different department who meets regularly to be supportive of trainee well-being.

4. Collaboration: Collaboration develops organically to accelerate a discovery or when discovery screening. Team science should not be forced. Through assessment, NIH should be wary of introducing investigator burden.

5. Entrepreneurship and Translation: I would encourage all predoctoral training grants to include a company internship requirement of 1 - 3 months. Also, there should be more cross-fertilization between business schools and the sciences. SBIR funding is outstanding for early stage company growth. VC investment beyond this stage can be very challenging.

6. Foundational Scientific Exploration: As a human enterprise, the burden and risk adverse nature of study section review can suppress enthusiasm for truly innovative proposals. The NIGM R35 mechanism is admirable.

7. Public Impact: N/A

8. Other Areas: N/A

42. T John Winhusen

I am responding: On behalf of myself

Name: T John Winhusen

Name of Organization: University of Cincinnati

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/24/2026

1. Rigor and Reproducibility: Multi-site clinical trials are among the most rigorous forms of biomedical research and already incorporate many features intended to enhance reproducibility, including prospective registration in ClinicalTrials.gov, pre-specified primary and secondary outcomes, statistical analysis plans, independent safety oversight, protocol standardization, monitoring, and adherence to CONSORT reporting standards. NIH should consider successful completion and dissemination of registered clinical trials as indicators of rigorous and reproducible science.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: Multi-site trials provide unique training environments that expose junior investigators to protocol development, regulatory oversight, participant recruitment, data management, and collaborative science. These contributions should be recognized as valuable mentoring activities.

Suggested indicators:

Junior investigators mentored within networks;
Authorship opportunities for trainees;
Career advancement of mentees;
Participation of early-stage investigators in trial leadership activities.

4. Collaboration: Multi-site clinical trials often require years of coordination among investigators, coordinators, statisticians, laboratories, and clinical sites. Leadership of such studies frequently results in fewer publications over a given period compared with smaller studies, creating disadvantages within promotion and funding environments that emphasize publication counts. NIH should develop metrics that explicitly recognize contributions to team science and leadership of large collaborative studies.

Suggested indicators:

PI or MPI roles in multi-site trials;
Number of participating sites coordinated;
Contributions to protocol development;
Steering committee leadership;
Mentorship within clinical trial networks.

Potential incentive:

Explicit recognition of trial leadership and network contributions in biosketches and grant review.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: The impact of clinical trials is often not adequately reflected by traditional citation metrics. Once trial findings are incorporated into systematic reviews, meta-analyses, clinical guidelines, or evidence-based recommendations, subsequent publications frequently cite these secondary sources rather than the original trials. NIH should consider inclusion in systematic reviews, meta-analyses, practice guidelines, and policy documents as indicators of scientific influence and public health impact.

Biomedical research evaluation should reward the generation of reliable evidence that informs clinical practice and public health, even when that work produces fewer publications and accrues citations more slowly than smaller, less resource-intensive studies.

Suggested indicators:

Inclusion in systematic reviews;
Inclusion in meta-analyses;
Citations in clinical guidelines;
Influence on healthcare delivery or policy;
Evidence of changes in clinical practice.

8. Other Areas: Multi-site clinical trials represent one of the most rigorous and impactful forms of biomedical research but are inadequately recognized by traditional measures of scientific productivity. These studies require substantial coordination, infrastructure development, regulatory oversight, and long-term commitment, often resulting in fewer publications over a given time period compared with smaller studies. Clinical trials already incorporate robust mechanisms that support reproducibility, including prospective registration, pre-specified analyses, independent monitoring, and standardized reporting. Furthermore, the scientific influence of clinical trials may be underestimated by citation-based metrics because individual trials are frequently incorporated into systematic reviews, meta-analyses, and clinical guidelines that subsequently become the preferred sources for citation. NIH should consider metrics that recognize contributions to multi-site trials, inclusion in evidence syntheses and guidelines, successful completion of registered studies, and leadership roles in team science initiatives.

Description: Multi-site clinical trials already embody many of the practices NIH seeks to incentivize

43. Desmond Heath

I am responding: On behalf of myself

Date Submitted: 6/24/2026

1. Rigor and Reproducibility: This communication fits your opening statement that NIH "welcomes all comments." It describes research outside the specific interests you listed.
It hardly relies on "measurable indicators" except that this research aims at identifying regularities in the behavioral expression of the constraint that two physical properties of matter have on each other. These physical properties of matter are expressed throughout nature and are utilized by or brains in the construction of mind. The "potential benefits" are in the construction of Laws of Mind that might set off a Sane Society Revolution just as Newton's Laws of Motion set off the Industrial Revolution.

I am happy to see that this initiative by NIMH hews to Bacon's Razor in that it focuses research on matters that might benefit human kind and relieve suffering.

If the construction of Laws of Mind interests you I will give you a full description of my research.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: I hope this Laws of Mind project qualifies as "basic research" that is of some risk but it is of m"high reward."m

7. Public Impact: Set off a Sane Society Rally evolution .

8. Other Areas: N/A

44. David Schopfer

I am responding: On behalf of myself

Name: David Schopfer

Name of Organization:

Type of Organization: Not Applicable

Role: Investigator/Researcher

Date Submitted: 6/24/2026

1. Rigor and Reproducibility: Rigor and reproductibility are already very well achieved in most federally funded research.

2. Data, Software, and Model Sharing: Validation of research should require that researchers publish their methods in detail (appendix or elsewhere), beyond the very cursory descriptions currently provided in manuscripts. Especially for research that involves datasets, common data models, machine learning, and AI, the specific computer code for every single decision, analysis, and results should be required to be directly published if federal funds are received.

As a researcher, numerous times I try to understand what others did to acheive their results, and the published information is too vague and nonspecific to make any conclusions, so of course I cannot replicate it even with the same dataset. That is unacceptable. It's not proprietary information. It should be shared.

3. Training and Mentorship: The new, existing policies and programs are going to directly undercut growing the biomedical research workforce. The administration does not understand or seem to care that their actions are directly harming the very thing they claim to care about. I know numerous young investigators and potential investigators who are completely avoiding this career path due to the current policies in place. No amount of training awards or programs will change that. Young investigators will not choose altruism, lower income, and significant job instability over higher paying and stable job options.

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

8. Other Areas: N/A

45. Donald Lynam

I am responding: On behalf of myself

Name: Donald Lynam

Name of Organization: Purdue University

Type of Organization: Not Applicable

Role: Investigator/Researcher

Date Submitted: 6/24/2026

1. Rigor and Reproducibility: I think that historic transparency should be considered in the reivew process. Has the investigator routinely engaged in Open Science practices in some preceding period (5 years)? Do they preregister their studies--a priori hypotheses; sample size; decisions rules for outliers, covariates, and missing data; outcomes; statistical approaches, etc. Do they make their data publicly available? If data are deemed too sensitive, do they make synthetic data sets available? Do they make their analytic code publicly avialble? Do they make publications open access (either by publishing in OA journals or sharing on preprint servers? This needs to be based on past behavior not future promises.

NIH could submit past publications (2, 3, 5 years) to a z-curve analysis to quantify false discovery rates as a means of detecting questionable research practices. I suspect AI will be capable of doing this shortly (if it cannot do so already).

2. Data, Software, and Model Sharing: why can't NIH demand it?

As above, make historic data sharing and code sharing an important part of the review process. I do not think there is ever a reason to not share code. If an investigator claims the data cannot be fully deidentified, then they can create synthetic data sets that at least allow checking of results.

3. Training and Mentorship: Again, I suggest a research history approach.
How many students have the mentored? How many students have successfully completed their degreees. How many students have first-authored publications? How many first authored publicatons do they have? Where have they been placed after receiving their degrees?

Has the investigator been recognized for their mentoring within their department, college, university, or society?

I do not believe mentoring plans for students will behelpful. They are simply promissory notes that are difficult to enfore and too easily gamed.

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: Historically, how many failures have they published? Null results are very informative and need to be published. The only legitimate reason for not doing so is a failed or grossly underpowered study. The first can happen but the second should never happen. Why is an investigator conducting a study where there is only outcome thatthey can publish.

7. Public Impact: N/A

8. Other Areas: N/A

46. Qinglin Yang

I am responding: On behalf of myself

Name: Qinglin Yang

Name of Organization: LSUHSC-New Orleans

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/24/2026

1. Rigor and Reproducibility: When a Principal Investigator's (PI) career survival depends almost entirely on winning the next grant, hyper-competition takes over, which naturally erodes rigor and reproducibility. Shifting PIs away from the "funding-first" survival loop could significantly improve research quality. fund a scientist's overall laboratory rather than specific, high-risk project proposals. Extend standard R01 grant periods from 4–5 years to 7–8 years to give labs breathing room to troubleshoot and replicate data without panic. Reward PIs for publishing well-controlled negative findings or validation studies that save the scientific community time and resources. We will also need to curb the trend of bloated papers in the name of reporting a complete story.

2. Data, Software, and Model Sharing: While well-intentioned, the escalating mandates for research rigor and reproducibility have inadvertently created a punishing "compliance tax" that disproportionately crushes small laboratories and alienates Principal Investigators (PIs) from actual science. Unlike well-funded mega-labs equipped with dedicated administrative staff, small labs lack the manpower and financial margins to seamlessly manage intensive requirements like complex Data Management and Sharing (DMS) plans, cell line authentications, and strict double-blind protocols. This operational imbalance forces small-lab PIs to transform from innovative thinkers into full-time bureaucrats, spending the majority of their time navigating paperwork and compliance portals rather than mentoring trainees or analyzing data at the bench. Consequently, this regulatory creep consolidates funding into massive "grant factories" that can easily absorb the administrative workload, systemically starving out the smaller, agile laboratories that historically drive diverse, niche scientific discoveries.

3. Training and Mentorship: Training and mentorship are the most direct ways to improve research reproducibility because they embed rigorous habits into scientists at the start of their careers. While administrative policies force compliance from the top down, effective mentorship builds a culture of precision from the bottom up.

4. Collaboration: To fairly recognize team-based science, institutions must replace traditional first/last authorship metrics with granular, portfolio-based evaluations. Embracing standardized systems like the Contributor Roles Taxonomy (CRediT)—already used by the NIH Intramural Research Program to resolve disputes—explicitly credits essential, specialized roles like data curation, software development, and validation. Furthermore, updating tenure criteria to include narrative CVs and collaborative portfolios rewards scientists for collective impact and high-value digital artifacts, such as open-source code and reusable public datasets. Redesigning these institutional promotion and grant structures ultimately

replaces isolated, high-volume publishing with an ecosystem that actively incentivizes collaborative transparency.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: To unlock truly innovative scientific exploration, funding agencies should transit from hyper-vigilant compliance monitoring to a model of trusted stewardship that liberates PIs from administrative overload. This shift requires expanding flexible "people, not projects" awards, and implementing streamlined, two-stage grant applications that review a short conceptual abstract before demanding extensive paperwork. Furthermore, adopting "just-in-time" compliance for institutional protocols and funding centralized administrative co-ops would effectively remove the bureaucratic burden from the researcher's desk. By stripping away this operational red tape, funding bodies can transform PIs from full-time managers back into active scientists, giving them the cognitive freedom to pursue high-risk, high-reward breakthroughs and directly mentor the next generation of innovators.

7. Public Impact: N/A

8. Other Areas: N/A

47. Malaz Boustani

I am responding: On behalf of myself

Name: Malaz Boustani

Name of Organization: Indiana University School of Medicine

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/24/2026

1. Rigor and Reproducibility: NIH should modernize rigor and reproducibility metrics by moving beyond publication counts, citation rates, journal impact factors, and grant totals. These traditional measures reward scientific production more than health creation. A paper, grant, dataset, or tool should not be assumed to have high value simply because it was published, cited, or funded. Its value should be judged by whether it produces reliable knowledge that improves health, reduces suffering, strengthens care delivery, reduces disparities, or improves decision-making for patients, caregivers, clinicians, communities, and policymakers. NIH should create a minimally viable universal set of reproducibility measures, then allow localization by scientific field, disease area, study design, and local context. The universal measures could include: whether the finding was independently replicated; whether methods, protocols, code, measures, and data are reusable; whether null and negative findings were reported; whether unintended consequences were measured; whether pre-specified termination or adaptation criteria were used; and whether the work reduced or increased scientific, clinical, or participant burden. Reproducibility should not mean rigid duplication of the same protocol in every setting. In complex adaptive health and research systems, reproducibility should include the ability to preserve essential scientific functions while allowing local adaptation. NIH should therefore distinguish between fidelity to core scientific mechanisms and appropriate localization of delivery form. NIH should also reward humility. Investigators should receive credit for identifying failed assumptions, stopping low-value work, publishing negative findings, and adapting based on evidence. These practices are signs of rigor, not weakness.

2. Data, Software, and Model Sharing: NIH should reward data, software, and model sharing when sharing creates usable scientific and public value, not merely when files are deposited into repositories. The key question should be: Can others actually reuse, validate, implement, or improve the resource? Measurable indicators could include: number and diversity of independent reuse cases; successful external validation; interoperability with other platforms; clarity of documentation; time from data collection to availability; privacy and security protections; user burden; and whether the shared resource accelerated discovery, replication, implementation, or public health decision-making.
NIH should avoid creating overly centralized data infrastructures unless the scientific problem truly requires centralization. Large centralized platforms can become slow, expensive, and disconnected from local scientific reality. NIH should instead support decentralized networks of smaller agile teams connected by common minimally viable data standards, open tools, and shared learning infrastructure. The principle should be: standardize the minimum, localize the rest. This would allow NIH to create a

common language for reuse while preserving the flexibility needed across basic science, clinical trials, implementation research, community-engaged research, and data science.

3. Training and Mentorship: NIH should measure the impact of training and mentorship by whether trainees develop the capacity to conduct rigorous, useful, reproducible, ethical, and adaptive science. Current measures often overemphasize publications, grants, titles, and institutional prestige. These are incomplete indicators of whether a scientist can improve health. Training metrics should include: ability to ask important and falsifiable questions; use of rigorous and transparent methods; capacity to work in teams; skill in data sharing and reuse; ability to report negative and null findings; competence in community and stakeholder engagement without advocacy capture; and ability to move discoveries toward implementation, diffusion, or real-world decision value. NIH should also reward mentors who help trainees develop scientific humility, learning velocity, and responsible risk-taking. A successful mentor should not be judged only by how many papers or grants their trainees produce, but by whether trainees become independent, ethical, collaborative, and mission-driven scientists. NIH should consider training programs in agile science and its derivatives. These methods help scientists develop solutions that can be adapted, implemented, sustained, and diffused in real-world systems.

4. Collaboration: NIH is right to reward collaboration and team science. However, the deeper problem is not only that team members receive insufficient credit. The deeper problem is that the measures used to judge team success are often misaligned with the NIH mission. NIH should reward teams for producing health impact, reproducible knowledge, reusable infrastructure, and learning that others can apply.
Team science should be measured by contribution to shared mission, not only by authorship position or grant role. Useful indicators could include: clarity of team roles; quality of interdisciplinary integration; shared data and tools; speed from idea to test to learning; evidence that collaboration improved rigor or usefulness; stakeholder-assessed value; and whether the team built infrastructure that others can reuse.
NIH should also minimize unnecessary centralization. Collaboration does not always require large projects, large consortia, or large coordinating centers. Large centralized structures can become slow, expensive, risk-averse, and administratively protected. NIH should support decentralized networks of smaller agile teams that can test, learn, adapt, and share discoveries rapidly. In complex adaptive systems, intelligence is distributed. NIH should fund collaboration models that capture distributed intelligence rather than suppress it through excessive central control.

5. Entrepreneurship and Translation: NIH should broaden its definition of translation. Translation is not only movement from bench to product or patent to company. Translation should include implementation into practice, diffusion across networks, reduction of burden, and measurable improvement in health, care delivery, trust, safety, access, or affordability.
NIH should reward entrepreneurship when it creates public value, not merely when it creates a company, patent, license, or investment event. Useful indicators could include: time from discovery to real-world test; evidence of user demand; adoption by patients, clinicians, communities, or health systems; sustained use; affordability; equity impact; interoperability; implementation readiness; and evidence that the solution solves a real problem without creating unacceptable unintended consequences.
NIH should also recognize that much current innovation occurs outside NIH-funded studies because NIH processes are often too slow and risk-averse. NIH should preserve scientific standards while reducing unnecessary administrative friction. It should create rapid-cycle mechanisms for minimally viable experiments, early implementation testing, and responsible risk-taking.

Agile Innovation, Agile Implementation, and Agile Diffusion offer one framework. They ask whether a solution addresses a real demand, fits the local context, can be tested quickly, can be adapted while preserving essential functions, and can be sustained or diffused across real-world networks.

6. Foundational Scientific Exploration: NIH should continue to protect foundational science and high-risk, high-reward research. However, foundational science should not be evaluated only by traditional prestige metrics. Basic research can create enormous value through mechanisms, methods, tools, models, datasets, conceptual breakthroughs, and future platforms for discovery. For foundational science, impact measures should be localized to the nature of the work. Useful indicators may include: validated mechanisms; reproducible methods; high-quality shared tools; new models; robust datasets; theoretical clarity; falsifiable predictions; reuse by independent investigators; and contribution to future scientific pathways. NIH should reward responsible scientific risk. Responsible risk is not the same as reckless speculation. It includes a clearly defined problem, plausible mechanism, transparent methods, pre-specified decision criteria, proportional safeguards, and willingness to report failure. NIH should also avoid forcing foundational science into immediate advocacy or premature claims of public impact. Basic science often creates long-term value that cannot be fully predicted at the time of discovery. NIH should protect curiosity-driven work while still expecting rigor, transparency, reproducibility, and humility.

7. Public Impact: NIH should move from a prestige-based measurement system to a mission-based measurement system. The NIH mission is to generate knowledge that enhances health, lengthens life, and reduces illness and disability. Therefore, public impact should be measured by how much health and trustworthy knowledge science creates, not merely by how much science it produces.
Public impact indicators could include: improvement in patient, caregiver, clinician, community, or population outcomes; reduction in disparities; improvement in safety, quality, access, trust, or affordability; real-world implementation; sustained use; policy or practice relevance; reduction in burden; and contribution to public trust.
Patients, caregivers, clinicians, and communities should help judge usefulness. Scientists are essential judges of rigor, but they are not the only judges of value. Patients can judge whether outcomes matter. Caregivers can judge whether interventions are usable. Clinicians can judge workflow fit. Communities can judge trust. Health systems can judge sustainability.
At the same time, NIH should keep science distinct from advocacy. Science should inform policy and practice, but it should not be confused with advocacy. Advocacy starts with a desired position and seeks support for it. Science starts with uncertainty and seeks a more accurate understanding of reality. NIH should reward clear separation between hypothesis and desired outcome, transparent reporting of null and negative findings, replication across independent contexts, and communication that informs without overstating certainty.
Public trust will not be restored by louder claims of impact. It will be restored by humble, transparent, rigorous science that is willing to learn in public.

8. Other Areas: NIH should reward agile bureaucracy, not rigid bureaucracy. Science needs bureaucracy: human subjects protection, fiscal accountability, data stewardship, privacy protection, conflict-of-interest management, peer review, and public reporting are essential. The problem is not bureaucracy itself. The problem is rigid bureaucracy.
Rigid bureaucracy asks whether every box was checked. Agile bureaucracy asks whether the process created trustworthy, ethical, useful, and timely science. Rigid bureaucracy adds layers. Agile bureaucracy learns what can be simplified. Rigid bureaucracy assumes one process fits every risk level. Agile

bureaucracy matches oversight to risk.

NIH should measure and reward institutions that reduce unnecessary administrative burden while preserving integrity. Indicators could include: time from award to study launch; time from IRB submission to approval, stratified by study risk; time from data collection to usable feedback; administrative cost per unit of scientific or health impact; investigator time spent on science versus administration; participant and clinician burden; redundant approvals eliminated; and evidence that oversight prevented harm without delaying low-risk science unnecessarily. NIH should not impose a new metric system nationally without testing it. NIH should run agile experiments across institutes, mechanisms, and review panels. These could include: progress reports focused on learning velocity and burden reduction; renewal criteria based on real-world usefulness; rapid-cycle R21 mechanisms for minimally viable experiments; mechanisms that fund decentralized agile teams; and institutional rewards for reducing the time and burden required to launch rigorous low-risk studies. NIH should consider creating an Agile Impact Score with a universal core and local adaptation. Core domains could include health impact, implementation impact, learning impact, collaboration impact, speed impact, burden reduction, replicability and reuse, and localization impact.

The overall principle is simple: NIH should measure success not only by how much science we produce, but by how much health we create.

1. Rigor and Reproducibility: Current scientific evaluation systems primarily reward outputs such as publications, citations, and grant funding. While these remain important indicators of productivity, many of the most valuable contributions to long-term scientific progress function as scientific assets: reproducible findings, shared datasets, software tools, validated methods, trained scientists, collaborative networks, and research infrastructure. Future evaluation systems should recognize both outputs and assets. Outputs measure scientific production, whereas assets measure the creation of enduring scientific capacity that continues generating value beyond a single publication or grant cycle.

Reproducibility and replication should be recognized as distinct scientific contributions rather than ancillary activities. NIH could establish dedicated funding mechanisms specifically for independent replication studies, multi-site validation projects, and methodological reproducibility assessments. Potential indicators include successful independent replication of key findings, adoption of standardized protocols across laboratories, publication of validation datasets, and demonstrated reproducibility of analytical pipelines.

To avoid creating incentives that favor only novelty, NIH could encourage portfolio diversification at both investigator and laboratory levels. For example, laboratories could be encouraged to allocate a portion of their research effort toward validation of influential findings within their field. Review criteria could explicitly recognize replication studies as contributions to scientific infrastructure rather than judging them solely on novelty. This approach would strengthen confidence in biomedical findings while reducing the systemic pressure toward publication of only positive and novel results.

2. Data, Software, and Model Sharing: Data, software, and computational models should be evaluated as scientific products in their own right. Rather than rewarding simple deposition of datasets or code, NIH should prioritize indicators of meaningful reuse. Examples include external dataset citations, incorporation into community benchmarks, reuse by independent laboratories, software downloads accompanied by documented scientific applications, and integration into training or educational resources.

NIH could support dedicated "scientific asset" grants focused on maintaining, curating, and expanding high-value datasets, software platforms, and computational models. Such mechanisms would recognize that the long-term value of many research investments depends on their accessibility and usability

beyond the originating laboratory. Evaluation systems should reward quality, interoperability, documentation, and demonstrated reuse rather than mere availability.

3. Training and Mentorship: Training should be evaluated based on development of scientific independence rather than trainee counts alone. Potential indicators include trainee retention in scientific careers, progression into independent leadership roles, interdisciplinary skill acquisition, and contributions to open science and collaborative research. NIH could support longitudinal tracking of trainee outcomes and recognize laboratories that consistently develop successful scientists across diverse career paths, including academia, industry, government, and healthcare. The goal of mentorship should be viewed not as producing assistants, but as producing future contributors and leaders within the scientific ecosystem.

4. Collaboration: Modern biomedical research increasingly relies on interdisciplinary teams whose contributions are not adequately captured by authorship position alone. NIH should encourage more structured contribution reporting and recognize activities such as development of shared infrastructure, coordination of multi-site studies, integration of expertise across disciplines, and leadership of collaborative networks. Evaluation systems should reward substantive collaborative contributions rather than simple co-authorship counts. Team science should be recognized as a scientific asset that increases the collective capacity of the research enterprise.

5. Entrepreneurship and Translation: Translation should be assessed based on real-world adoption rather than only patents or startup formation. Potential indicators include incorporation into clinical workflows, regulatory milestones, technology licensing, commercial deployment, implementation in healthcare systems, and measurable improvements in patient care. NIH could encourage partnerships between academia, industry, and healthcare organizations while recognizing translational activities as legitimate scientific contributions. The goal is not merely commercialization but successful movement of discoveries into practical use.

6. Foundational Scientific Exploration: High-risk, high-reward science requires evaluation frameworks that tolerate uncertainty and failure. Many transformative advances arise from projects that initially lack obvious translational outcomes or immediate publication opportunities. NIH could support dedicated mechanisms for foundational studies, method development, theoretical frameworks, and exploratory investigations. Evaluation should focus not only on immediate outcomes but also on whether a project generated new questions, methods, conceptual frameworks, or research directions. Scientific failure should not automatically be interpreted as lack of scientific value when rigorous approaches are used to address important questions.

7. Public Impact: Public impact should be assessed across multiple timescales. Near-term indicators may include contributions to clinical practice, health outcomes, public health initiatives, educational resources, and economic activity. Longer-term indicators should include public trust, accessibility of scientific information, community engagement, and development of scientific literacy. Because many societal benefits emerge years or decades after discovery, evaluation systems should recognize both direct impacts and contributions that strengthen the broader scientific ecosystem. Public benefit is often produced through cumulative scientific assets rather than single publications or individual grant cycles.

8. Other Areas: NIH should complement traditional output-based metrics with asset-based metrics. Publications, citations, and grants measure productivity. Reproducible findings, datasets, software,

methods, trainees, collaborative networks, and shared infrastructure measure the creation of enduring scientific capacity. Long-term scientific impact arises from both outputs and assets, and future incentive systems should recognize the complementary roles of each.

1. Rigor and Reproducibility: I recently read a speech by Dr. Battacharya in which he espoused the repeating of published experiments to ensure reliability. I fully concur that reproducing published data is important to ensure that the data are correct when reproduced in a different laboratory. The problem is that NIH grants are based to a large extent on innovation, and if you are proposing to repeat someone else's findings (even in a different way), you will not be considered innovative.

2. Data, Software, and Model Sharing: While all of our primary data from publications are uploaded into OSF, how is NIH going to incentivize and reward these activities unless they have a method of checking them for completeness? As far as I know, there is no mechanism for this to catalyze collaborations or accelerate scientific impact.

With the exception of high-value data sets, and promoting data reuse for other studies, is there a mechanism to check if storing all this primary data is actually benefitting anyone?

3. Training and Mentorship: Evaluate the number of trainees who advance into scientific/science-related professions within a department.
Individuals who oversee or participate in training programs (e.g., T32) should be used to quantify impact.
Evaluate the proportion of graduate students/post-docs who obtain F awards within a department.

It is really not clear to me how NIH "protects time through existing policies and programs." I direct a T32 and the NIH does not cover any of my salary, for example.

4. Collaboration: You should be able to create an "interactome" to illustrate the number of interactions between a specific PI and other scientists.

5. Entrepreneurship and Translation: The STTR and SBIR programs should be greatly expanded to support additional translational studies.
If a R21 or R01 has a translational component that is deemed highly innovative by study section or Program, perhaps this could be used to move them into a more fundable range.

6. Foundational Scientific Exploration: This is what the R21 mechanism was supposed to be -- high risk/high reward without the need for preliminary data; however, this is not what R21s have morphed into.

7. Public Impact: N/A

8. Other Areas: The bottom line is that unless more grants are funded, academic science will be lost for a generation. The new rules proposed by OMB are onerous and will destroy many individual careers as well as institutions.

1. Rigor and Reproducibility: CIRCADIAN RHYTHMS CHARACTERIZE EVERY NORMAL PHYSIOLOGICAL EVENT IN EVERY LIVING THING -SEE 2017 NOBEL PRIZE FOR PHYSIOLOGY OR MEDICINE. NOTHING IN BIOMEDICAL RESEARCH, THEREFORE, IS HOMEOSTATIC. CHRONOBIOLOGICAL INVESTIGATIONS REPEAT THE SAME EXACT EXPERIMENT IN DIFFERENT GROUPS OF ANIMALS OR HUMANS EVERY 3-4 HOURS OVER ONE OR MORE 24 HOUR PERIODS. WITH THIS FREQUENCY OF SAMPLING IT IS NOT UNCOMMON, WHEN ADDING THE DIMENSTION OF TIME TO RESEARCH EFFORTS, TO FIND BODY CLOCK TIMES WHEN THE SAME TREATMENT STIMULATES OR INHIBITS OR HAS NO EFFECT ON AN ACTIVITY COMPARED TO TIME-MATCHED TREATED CONTROLS. PUBLICATIONS USING ONLY USING SINGLE TIME-POINT SAMPLING OVER A DAY – THE CURRENT USUAL PRACTICE CAN REACH VERY DIFFERENT CONCLUSIONS EXPLORING THE SAME STUDY, BUT NOT CONTROLLING FOR THE IMPACT THAT CIRCADIAN RHYTHMICITY HAS ON BOTH THE EXPERIMENTAL DESIGN AND THE DATA INTERPRETATION. THERE IS NO FICKLENESS OR NON-REPRODUCIBILITY WHEN CHRONOBIOLOGY IS PRACTICED, JUST REMARKABLE REPRODUCIBILITY OF RESULTS, EVEN BETWEEN DIFFERENT LABS.

FOR EXAMPLE, THE PERCENT MORTALITY IN MICE CAN RANGE FROM 10% TO 70% FOR ANY DRUG TESTED ACCORDING TO BEST PRACTICES OF CHRONOBIOLOGICAL INVESTIGATION. THE SAME CONCEPT IS TRUE FOR THE LONG-TERM CURE RATE OF TUMOR-BEARING MICE TREATED WITH THE SAME CHEMOTHERAPY DRUGS AND DOSAGES, AND ONLY CHANGING THE BODY CLOCK TIME OF TREATMENT. THE CONCEPT OF CHRONOCHEMOTHERAPY HAS PRODUCED EXCELLENT CLINICAL RESULTS WITH HUMAN CANCER.

NO BIOMEDICAL RESEARCH SHOULD BE DESIGNED AND CONDUCTED WITHOUT AN UNDERSTANDING OF THE ROLE THAT CIRCADIAN RHYTHMICITY PLAYS IN THE EVENT BEING INVESTIGATED. USE BIOLOGICAL TIME AS AN ALLY, NOT A CONFOUNDING FACTOR.

Circadian chronotherapy for human cancers

Francis Lévi

Cell physiology is regulated by a 24-hour clock, consisting of interconnected molecular loops, involving at least nine genes. The cellular clock is coordinated by the suprachiasmatic nucleus, a hypothalamic pacemaker which also helps the organism to adjust to environmental cycles. This circadian organisation brings about predictable changes in the body's tolerance and tumour responsiveness to anticancer agents, and possibly also for cancer promotion or growth. The clinical relevance of the chronotherapy principle, ie treatment regimens based upon circadian rhythms, has been demonstrated in randomised, multicentre trials. Chronotherapeutic schedules have been used to document the safety and activity of oxaliplatin against metastatic colorectal cancer and have formed the basis for a new approach to the medicosurgical management of this disease, which achieved unprecedented long-term survival. The chronotherapy concept offers further promise for improving current cancer-treatment options, as well as for optimising the development of new anticancer or supportive agents.

Lancet Oncol 2001; **2:** 307–15

Anticancer treatments are generally given at doses near their maximum tolerated dose (MTD), to achieve best efficacy. However, cancer chemotherapy and radiation therapy are toxic to both malignant and normal cells. This lack of specificity leads to the narrow therapeutic index of cytotoxic agents; it also hampers the demonstration of *in vivo* anticancer activity for most biologically targeted molecules currently in development.

Normal cell physiology is characterised by predictable changes over a 24-hour timescale coordinated by the suprachiasmatic nucleus (Figure 1). These circadian rhythms can be used to reduce cytotoxic treatment insults provided that temporal adjustments are made to the administration schedule (chronotherapy). Drugs that target the regulation of cell-cycle events or angiogenesis may also be more effective if administered at specific times, so as to achieve fully *in vivo* the pharmacodynamic effects they display *in vitro*. Preclinical and clinical evidence supports investigations of the chronotherapy hypothesis in cancer patients.

Indeed, the tolerability and the efficacy of chemotherapeutic drugs, as well as of radiotherapy, and cytokines vary by 50% or more as a function of dosing time in mice or rats.[1] The main circadian rhythms of the body, for instance those that modulate secretion of cortisol[2] or melatonin, show nearly normal patterns in groups of patients with advanced or metastatic cancer (Figure 2).[2] This review of the main experimental and clinical prerequisites will be followed by a discussion of the present status and perspectives of chronotherapy in cancer patients.

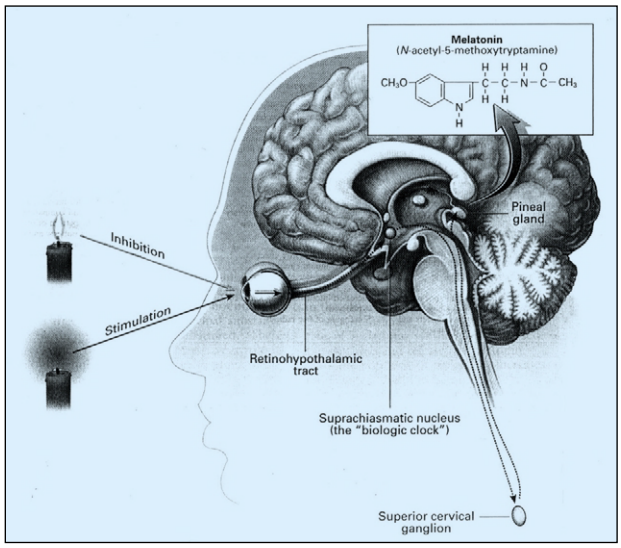

Figure 1. The suprachiasmatic nucleus controls circadian rythyms in response to hormonal signals.

From circadian rhythms to chronotherapy

Circadian rhythms have surprisingly similar properties in cyanobacteria, in plants, and in mammals. They are not merely the reflection of the regular alternation of light and darkness, but persist even in constant environmental conditions, and are therefore endogenous. Interacting molecular loops involving nine genes generate circadian rhythmicity in mammalian cells, and this cellular circadian clock modulates the transcriptional and post-transcriptional processes of several other genes, thereby creating 24-hour changes in cell physiology.[3–5]

The cellular circadian clocks are coordinated by a central

one, located at the floor of the hypothalamus, the suprachiasmatic nucleus (SCN), through mechanisms which are yet to be clarified.[6] The SCN generates the circadian rest–activity cycle and coordinates the 'peripheral' oscillators. It also controls the adaptation of the whole circadian time structure to various environmental cycles, known as synchronisers. The regular alternation of light and darkness over a 24-hour period is the main synchroniser of the circadian system (Figure 3). Melatonin, which is mainly secreted by the pineal gland during darkness, contributes to the calibration of the endogenous period to precisely 24 hours.[7] As a result of this synchronisation, mammals with normal circadian function show rhythms in their cellular metabolism and proliferation, with predictable amplitudes and times of peaks and troughs. These rhythms modulate anticancer-drug pharmacology and, ultimately, the tolerability and efficacy of cancer treatments.[1]

Experimental models

Time of administration of anticancer agents influences the extent of toxicity in mice or rats synchronised with an alternation of 12 hours of light and 12 hours of darkness. In most cases, survival varies by a factor of two to eight as a function of dosing time.[1] Although drug pharmacokinetics can vary with time of administration, cellular rhythms appear to be the main determinants of anticancer drug chronopharmacology, because they can modulate the generation or the catabolism of intracellular cytotoxic substances, their interactions with the molecular targets leading to cell dysfunction or death, and the repair of cytotoxic damage (Table 1).[8–14]

A drug usually achieves the best antitumour activity when it is administered at the particular point in the circadian cycle when it is best tolerated; this is true of antimetabolites, alkylators, intercalants, and antimitotic agents (Figure 3). A survival improvement has been achieved in most studies, because drug doses could be safely and selectively increased by 30–50% at the time of best tolerability.[13,15] Nevertheless, in some tumour models, researchers were able to identify a circadian rhythm in anticancer activity, which was coincident with one of drug tolerance, despite the fact that chemotherapy doses were below the MTD.[16–18] The biological and cytokinetic effects that follow the administration of a first drug may influence both the interval and the best time to give a second agent, to achieve optimum therapeutic index in a combination therapy.[14] Fortunately, in many cases, the optimum therapeutic index from combination therapy results from the delivery of each drug near its respective circadian time of best tolerability.[1, 14] Thus, in the experimental model, the delivery of standard doses of chemotherapy at the least toxic time improves tolerability, while anticancer efficacy remains similar or improves, compared with administration every 12 hours. However, in several tumour-bearing animal models, the administration of the MTD at the least toxic circadian time is necessary to improve survival. The application of these strategies to cancer patients would allow the 'best' chronotherapy schedule to enhance patients' quality of life, through a reduction in the incidence of toxic effects, while achieving at least similar antitumour activity, or to prolong survival or to increase cure rate, while producing a tolerability similar to that of standard treatment schedules.

Table 1. Mechanisms of circadian changes in anticancer drug toxicity in rodents

Rhythmic variable	Drug affected
Pharmacokinetics	
(plasma, urine, or cellular)	Mitoxantrone, methotrexate, cisplatin, carboplatin,oxaliplatin, irinotecan
Cellular functions	
Dehydropyrimidine dehydrogenase Orotate phosphoribosyltransferase Uridine phosphorylase Thymidine kinase Thymidylate synthase	Fluoropyrimidines (fluorouracil, floxuridine)
Topoisomerase I	Camptothecins (irinotecan)
Reduced glutathione	Platinum complexes (cisplatin, carboplatin, oxaliplatin) alkylating or intercalating drugs
O^6 alkyguanine methyltransferase	Alkylating agents (nitrosoureas, such as cystemustine)
BCL2, BAX	Taxanes (docetaxel)
Cell cycle regulation	Nearly all agents

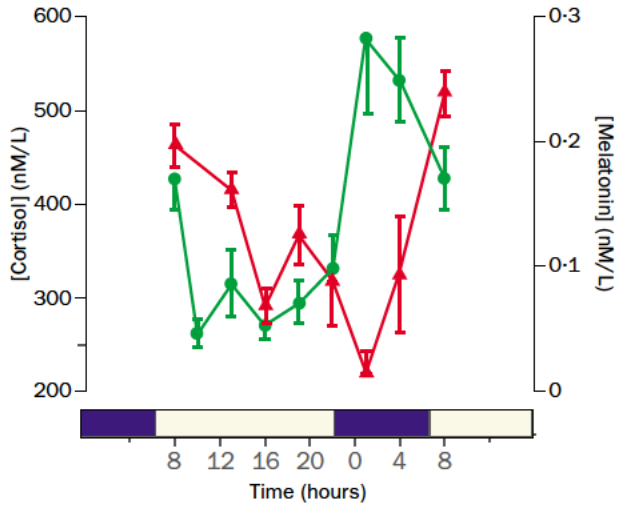

Figure 2. Circadian rhythms in plasma concentrations of cortisol (red) and melatonin (green) in a group of 18 patients with metastatic colorectal cancer. All the patients had received chemotherapy for metastatic disease before the study. Blood samples were obtained every 3–6 h for 2 days in each patient. Light–dark synchronization is shown on the x axis.[2]

Chronomodulated infusions

Rhythms in target tissues

Cells that are engaged in DNA synthesis (S-phase) are generally more susceptible to antimetabolites or intercalating agents. The proportion of S-phase cells in bone marrow, gut, skin, and oral mucosa varies by 50% or more over each 24-hour period in healthy human beings[19] (also reviewed in 1). Similar changes have been found for the

For personal use. Only reproduce with permission from The Lancet Publishing Group.

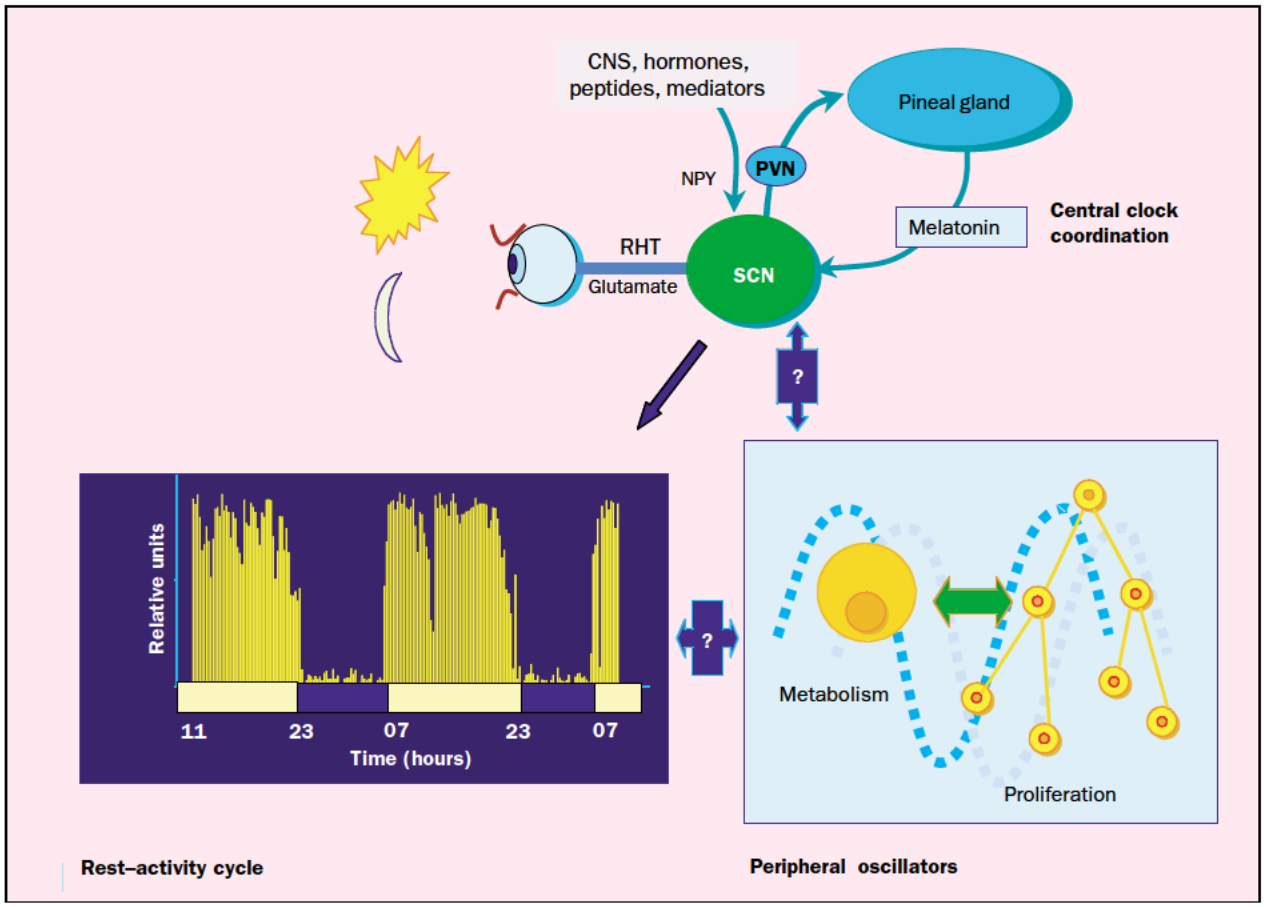

Figure 3. Schematic view of the human circadian system. The SCN is a biological clock located at the floor of the hypothalamus. It displays an approximate 24-hour cycle in the expression of several genes and biochemical functions. Its period (cycle duration) is calibrated by the alternation of light (directly) and darkness (through melatonin secretion by the pineal gland). The SCN generates the rest-activity cycle (left) and coordinates many circadian rhythms in the body, and possibly those that modulate cellular metabolism and proliferation (right). RHT, retinohypothalamic tract; PVN, paraventricular nucleus; NPY, neuropeptide Y.

expression of P53, cyclin E, cyclin A, and cyclin B1 in human oral mucosa.[20] The circadian amplitude of cyclin E was nearly twice as large as that of the other variables, which supports circadian regulation of the G1-S checkpoint. Furthermore, the expression of *PER* and that of *BMAL-1*, two of the main circadian genes, also show 24-hour rhythms in this tissue, indicating that oral mucosal cells are equipped with a molecular circadian clock.[21] The mechanisms through which the cellular circadian clock regulates cell-cycle checkpoints are unknown.

In all these tissues, the mean values for the proportion of S-phase cells are lower between 0000 h and 0400 h, while higher mean values occur between 0800 h and 2000 h.[1] The activity of dehydropyrimidine dehydrogenase (DPD), the rate-limiting enzyme of fluorouracil catabolism, increases by nearly 40% between 2200 h and 0000 h, in the circulating mononuclear cells of both healthy individuals and cancer patients (Figure 4).[22–24] These mechanisms of anticancer-drug chronopharmacology display a similar phase relation to the rest–activity cycle in mice and in human beings, despite the fact that the former are active at night and the latter during the day. During constant-rate infusion of fluorouracil, a circadian rhythm can be detected in the plasma concentrations, both in mice and in cancer patients. The peak concentration of fluorouracil occurs in the early part of the resting period in both species, even if the drug is infused continuously over a week or less.[25–28] On the other hand, patients with very advanced cancer, who are in poor

Table 2. Endogenicity of the rest activity circadian cycle

Property	Comments
Ubiquitous	In flies, rodents, human beings
Endogenous	Persists in constant environmental conditions
Molecular basis	Rhythm suppressed in case of mutation or deletion of: *per* gene in *Drosophila* *clock*, *cry1* or *cry*$_2$ genes in mouse Mammalian genes involved: *Per1*, *Per2*, *Per3*, *Clock*, *Bmal1*, *Cry1*, *Cry2*, *Tim*, *CKI*$_\varepsilon$
Central coordination	Rhythm suppressed if SCN destroyed, restored if in mammals
SCN transplanted (rodents)	
Monitoring (human beings)	Wrist-worn actimetry watch for a minimum of 3 days (sampling of wrist movements with a frequency of 1–10 per min)
Pathology (human beings)	Rhythm alteration in psychiatric or malignant diseases Sleep disorders

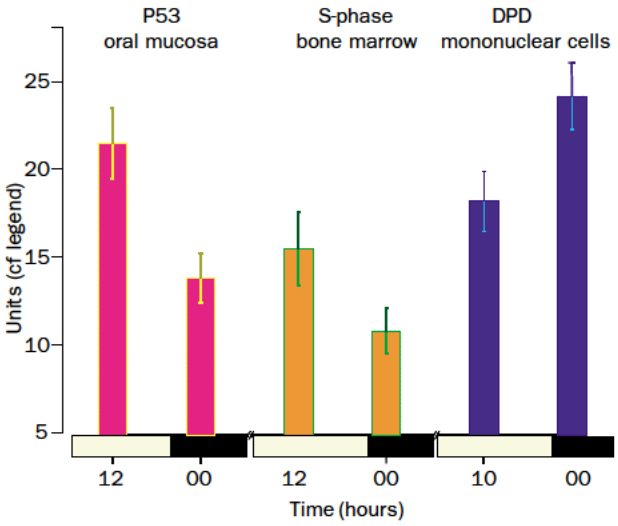

Figure 4. Circadian changes in cellular parameters relevant for chemotherapy tolerability in humans. Oral mucosa P53 in healthy subjects;[20] bone marrow S-phase cells,[19] and mononuclear cell dehydropyrimidine dehydrogenase activity in cancer patients.[23]

general condition, have received prior or concurrent treatments, or are on a low-dose, protracted infusion schedule may show altered DPD or fluorouracil rhythmicity.[22, 29]

The rest-activity circadian cycle

The regular alternation of rest and activity over a 24-hour cycle is one of the most obvious and extensively studied circadian rhythms (Table 2). [4–7, 30] The usual onset of the rest period occurs at the transition from darkness to light in mice or rats and between 2100 h and 2400 h in human beings. These synchroniser clock hours have been used as references for the average optimum times for anticancer drug exposure, because of the physiological coupling between the circadian rest–activity cycle and several chronopharmacology mechanisms, seen in all species. This strategy does not take into account the variability between patients in circadian-rhythm function. Indeed, the demonstration of a circadian rhythm in the hormone production of a single person requires sampling every 10–20 min for 24 h.[31] In other words, the demonstration of individual circadian rhythms in cancer patients is limited to the variables that are amenable to non-invasive monitoring, such as the rest–activity cycle which can be recorded by wrist actimetry. Individual rhythms in mechanistically related variables can be estimated only on data from samples obtained every 2–8 hours for 24–48 hours. With this approach, individual rhythms can be classified as being 'normal' or 'altered'. Rhythm alterations may consist of a decrease in amplitude, modification in peak time or cycle duration, or circadian rhythm suppression.[32]

Programmable multichannel pumps

Two randomised clinical trials, each involving 30 patients with advanced ovarian cancer, have shown that doxorubicin and theprubicin (5–10 min infusion) were better tolerated near 0600 h and cisplatin (1–4 h infusion) between 1600 h and 2000 h than 12 hours apart.[33–34] However, further testing of this treatment method was hampered by the difficulties involved in administering drugs at odd times of the day or night.

Since infusional chemotherapy generally results in better tolerability and antitumour activity than bolus administration,[35] semi-intermittent infusions at a constant rate over 8 or 12 hours have also been investigated, but with limited success.[36,37] The administration of quasi-sinusoidal infusions, with several consecutive steps involving constant-rate infusion at different flow rates over 24 hours, or chronomodulated sinusoidal infusion, a pattern similar to the simplest rhythm model, have become feasible without admission to hospital, through the development of time-programmable pumps.[38–40] This system has mainly been used to test the clinical relevance of chronotherapy. Multichannel devices have facilitated outpatient chronomodulated chemotherapy, with selected peak delivery times for up to four agents over a period of several days. Stability and reservoir compatibility were shown for periods of chronomodulated infusions of floxuridine, interferon-α, fluorouracil, leucovorin, oxaliplatin, and irinotecan at ambient temperature and under normal lighting conditions. Peak delivery was scheduled at 0400 h for fluorouracil and leucovorin, at 1600 h for oxaliplatin, and at 0500 h for irinotecan, based on previous experimental and clinical findings (Figure 5).

Drug pharmacokinetics during chronomodulated infusions

The time course of plasma drug concentrations parallels that of chronomodulated delivery for up to 14 days for fluorouracil,[26, 29] which has a half-life of 10–20 min.[41] This was also true for unbound platinum, during chronomodulated infusion of oxaliplatin, an agent with an initial half-life of 5–30 min and a terminal half-life of one to several days.[42] However, this terminal half-life accounted for plasma accumulation, which resulted in persistent exposure at unappropriate circadian times. Chronomodulated delivery of fluorouracil and leucovorin allowed better control of the plasma concentrations of these drugs if peak flow rates were scheduled at 0400 h than if they were scheduled at 1300 h or 1900 h, or constant-rate infusion. The three latter schedules also had greater toxicity than the first.[23]

These examples show that 24-hour changes in drug plasma concentrations match reasonably well with the chronomodulated delivery waveform, if peak delivery is scheduled at an appropriate time in the circadian cycle. The terminal half-life of the drug accounts for possible drug accumulation in the plasma, and may alter drug exposure patterns, either by shifting peak concentration time or by producing significant concentrations at delivery nadir. There is a need for pharmacokinetic studies on chronomodulated infusions, in order to optimize the alignment of chronotherapy delivery with the targeted circadian exposure pattern.

Chronotherapy for human cancers

The clinical relevance of the chronotherapy principle has been tested in over 1500 patients with gastrointestinal

For personal use. Only reproduce with permission from The Lancet Publishing Group.

disease enrolled in phase I, II, and III clinical trials. Chronomodulated infusions of fluorouracil, generally given with leucovorin, have formed the basis of most chronotherapy schedules developed so far,[24, 43] as a result of the well-established schedule dependency of fluoropyrimidine pharmacology and its toxicity profiles.[41]

MTD of chronomodulated infusions

Patients with gastrointestinal cancers receiving chronomodulated infusions of fluorouracil (alone or with leucovorin), oxaliplatin, or irinotecan at conventional doses showed a low frequency of severe toxic side-effects, in phase I/II trials of 25 to 35 patients each.[24, 38-40, 43] This apparent improvement in tolerability was used to increase the dose and/or to shorten the interval between courses, so as to achieve equivalent toxicity with conventional schedules. Chronomodulated delivery therefore enabled the dose intensity (cumulative dose over a given timespan) and/or the recommended dose of these drugs to be increased up to 100% (Table 3). The antitumour activity of these regimens was assessed near MTD in most trials. This strategy was used early in the course of oxaliplatin development.[24, 39, 42, 44-46] For fluorouracil plus leucovorin, a 4-day chronomodulated infusion of both drugs was administered with a fixed daily dose of 150 mg/m² of leucovorin, and the fluorouracil dose ranged from 900 to 1100 mg/m² daily (nearly twice the conventional MTD). This chronomodulated schedule was given every 2 weeks to 100 patients with previously untreated metastatic colorectal cancer in a phase II trial. The median fluorouracil dose intensity was 1800 mg/m² per week and the objective response rate, as assessed by computed tomography reviewed by an independent panel, was 41% (31.5–50.5 95% CI range). Median survival was 17 months, with 3-year survival of 18·6%.[47] This schedule achieved a 45% objective response rate in a separate Canadian study.[48] These results compare favourably with conventional or intermittent non-chronomodulated treatment schedules for this drug combination,[37] which have produced objective response rates of 10–30% and median survival of 10–14 months in multicentre trials.

Combination chronotherapy schedules

The good tolerability of chronomodulated fluorouracil with or without leucovorin allowed this regimen to be combined with other agents, including oxaliplatin, carboplatin or cisplatin, irinotecan, mitomycin, paclitaxel, mitoxantrone, vinorelbine, or floxuridine into the hepatic artery, or radiation therapy, in order to devise safe and effective outpatient combination regimens against several malignant diseases, without compromising on drug doses.

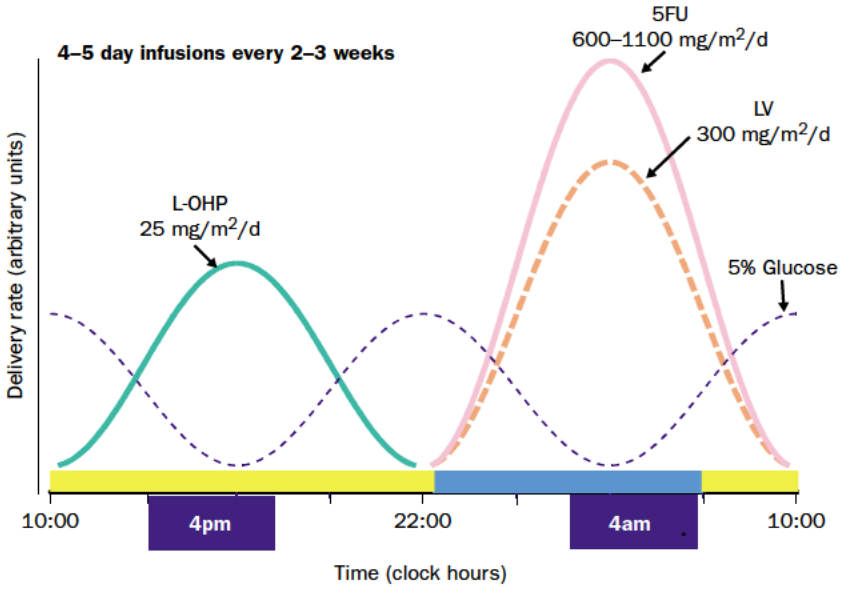

Figure 5. Example of a current chronotherapy schedules delivered to outpatients using a multichannel infusion pump: chronomodulated infusion of fluorouracil (5FU), leucovorin (LV), and oxaliplatin (L-OHP).

The role of oxaliplatin addition to chronomodulated fluorouracil and leucovorin was investigated in a multicentre, open, randomized, phase II/III study.[46] Fifteen centres recruited 200 patients with previously untreated, measurable metastases from colorectal cancer; they were randomly assigned chronomodulated fluorouracil and leucovorin (700 and 300 mg/m² daily, respectively; peak delivery rate at 0400 h) with or without oxaliplatin. Oxaliplatin (125 mg/m²) was given as a 6-hour flat infusion from 1000 hours to 1600 hours on the first day of each course, every 3 weeks. This infusion schedule was devised to remain close to the least toxic time for oxaliplatin. Response, the main judgment criterion, was assessed by means of extramural review of computed tomography scans. Severe gastrointestinal toxic effects (grade 3–4) occurred in 5% of patients given chronomodulated fluorouracil plus leucovorin and 43% of those also receiving oxaliplatin. An objective response was obtained in 16% (95% CI: 9–24%) of patients on fluorouracil plus leucovorin, and 53% (42–63) of those receiving additional oxaliplatin ($p < 0.001$). Median progression-free survival time was 6.1 months (4.1–7.4) and 8.7 months (7.4–9.2), respectively ($p = 0.048$). Median survival times were similar in the two treatment groups (19.9 and 19.4 months, respectively). A possible explanation

Table 3. Maximum tolerated dose of chronomodulated chemotherapy

Drug	Schedule	% Increase in MTD	Reference
Fluorouracil	5d every 21d	40%	65
Fluorouracil–leucovorin	5d every 21d	80%	43
Oxaliplatin	5d every 21d	33%	66
Floxuridine	14d every 20d	45%	38

was that 57% of the patients from the fluorouracil plus leucovorin group received second-line therapy with the three-drug regimen, which was given as an intensified chronomodulated schedule in most cases.

Validation of chronotherapy in randomised multicentre studies

The importance of chronomodulated delivery rate in cancer therapy was investigated in two consecutive international, multicentre, phase III studies, which compared flat and chronomodulated infusion of fluorouracil plus leucovorin and oxaliplatin in 278 patients with previously untreated metastatic colorectal cancer.[24] In the second study, which involved 186 patients,[44] severe stomatitis was seen in 76% of the patients receiving fixed-rate infusion, and 14% of those on chronotherapy. Cumulative peripheral sensory neuropathy with functional impairment was reported in 31% patients on constant delivery and in 16% patients on chronotherapy (illustrative figures can be found on the website at http://oncology.thelancet.com). The better mucosal status in the chronotherapy group allowed a 40% increase in median dose, a 22% increase in median dose intensity of fluorouracil, and a 30% prolongation of the oxaliplatin treatment span. Objective response rate was 51% for chronotherapy and 29% for constant-rate delivery ($p = 0.003$). According to this multicentre randomised trial, therefore, the most active chronomodulated schedule was also the least toxic one. Median survival was 16 months in both modalities, possibly because 24% of the patients crossed over from the flat schedule to chronotherapy.[44]

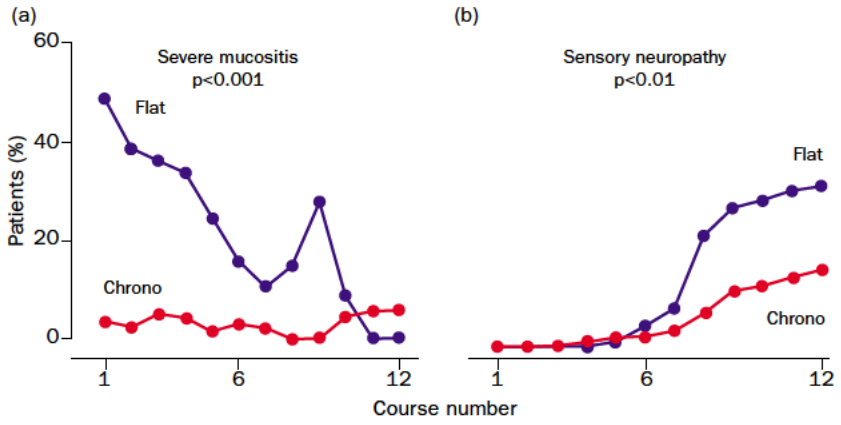

Figure 6. Comparative mucosal (a) and neurologic (b) toxicities of 5-day infusions of fluorouracil, leucovorin and oxaliplatin during treatment, as a function of drug delivery schedule.[44]

Dose intensity and antitumour activity

The good tolerability of a 5-day infusion of chronomodulated fluorouracil plus leucovorin with oxaliplatin allowed an increase of 20% in the 5FU daily dose and a shortening of the interval between courses of 1 week, in two consecutive trials involving a total of 103 patients with previously untreated metastatic colorectal cancer.[45, 49] This resulted in an increase of median dose intensity of 32% for fluorouracil and by 18% for oxaliplatin, compared with the previous 5-day chronomodulated schedule. In this multicentre trial, objective response rate was 66% (95% CI: 57–75) and median survival was 19.4 months (15.2–23.6). A summary of the data obtained by our multicentre study group, from patients receiving first-line chemotherapy for metastatic disease, illustrates the respective roles of chronomodulation and fluorouracil dose intensity on objective response rate.[24]

The achievement of a 50% or greater objective response rate with the three-drug chronomodulated regimen allowed surgical resection of metastases in a substantial proportion of patients.[50] The clinical relevance of this strategy was first demonstrated in a series of 151 patients with initially unresectable colorectal metastases confined to the liver, 80% of whom underwent chronomodulated chemotherapy with fluorouracil, leucovorin and oxaliplatin. Liver surgery with curative intent was attempted in 51% of the 151 patients and was successful in 38% of the total. A complete histological response was documented in four patients. The median overall survival for the 151 patients with liver-only disease was 24 months (95% CI: 19–28) with 28% surviving at 5 years (20–35). The estimated 5-year survival rates were 50 % (38–61) for the 77 operated patients and 3% for the 74 unoperated patients. Therefore, combination of effective and safe chemotherapy with surgery appears to alter the natural history of primary unresectable colorectal cancer metastases.[50] Indeed, surgery of metastases after chemotherapy was the major independent prognostic factor of survival in patients with previously non-resectable metastatic disease. In our multicentre experience, which is not limited to patients with liver-only disease, nearly twice as many patients underwent successful metastases surgery after first-line chronotherapy, as compared with those who received constant-rate infusion (25% versus 13%),[51] and this rate was further increased by intensification of chronotherapy (illustrative figures can be found on the website at http://oncology.thelancet.com).[24]

Circadian rhythm as a prognostic indicator of survival

Several clinical and biological variables influence the natural history of human malignant disease and have been identified as independent prognostic indicators of survival. The combination of several of these factors accounted for median survival times ranging from 3.8 to 21.3 months in patients with metastatic colorectal cancer who did not receive specific therapy.[52] Circadian rhythm alterations were found in patients with breast, ovarian, and colorectal cancer, and were usually associated with increased tumour burden or poor general condition (WHO performance status of 2 or greater).[32] However, two recent studies have shown that circadian rhythm alterations can be encountered in patients of good performance status with colorectal or breast cancer, and constitute an independent prognostic indicator of survival.[53,54]

The relevance of the rest–activity and cortisol circadian

For personal use. Only reproduce with permission from The Lancet Publishing Group.

rhythms to quality of life and survival was prospectively investigated in 200 patients with metastatic colorectal cancer.[53] This assessment took place before the administration of a first course of chronotherapy with fluorouracil, leucovorin and oxaliplatin. Previous chemotherapy or radiotherapy had been given to 59% of the patients. An abnormal cortisol rhythm was defined as a decrease of less than 40% in plasma concentration between 0800 and 1600 h. An abnormal rest–activity cycle was characterised by an autocorrelation coefficient at 24 hours of less than 0.28, an indication of poor reproductibility in the rest–activity pattern from one day to the next. About 30% of the patients had circadian rhythm alterations, by these criteria. Although cortisol-rhythm estimate was unrelated to quality of life or survival, the patients with a marked rest–activity cycle had a better quality of life and longer survival than those with poor rhythmicity. Survival at 4 years was twice as high in the patients with a marked rest–activity cycle, as in those with damped or altered rhythms. Multivariate analysis indicated that the prognostic value of circadian rhythmicity for rest–activity was independent of other well-known prognostic factors such as performance status, number of metastatic organs, or degree of liver replacement by tumour.[53]

The relation between the salivary cortisol cycle and survival was explored in 104 patients with metastatic breast cancer, previously given chemotherapy, radiotherapy, or both; 69% were receiving hormonal therapy at study entry.[54] While 37% of the patients had cortisol concentrations that peaked at 0800 h and declined thereafter, 49% of patients had peaks that occurred later in the day, and 14% had no apparent rhythm. Patients from the two latter groups were considered to have altered rhythms. The 4-year survival was nearly twice as high in the patients with normal cortisol patterns as in those with altered patterns. Furthermore, cortisol diurnal slope remained a highly statistically significant factor in multivariate analysis, indicating that it was an independent predictor of survival (illustrative figures can be found on the website at http://oncology.thelancet.com).

These data indicate that patients with metastatic colorectal or breast cancer may display circadian rhythm abnormalities, which either reflect aggressive disease or contribute to disease aggressiveness, via mechanisms that need to be explored further. Both studies suggest that circadian clock alterations may contribute to the acceleration of cancer growth. Another study has shown that hormonal circadian rhythms were altered in women at high risk of breast cancer, compared with women at low risk.[31, 55] The circadian rhythm abnormalities that result from frequent transmeridian flights could contribute to an increased risk of developing cancer in flight attendants, a hypothesis supported by epidemiological data[56, 57] as well as by results from experimental studies.[58, 59]

Conclusions

Rhythms in cell function and proliferation circadian rhythms account for predictable circadian changes in cancer-treatment tolerability and efficacy. The extrapolation, from mice to human beings, of the least toxic times to administer chemotherapy has been validated in patients with metastatic colorectal cancer in phase III clinical trials. The chronotherapy concept has played an important part in the recognition of the activity of a new drug, oxaliplatin, against colorectal cancer, and has given rise to a new medicosurgical strategy with curative potential in patients with metastatic disease. Thus, the median survival of patients with colorectal cancer metastases who receive chronotherapy has consistently ranged from 16 to 21 months, the longest time reported for this disease in multicentre trials.

Most patients who participated in the control groups of chronotherapy trials received chronotherapy later in the course of their disease, once the main endpoint (ie tumour response) had been reached. The selection of survival as the main endpoint may thus be unrealistic for metastatic disease, since patients should not be denied the benefit of proven active therapeutic modalities. Nevertheless, current multicentre trials by the Chronotherapy Group of the European Organization for Research and Treatment of Cancer (EORTC) are investigating the use of chronotherapy in prolonging the survival of patients with colorectal or pancreatic cancer (EORTC 05962 and 05963). Nevertheless, meta-analyses may be required to demonstrate survival differences between chronotherapy and conventional treatment schedules in patients with metastatic disease, because survival was only weakly correlated with response rate.[60] However, the findings do suggest the need for further investigations of chronotherapy for prolonging survival in the adjuvant setting. Indeed, survival was largely improved with evening rather than morning administration of maintenance chemotherapy in children with acute lymphoblastic leukaemia.[61, 62]

The role of this treatment concept for improving the tolerability of chemotherapeutic drugs such as irinotecan or vinorelbine (EORTC 05971) is being explored in colorectal and breast cancer, respectively. Infusional chrono-chemoradiation is also being carried out in clinical phase II evaluation in patients with primary biliary cancer (EORTC 05991 and Radiation Therapy Oncology Group – RTOG), and the role of radiation timing on mucosal toxicity is being studied in patients with head and neck tumours by the National Cancer Institute of Canada. These trials involve up to 30 centres from ten countries and mostly follow up on interesting data gathered by single institutions.

The results obtained in colorectal cancer further warrant the assessment of chronochemotherapy in patients with breast, lung, or other malignant disease, and in the adjuvant setting. Yet circadian rhythms also modulate cell-cycle proteins, growth factors, coagulation factors, immune functions, and the expression of many genes.

Search strategy and selection criteria

Published data for this review were identified by searches of NCBI PubMed over the past 5 years using 'circadian rhythms' and 'cancer' as keywords and without any restrictions on language of publication. Also, the references of relevant articles from the authors' own database were used.

For personal use. Only reproduce with permission from The Lancet Publishing Group.

Chronomodulated delivery may therefore help to improve the therapeutic index of cytokines and regulators of cell growth or angiogenesis.[63, 64] The genetic origin of circadian rhythmicity may make chronotherapy potentially relevant for gene therapy as well. Finally, the association of circadian system dysfunctions with accelerated cancer growth is puzzling and may indicate a need for specific supportive care, a measure that could improve quality of life, and possibly survival, in these patients.

1. Rigor and Reproducibility: SUMMARY

The single most effective way to improve the rigor of American biomedical science is to stop rewarding investigators for where they publish and start rewarding them for whether their findings hold up. Today, NIH effectively outsources the definition of scientific merit to commercial journals whose business model rewards novelty, citations, and attention — none of which is reproducibility, and several of which actively work against it. Career advancement and future funding hinge on publishing in a small set of high-prestige venues; those venues, in turn, are incentivized toward splash over durability. The result is a system that selects, generation over generation, for productivity at the expense of reliability. This is not a problem of a few bad actors. It is a problem of a misaligned social contract, and it can be fixed by changing what the enterprise measures and who controls the measurement.

NIH is uniquely positioned to fix it, because NIH funds the largest share of biomedical research in the world and already owns the necessary infrastructure (PubMed Central). The proposal below is a public, rigor-gated system for reviewing and recording NIH-funded findings, with a credit currency that rewards reliability rather than prestige. It can be piloted on existing infrastructure and scaled deliberately.

A single principle organizes the recommendations that follow: innovation should be rewarded when an idea is funded; novelty should never be rewarded when a result is evaluated. The worth of a finding is whether it is true and useful, not whether it was first.

RIGOR AND REPRODUCIBILITY

The core recommendation: relocate peer review out of commercial publishers and into a public, rigor-gated review-and-record system, required for work supported by NIH funds.

The current model asks one or a few overburdened, anonymous reviewers to assess an entire multi-disciplinary study — often with dozens of distinct assays — against a journal's appetite for novelty. No single reviewer is competent across all of it; brand name substitutes for verification; and the verdict measures perceived importance rather than reliability. We propose a two-tier structure that decouples those functions:

1) A standing review panel, modeled on a study section: a small group of subject-matter experts who know one another and must defend their judgments to colleagues, not under cover of anonymity. This panel does not itself certify individual experiments.

2) Modular, registry-matched expert review of individual assays: When NIH investigators apply for funding, they register the specific methods and assays in which they hold expertise. When a study is submitted, the standing panel identifies the assays requiring specialized scrutiny and routes each to qualified experts drawn from that registry. These assay-level reviews are anonymous to the author and double-blind, and each assay is certified satisfactory or not on the basis of rigor alone. Crucially, certification is conditioned on access to deposited, runnable data, code, and unprocessed images (see Data, Software, and Model Sharing), so that "satisfactory" means an expert actually checked the evidence rather than the figure. Participation in assay-level review could be made mandatory for good standing in progress reports — the effort to evaluate individual assays should be significantly less than the current effort to review an entire manuscript.

Thus, this division reduces per-reviewer burden (experts assess only what they are expert in), removes brand and perceived-novelty from the rigor judgment entirely, and places accountability where it belongs at each level.

The competence registry.
Two features of this registry deserve emphasis, because the rest of the proposal draws on them. First, reviewer identities are tracked by the system even when blinded to the author. This permits a reviewer's own record to be assessed over time — specifically, whether the assays they certified continue to reproduce — and it is the basis for the portable rigor credential described under Training and Mentorship. Second, because reviewing is not itself a funded activity, the registry can be extended to qualified non-NIH-funded and international experts. This widens access to scarce methodological expertise and, importantly, dilutes the conflicts of interest that arise in small subfields, where the few qualified reviewers and the authors they assess inevitably overlap. Together these features convert peer review from invisible, unrewarded, anonymous labor into a tracked, creditable, and accountable contribution.

Classification, not ranking.
Once every component is certified, the standing panel renders one further judgment — does the overall claim follow from the certified evidence? — and then classifies the study by what it is: reproduction (successful or failed) of prior work, method or assay development, target discovery, mechanistic advance, and so on. This classification step is the natural home for what the RFI calls defining causal research: the panel's explicit task is to assess whether the certified bricks (assays) actually support the building (the conclusions of the full study), including whether a causal claim is warranted by the design. The system records what a study established; it does not anoint a winner. Importantly, it does not assign some concept of 'Impact' at the time the study is published. Impact, by definition, must be assessed longitudinally, and be looked at by reproducibility (captured by the proposed system), citations of the study (as opposed to "Impact Factor" of the journal, and links to emerging technologies, clinical tests, or clinical trials.

Defining causal research and confirmatory claims.
For claims sold as confirmatory, replicative, or near-translational, a registered-report track — in-principle acceptance based on question and methods before results are known — should be available and, where stakes warrant, required. This destroys publication bias and analytic flexibility at the root for precisely the claims where reliability matters most, similar to what is already required of clinical trials. Exploratory and discovery science must remain free to pivot; it should simply be labeled exploratory so it cannot later masquerade as a definitive test. (An NIH grant is, in effect, already a pre-registered protocol; this track formalizes that logic at the reporting stage.)

2. Data, Software, and Model Sharing: In the afore described system, make deposit the precondition for review eligibility, not an optional supplement. A panel cannot be certified unless the underlying data, analysis code, and raw images are deposited and runnable. This reframes sharing not as a compliance burden but as the thing that makes rigorous review possible — it eases the honest path rather than policing the dishonest one. As a measurable indicator, the fraction of an investigator's certified panels backed by independently re-executable data and code is a direct, gameable-resistant signal of rigor that current metrics cannot capture.

3. Training and Mentorship: The competence registry described above doubles as a training and recognition instrument. Performing structured, accountable assay-level review is itself rigorous training; trainees learn what "satisfactory" actually requires by doing it, under the standing panel's oversight. More importantly, a reviewer's record — and specifically whether the panels they certified continue to reproduce over time — becomes a portable, verifiable credential of judgment and rigor. This recognizes a form of scientific labor that is presently invisible and unrewarded, and it gives mentorship and rigor-training a measurable footprint: a mentor's contribution can be assessed in part by the certified, reproducing output of those they train.

4. Collaboration: The indivisibility of authorship is a central pathology of large-team science: on a fifteen-author paper with hundreds of panels, no one is accountable for any specific result, and supervisors cannot — and demonstrably do not — verify all of it. The system above produces accountability as a byproduct of review. Each certified data panel is tied to the authors who stand behind it; supervising investigators stand behind every panel under their direction. This yields a granular, contribution-level record of who is accountable for what — a far more honest substitute for authorship-order conventions, and a concrete mechanism for recognizing genuine team contributions without diluting accountability into anonymity. Recognition scales with verified contribution rather than with position in an author list.

5. Entrepreneurship and Translation: Translation is where reliability carries the highest stakes and where irreproducibility is most expensive. The registered-report track and mandatory data and code deposit are most valuable here: a public, rigor-certified record of what has actually been established accelerates legitimate translation and reuse, while denying downstream developers the false starts that a hype-optimized literature currently supplies. A trustworthy record is an accelerant for entrepreneurship, not a brake on it — capital and effort flow more efficiently when the underlying findings have been verified rather than merely published.

6. Foundational Scientific Exploration: The reform protects high-risk, high-reward work rather than threatening it, provided two safeguards are built in. First, the innovation/novelty distinction: bold,

unprecedented ideas should continue to be rewarded at the funding stage (innovation is a legitimate criterion for backing an idea), while the evaluation of results is stripped of any premium for mere priority. In other words, great solution's value is its greatness, not its novelty and a useless finding is not redeemed by being first. Second, a rigor-rate metric must not punish ambition: an investigator attempting one of the few assays only a handful of labs in the world can perform must not be penalized for a difficult initial verdict. Only the final, post-revision certification should count toward an investigator's record, so that a hard first attempt is a draft, not a permanent scar. Reproducible discovery and bold exploration are then complementary, not competing.

7. Public Impact: This is, fundamentally, a public-trust proposal. The scientific record produced with public funds should be public infrastructure, governed for reliability and accessible to the citizens who paid for it — not rented back from commercial intermediaries whose incentives diverge from the public interest. A system that certifies whether findings hold up, and that records reproduction and replication as first-class outcomes, speaks directly to the erosion of public confidence in science. The most durable measure of impact is not the "impact factor" of the journal is was published in, but whether others can build on a result — and that is precisely what this system would, for the first time, measure directly.

WHAT HAPPENS TO THE JOURNALS?

Commercial journals are not abolished, and they are not the enemy of this proposal — they are simply moved out of a role they were never well suited to. Under this model they continue to do what magazines do well: sell subscriptions and advertising in exchange for curating content. What changes is that they exit the business of gatekeeping peer review and enter the business of surfacing the most interesting results from the public record and explaining them — to the general public, to scientists outside the field, and to clinicians — each audience served by the kind of clear, compelling writing that journals already excel at when freed to do it.

This is a net gain for science on its own terms. There is a well-documented gap between what biomedical research establishes and what the public understands, and that gap is corrosive to the public trust the NIH is explicitly trying to rebuild. A communication-and-curation layer that competes on the quality of its explanation, sitting atop a record that has already been certified for rigor, is far better positioned to close that gap than the current arrangement, in which the same outlets are responsible for both judging science and selling it.

It is worth being candid about the one party that loses. Today the public pays three times over: taxpayers fund the research, then pay again — through institutional subscriptions and publication charges — to put it in print, then pay a third time to read it. Removing peer review and the scientific record from commercial control ends that arrangement. Journals would earn less from taxpayer-subsidized labor and would have to compete harder, on the merits of their communication, for the revenue they keep. That is not a cost to science or to the public; it is the correct alignment of incentives finally reaching the last actor in the chain.

8. Other Areas: SUMMARY OF MEASURABLE INDICATORS OF PROPOSED SYSTEM

1) Rigor rate: the percentage of an investigator's panels that achieve final certification — a direct

measure of reliability that resists padding, because low-quality panels lower the rate.

2) Durability / build-on rate: credit accrues to a panel when others successfully reproduce or build upon it — an impact measure that rewards being right over being first, and that operationalizes the value of doubling down on solid prior observations.

3) Reproducibility-backed deposit rate: the fraction of certified panels supported by independently re-executable data and code.

4) Reviewer reliability: whether the panels a reviewer certified continue to reproduce over time.

These two axes — a rigor rate and a durability rate — deliberately separate the two things the RFI asks NIH to measure: reproducibility discipline and impact. Collapsing them into one number is what produced the current generation of gameable metrics.

UNINTENDED CONSEQUENCES AND FEASIBILITY

A serious proposal must name its own failure modes.

Conflict of interest in small fields. In assays only a few labs perform, reviewers and authors overlap, compete, and co-fund. The mitigations are structural and largely built into the architecture above: assay-level review is double-blind to the author; the reviewer pool extends beyond NIH-funded investigators (see The competence registry, above), diluting conflicts in small subfields; and the standing panel — which is not anonymous to itself — must defend its classifications, deterring capture.

Metric gaming (Goodhart's Law). Any single metric will be gamed. The two-axis design is the defense: the rigor rate punishes panel-proliferation, and durability weighting makes commodity-assay farming worthless, because easy panels are not the ones others build upon.

Fraud is out of scope. This system repairs the incentives that drive otherwise-honest investigators toward poor practice; it is not a fraud-detection apparatus. Deliberate fabrication requires separate detection and enforcement and should be addressed as such. Stating this boundary matters: the goal of this proposal is to repair a broken social contract for the honest majority, not to assume bad faith.

The transition cost and career-stage feasibility. If the proposed system, or any new system is adopted, for an interval, NIH-funded investigators would operate under a standard the rest of the world has not yet adopted. The investigators most exposed are likely also our most vulnerable: post-docs and early-stage investigators at conventional research universities whose promotion-and-tenure committees still weight prestige-journal placement — a domain NIH does not directly control. A related risk is that well-resourced laboratories able to fund themselves through other means decline NIH support to keep pursuing prestige, inverting the intended hierarchy. Mitigations: phase the mandate; condition institutional support on adoption of responsible, venue-independent assessment in promotion (NIH's funding relationship is the lever); and pilot on PubMed Central before scaling. The forcing function is

NIH's own scale — as with public-access policy, an NIH mandate can move the global norm.

Governance and durability. A publicly owned record must not become a politically controlled one. Editorial and certification authority should be vested in a statutorily independent, firewalled entity — chartered for operational independence in the manner of the National Academies, with scientific-society co-governance to import the editorial culture of the most rigorous existing journals. The system must be designed to remain independent of whoever holds power; that durability across administrations is not a vulnerability to be hidden but the central feature that distinguishes a public record from both political and commercial capture.

1. Rigor and Reproducibility: Incentives to skew scientific findings to make them "look" better than they are (to get into a fancy journal) will never be fixed until metrics focus on the process of doing a good experiment/study and completely separates it from the particular outcome of the study. Reward should be placed on rigorous experimental design (blinding, randomization, sample size estimation, proper positive and negative controls, transparent reporting of data exclusions and analysis plans), on asking an important question that can be answered by the experiment as designed, and on the replication and expansion of collective knowledge in the area by other researchers. The outcome of any single experiment should be irrelevant to crediting the scientist as a "good" scientist. Metrics should extract and consider important experimental design elements within protocols that reduce experimental bias and facilitate the probing of causality, and these metrics should proactively block consideration of the outcome of the experiment. (Outcomes would be more relevant to an overall long-term "impact" metric but should still only be considered in the context of the body of scientific evidence and should not rely on a single experiment or study.) Journal impact factor, journal reputation, citation counts, and other superficial "popularity" metrics are completely irrelevant to the rigor of a study and are, themselves, prone to bias and skewing in a way that does not even correlate with rigorous experimental design.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: In order to promote high-risk, high-reward research, publication counts and other "productivity measures" need to be retired. Similar to the rigor question above, the focus of any metric should be on the design of the study and how likely it is to provide a valid answer to an interesting question, regardless of what that answer happens to be. The process of doing good science should be assessed and not the outcomes of particular lines of research, publications, or individual experiments. Was the protocol rigorously planned? Did the experiments blind, randomize, ensure sufficient sample size, have proper controls, remove subjectivity to the extent possible? Was the design of the experiment actually capable of providing an answer to the specific question posed?

7. Public Impact: The issue with providing any specific metric of public impact (such as contributions to patents or medical guidelines) is that this presumes a single experiment or the work of a single experimenter can or should be linked directly to these outcomes. Science is a collective body of evidence, with multiple lines of research asking orthogonal questions with different experimental designs to build a full context of our knowledge. Single experiments are, by definition, not worth much without this broader context. It is antithetical to the goals of promoting high-quality individual studies that are rigorous and carefully designed so that they properly contribute to the collective knowledgebase to then reward people most highly for producing high-profile, individually recognizable claims of knowledge. That way lies perverse incentives. Rather, models should build collective knowledge by integrating all evidence available, but it should not then be credited to any specific single individuals or studies. Popularity, visibility, and fame do not measure quality. Rather, NIH should instead focus on using these collective knowledgebases to provide a larger story of how NIH-funded research contributes overall to these larger impacts.

1. Rigor and Reproducibility: Rather than tactical, the fundamental problem is the disincentivization of R&R throughout research ecosystems, which impacts human behavior at all levels of these ecosystems. Promotion and tenure, private funding, publication, and even training are based principally on impact and productivity. In general, this comes at the expense of rigor and reproducibility. Until there is meaningful cultural movement to combat the disincentives for R&R at multiple levels within these ecosystems, most useful tactics will die on the vine. Actually, in my view, NIH/CSR has been the one meaningful breath of fresh air in this space. NIH/CSR cannot tackle this problem alone, but I do applaud the persistent effort.

For institutions, incentives and infrastructure to support R&R of existing findings could make a difference, but would not address root causes. Just like clinical trials, it is impossible and impractical to have "gold standard" evidence for everything.

Funding that directly (or indirectly) motivates institutions and journals to elevate R&R in their review processes could help, although this may not be within scope for NIH/CSR. Somehow taking advantage of the increasingly-popular preprint mechanisms to modify journal behavior strikes me as an opportunity.

The R&R problem only gets bigger with the promotion of multidisciplinary "large team" science. Thus, another strategy to consider would be shifting project funding back towards small team science, where accountability for R&R is clearer and impact is more disruptive than incremental (Wu et al., Nature 2019; PMID: 30760923).

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: As with grant review, I also applaud NIH/CSR efforts to institutionalize Responsible Conduct in Research (RCR) training, and there is some overlap in the Venn diagram of RCR with R&R trainings. However, in reality, these only partially overlap. Specific training requirements for R&R would be one concrete suggestion.

4. Collaboration: Is the assessment and recognition piece something that NIH/CSR needs to actually worry about? This sound more like an academia problem.

5. Entrepreneurship and Translation: My only comment is that this area, too, comes at the potential cost and diminution of R&R incentives at the front end of the research process. Attention to R&R in this process will be key to avoiding wastage of taxpayer dollars and setting back research fields.

6. Foundational Scientific Exploration: I fully agree. See above comment re: Wu et al., Nature 2019 (PMID: 30760923). Journals and reviewers naturally hold authors to a higher bar for the "burden of proof" for disruptive ideas, which then naturally aligns with R&R incentives. NIH shifting more resources towards rigorous high-risk, high-reward R01s (and not just R21s) seems like a great idea.

7. Public Impact: Come to think of it, this category is also a disincentive to R&R and comes with substantial overpromising risk. Also, while communication with the public is critical, effective communication is hard and public subset-dependent. For NIH/CSR, it would seem that the most relevant subset are the lawmakers. Whatever approaches at lower levels also align with helping NIH message better to the lawmakers would make the most sense. And seems budgetarily feasible.

1. Rigor and Reproducibility: you could look at researchers that have had papers retracted and have harsher penalties for having work retracted if it was NIH funded. There are certain journals that are also more likely, statistically, to have retracted papers within them - this could be looked at.

2. Data, Software, and Model Sharing: NIH has already put in rules to make sure that researchers share their data and tools with others if the work has been funded by NIH research. this isn't always followed. My team and I have come up against several scenarios where we write to corresonding authors for data and tool request and often they don't even email back. there should be something in place that's stronger to make sure PIs share their work.

3. Training and Mentorship: Too often reviewers review training grants or fellowships with an eye toward how many students go on to academic positions . this is an antiquated view, and instead we should be assessing whether graduates are contributing in any way to further knowledge or to the US economy by obtaining their career of choice with strong training.

4. Collaboration: n/a

5. Entrepreneurship and Translation: having a place specifically for patents could demonstrate translation of NIH funded work.

6. Foundational Scientific Exploration: You could weigh innovation of proposals heavier. right now that's buried within significance in the scoring criteria. More specific calls for high risk proposals, such as those funded under the common fund, could also help here.

7. Public Impact: N/A

Name: Ji-Hyun Lee

Name of Organization: University of Florida

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/26/2026

1. Rigor and Reproducibility: One issue I would like NIH to consider is what happens to study size after a grant is funded.

When investigators submit an NIH proposal, they spend a great deal of time justifying the sample size. The study is designed to detect a clinically meaningful effect with adequate statistical power, and reviewers carefully evaluate those assumptions. The proposed sample size is one of the scientific foundations of the grant.

However, after funding, the reality is often very different. Across many NIH-funded studies that I have collaborated on as a biostatistician, it is actually uncommon for a study to reach its planned enrollment. Recruitment is slower than expected, budgets change, and investigators proceed with a substantially smaller study.

Some reductions are unavoidable. That is not the issue.

The issue is that this has become an accepted part of the research culture. Investigators expect it, reviewers know it happens, and NIH has largely tolerated it as long as the study is completed. As a result, we have become comfortable proposing one study during peer review and conducting another after funding.

I believe this culture should change. If a study undergoes a major reduction in sample size, investigators should transparently justify the change and demonstrate that the revised study can still answer the original scientific question. Scientific success should not be measured only by publications. It should also reflect whether the funded study was conducted with the rigor that justified the award.

2. Data, Software, and Model Sharing: In my experience, I have rarely seen data sharing or software sharing become as valuable as NIH envisions. The reason is not a lack of willingness to share. Rather, high-quality sharing requires a substantial amount of additional work that is often overlooked.

Preparing a dataset for others to use is much more than uploading a file. The data must be cleaned, documented, quality checked, and accompanied by reproducible statistical code. Otherwise, other investigators cannot reproduce the findings or confidently reuse the data.

In many collaborative projects, this work falls largely on statisticians. Yet this effort is rarely reflected in grant budgets, scientific recognition, or measures of research productivity. If NIH truly wants to promote reproducibility through data sharing, it should explicitly recognize the statistical effort required to make shared data scientifically useful, not simply publicly available.

3. Training and Mentorship: None.

4. Collaboration: NIH has been promoting team science and interdisciplinary collaboration for many years. However, I do not think the academic reward system has changed accordingly.

Take a look at tenure and promotion criteria at most universities. They still place the greatest value on being the PI of a grant and the senior or corresponding author of publications. Collaborative contributions are often viewed as secondary, even when they are essential to the success of the research.

This creates a mismatch between what NIH encourages and what academic institutions reward. Why should faculty spend substantial time on collaboration if those efforts are not valued in their careers—or may even work against promotion?

If NIH wants to promote team science, collaboration should be recognized and rewarded not only in NIH funding, but also in the academic evaluation system.

5. Entrepreneurship and Translation: None.

6. Foundational Scientific Exploration: I strongly support basic research and high-risk, high-reward science. However, I wonder whether the current research environment places too much emphasis on the number of funded projects and publications rather than the scientific value they generate.

Biomedical research has grown tremendously over the past several decades. Yet it is not clear that a larger number of grants and publications has always translated into a proportional increase in meaningful scientific discoveries or improvements in human health.

NIH should consider placing greater emphasis on the quality, rigor, and long-term impact of research rather than the quantity of funded projects or published papers. This also requires rewarding the practices that make research more valuable, including conducting studies as originally designed, sharing high-quality and reproducible data and software, and recognizing meaningful contributions to team science. Scientific success should be measured by the knowledge generated and its contribution to society, not simply by research output.

7. Public Impact: None.

8. Other Areas: None.

8. Other Areas: GENERAL COMMENT

I am an academic clinician-scientist with 40 years of basic and translational research experience. My professional activities have included more than twenty years as a journal editor, and I have served on many scientific review panels. Therefore, I am very familiar with the challenges in measuring scientific impact. One of the most important limitations is that impact can only be assessed in retrospect, and the amount of time required to fully appreciate a scientific discovery is often in direct proportion to its importance. The ultimate importance of a scientific contribution can be measured by the size of the problem, its practical utility, its integration with other knowledge, and its novelty (Casadevall and Fang, Infect Immun, 2009).

My recommendation is that the NIH focus on research quality, not quantity nor impact. A scientist can ensure the quality of his research, but not the impact. If a broad range of investigator-initiated research is supported, and the work is of high quality, societal rewards will follow. Aggressive, top-down efforts to manage this process with the goal of maximizing impact are likely to backfire. History has repeatedly shown us that we do a poor job of predicting the future of scientific progress, and it is better to cast as wide a net as possible, investing both broadly and deeply.

With regard to the post-hoc assessent of research impact, it would be wise to remember that not everything that counts is easily counted. Bibliometric indicators are only one measure of impact. Beyond the # of publications, citations and h-index, a bibliometric measure should account for first/senior vs co-authorship (Ioannidis et al. PLoS Biology, 2019) and laboratory size. How is it reasonable to compare the publication output of a lab with three members versus one with thirty?

In addition to bibliometrics, for assessment of an individual researcher's productivity I favor the use of multiple "metrics" that include influence, societal engagement, innovation, commercialization, research funding, mentoring activities, rank in the field, etc. No single researcher can contribute in all these respects, but for the research community collectively, each kind of contribution is invaluable. No single metric will fit all researchers.

Response to NIH Request for Information: Measuring and Rewarding Scientific Impact

Biomedical research has become increasingly collaborative, interdisciplinary, and data intensive, yet many of NIH's funding mechanisms and measures of scientific success continue to emphasize individual investigator-led projects. While investigator-initiated research remains an essential driver of innovation, there is an opportunity to complement this model by recognizing and incentivizing collaborative approaches that maximize rigor, reproducibility, efficient use of resources, and progress toward high-priority scientific objectives. Advances in artificial intelligence provide a unique opportunity to help NIH identify complementary scientific efforts and organize research in ways that better leverage the collective strengths of the biomedical research community.

One potential approach would be for NIH to develop an AI-assisted portfolio optimization program that analyzes scientifically meritorious but unfunded grant applications to identify complementary objectives aligned with NIH strategic priorities. Rather than evaluating applications solely as independent projects, the system would identify common hypotheses, complementary expertise, shared technologies, and overlapping scientific goals across multiple proposals. Based on these analyses, AI could generate integrated "plans of work" that decompose ambitious research objectives into coordinated modules assigned to laboratories with demonstrated expertise and strong preliminary data in specific areas. NIH program staff would retain responsibility for selecting research priorities, evaluating AI-generated recommendations, approving project plans, and overseeing program implementation.

Such a model would naturally promote team science by recognizing that many important biomedical questions are best addressed through complementary expertise distributed across multiple laboratories rather than expecting a single laboratory to possess every required capability. Participating laboratories could voluntarily opt into this collaborative funding mechanism and receive milestone-based subawards for completion of clearly defined experimental objectives. This approach would provide opportunities for highly capable investigators whose individual applications narrowly missed funding while allowing NIH to assemble research teams optimized for scientific success rather than institutional boundaries.

This framework also offers a practical mechanism for improving rigor and reproducibility. Instead of treating replication as a post-publication activity, NIH could intentionally design independent replication into selected projects by assigning critical experiments to multiple laboratories using standardized protocols and predefined analysis plans. Independent confirmation of key findings would become an expected component of high-impact research rather than an infrequent follow-up study. Differences in outcomes between laboratories would also provide valuable scientific information by identifying sources of experimental variability early in the research process.

The proposed model would further strengthen data sharing and transparency by encouraging participating laboratories to adopt common experimental protocols, standardized data formats, shared repositories, preregistered analysis plans where appropriate, and coordinated reporting of milestones. Because participating investigators would contribute individual components toward a common scientific objective, success would depend upon open communication and timely sharing of methods, data, and intermediate findings. These collaborative practices would increase the long-term value of federally funded research resources beyond individual publications.

Importantly, this framework suggests that NIH broaden the activities it recognizes and rewards when assessing scientific impact. In addition to publications and citations, NIH could recognize meaningful contributions such as successful completion of collaborative research milestones, independent replication of key findings, generation of reusable datasets and validated protocols, development of shared technologies, participation in multidisciplinary research teams, and demonstrated commitment to open science practices. These activities frequently generate substantial scientific value but are not consistently recognized within traditional measures of academic success.

Several measurable indicators could be used to evaluate the success of such a program. These include rates of successful independent replication, time required to achieve predefined research milestones, adoption of shared datasets and experimental protocols by external investigators, efficiency gains through reduced duplication of effort, successful completion of collaborative project modules, production of broadly reusable research resources, and downstream scientific impact as measured by follow-on discoveries, clinical translation, or incorporation into future NIH-funded research programs.

As with any new funding model, safeguards would be essential. AI should serve only as a decision-support tool rather than replacing peer review or programmatic oversight. Final funding decisions, project design, investigator selection, and milestone evaluation should remain under NIH leadership. Participation should be voluntary, intellectual property and authorship expectations should be established before project initiation, and investigators should retain opportunities to pursue independent research alongside collaborative efforts. Initial implementation through pilot programs within selected NIH Institutes or Centers would allow careful evaluation of feasibility, investigator acceptance, and scientific outcomes before broader adoption.

Overall, an AI-assisted portfolio optimization program offers an opportunity to better align NIH incentives with the collaborative nature of modern biomedical research. By recognizing contributions that improve rigor, reproducibility, data sharing, and complementary team science, NIH could increase the return on public investment while reducing unnecessary duplication and enabling scientifically meritorious ideas that might otherwise remain unfunded to contribute meaningfully toward national biomedical research priorities.

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/26/2026

1. Rigor and Reproducibility: NIH should fund dedicated replication studies, recognize replication as a valued contribution in peer review, and build infrastructure for data/code sharing and multi-site validation networks.

2. Data, Software, and Model Sharing: NIH should treat data and tools as core research outputs in peer review, biosketches, and promotion. It should fund data curation and require FAIR practices supported by shared repositories and interoperability standards. Embedding sharing into grant evaluation will accelerate validation, collaboration, and scientific impact.

3. Training and Mentorship: NIH should track trainee career progression and long-term engagement in biomedical research. Additional metrics should include mentorship quality, diversity and inclusion across career stages, and equitable access to funding and leadership opportunities. Tracking trainee outcomes, team science participation, and contributions to collaborative research networks will better reflect training and mentorship.

4. Collaboration: NIH should use structured contributor frameworks to document individual roles in team science. It should also recognize team science leadership and cross-disciplinary integration. It should align funding and promotion criteria to value collective impact alongside individual contributions.

5. Entrepreneurship and Translation: NIH should incentivize entrepreneurship by recognizing patents, startups, licensing, and clinical or commercial adoption as meaningful research outputs in peer review and career advancement. It should fund partnerships that accelerate scale-up and real-world use. Innovation impact metrics should be included in grant evaluations to better align incentives with meaningful translation to patient care.

6. Foundational Scientific Exploration: NIH should reward high-risk research by expanding dedicated funding mechanisms where outcomes are uncertain. Proposal evaluation should emphasize originality, scientific premise, and potential for transformative impact rather than short-term productivity.

7. Public Impact: NIH should adopt a balanced, mission-aligned public impact framework that recognizes biomedical research contributions across six domains: health outcomes, clinical practice, economic value, public trust, accessibility, and societal benefit. The framework should combine quantitative indicators with structured narrative evidence, be tailored by discipline and career stage, and emphasize team-based contributions. Most importantly, NIH place less emphasis on research publications, and

more emphasis on whether the research generates reliable knowledge, usable tools, better care, improved health, reduced disparities, and tangible value for the American public. In the past, NIH's Office of Portfolio Analysis developed iCite to quantify the scientific influence of a research scientist. A new tool should be developed to measure the impact of an investigator's research on the six domains listed above.

1. Rigor and Reproducibility: The NIH's rigor and reproducibility requirements, while well-intentioned, have created a bureaucratic burden that disproportionately increases administrative workload without meaningfully improving research quality.
The policy mandates extensive documentation across authentication of key biological resources, consideration of sex as a biological variable, scientific premise, and experimental design, requirements that often translate into boilerplate language cut-and-pasted across applications rather than genuine reflection on study design. Reviewers, already stretched thin, lack the bandwidth to critically evaluate these sections, reducing them to checkbox exercises.
Moreover, the policy applies uniformly regardless of study type, scale, or risk of irreproducibility. A small mechanistic study in a well-characterized system faces the same documentation burden as a large multi-site clinical trial, a one-size-fits-all approach that misallocates effort.
The root causes of irreproducibility: underpowered studies, publication bias, inadequate methods reporting, and perverse incentive structures, are largely unaddressed by form-filling. Structural reforms, that address these issues, would more directly target the reproducibility crisis.

In short, the current framework creates the appearance of rigor without the substance of it, and risks training researchers to perform compliance rather than practice it.

Additionally, the form-filling creates a burden for the vast majority of studies that are unfunded. A better system might ask for the reformed rigor and reproducibility documents after a grant has received a fundable score...similar to a Just In Time.

2. Data, Software, and Model Sharing: Again form-filling to satisfy the language the RFA does the field a disservice.
Ask for evidence of data, software, model-sharing.

3. Training and Mentorship: Agreed. There are currently minimal mechanisms or incentives to be a superb mentor.

4. Collaboration: Dedicated MPI RFAs are essential for the future of science

5. Entrepreneurship and Translation: NIH's focus on fostering the translation of discoveries from bench to bedside and on better incentivizing and measuring entrepreneurial impact is both timely and

essential. However, the NIH is conservative and has a limited budget.
It will be necessary to accept risk, assume failure, and provide greater support than current to some studies.

6. Foundational Scientific Exploration: Unbiased basic discovery forms the foundation of everything else.

7. Public Impact: Impact is often delayed sometimes by several decades. Therefore, this metric is not practical

1. Rigor and Reproducibility: Because there is inherent diversity among individuals and there is noise in any physical phenomenon or measurement, ensuring irreproducibility at some level, any conclusion reached in medical research should be repeated by individuals other than those who undertook the original study. When the second study differs from the original, which is inevitable, the question should not be, "which study is right," but rather "given that more information is now available, what can we learn from the replicate study that could not be learned from one study alone?" Replica studies consume resources -- researchers, patients, laboratory animals, space, and funds. Thus reproducibility studies are most important when results are unclear. Why might a drug help only 1/2 of patients? Why might a surgical procedure go awry for 1/4 of patients? When a result is clearly positive (say, 90% of patients are helped), then follow-up studies may be unnecessary. The problem will be how to devise repeated study proposals so that they are allowed some creativity while not hitting predictable barriers: lack of enthusiasm by review committees, insufficient success rates of proposals, proposals excessively from second-tier researchers or institutions who may inadequately understand the subtleties of research procedures, or considering those who repeat research as being second-tier researchers (which would discourage all but the most senior people from pursuing such studies, as being a "me too" is fatal to a career).

2. Data, Software, and Model Sharing: No comment on this item.

3. Training and Mentorship: Research assistantships should last for the duration of a graduate program rather than being tethered to the standard length of a research grant. Once a student enters a graduate program, provided they apply themselves, they need continuing access to a living salary and research consumables. The long-time practice of funding students via 3-year (NSF) or 5-year (NIH) research grants makes funding stability precarious. While programs to train entering students (initial two years of graduate school) might well continue the current traineeship programs, the long-standing practice of hanging advanced students out to dry when grants are not renewed has long been an impediment to research completion.

4. Collaboration: No comment on this item.

5. Entrepreneurship and Translation: The "valley of death" between academic progress and societal impact for development of pharmaceuticals, instrumentation, diagnostics, and procedural advances is real. Review committees prevent progress by labeling a proposal too fundamental or too applied, too

narrow or too broad, when one phase of development ends and support of the next phase is sought. SBIR has PIs seeking a pinhole that isn't too focused on business development, too focused on fundamental science, too narrow or too broad in its scientific questions, has too few or too many resources invested in particular enterprise. Translation now works when the pace of that translation matches preconceived agency guidelines. The guidelines should be more flexible. The proposal should state: where is the science and the business development at the moment? What path is envisioned to achieve translation? Review, rather than looking for excuses to decline the proposal, should be focused on incrementally moving technology to where it can help people and businesses. Should Phase I proposals only lead to Phase II SBIR support, or might multiple years of Phase I level support be useful? If the business plan is weak but the science strong, should the science continue to be supported with NIH or NSF helping match the scientist to plausible business partners? If the business plan is strong but the science is weak, might NIH or NSF connect the business to scientists who could strengthen the technical side of the work? If the project is worth doing, the review process should aim to help the work support the public interest. Too often, current proposal review is focused on finding weak spots in the proposals with the goal of saying no to as many approaches as possible, particularly those that don't fit into normal program straitjackets, so that those proposals that succeed fit neatly into bureaucratic or conceptual silos.

One might imagine a graduate student completing a thesis that has commercial possibilities. An SBIR saying, "I want to continue this research and eventually build a business around it" stands little chance of being funded. An approach based on ICorp would focus on finding customers for the incomplete product rather than further developing the technology to the point that a discerning customer would see value in that technology. Meanwhile, business school graduates might want to be part of a startup, but not know what technology needs to be developed. Whether the science needs 6 months or 20 years to develop, whether the scientist is a good salesperson or an utter failure at sales should not be the criterion for subsidizing entrepreneurship and translation. If it looks like a promising idea, back it!

6. Foundational Scientific Exploration: Truly fundamental research has unclear impact, looks absurd to the non-specialist (especially politicians and lawyers), often is at odds with accepted understanding, and may not pay off for extended periods, if ever. The idea that politicians should have any involvement in deciding whether to support high risk or controversial work is absurd. Remember Lysenko in the Former Soviet Union and the work on mRNA vaccines. There are still politicians who, based on dogma, refuse to believe the success of such technology. If the scientific community thinks something is interesting, fund it and leave people alone to follow their noses. If 90% of high risk or fundamental science leads to dead ends, that is useful in the long run by showing where certain ideas or ill-founded. It's the 10% that build the future. And that 10% can only be identified in retrospect.

7. Public Impact: US life expectancy lags that of other advanced societies. Since the science underpinning medical practice has in large measure come from US research since 1945, the problems we see in routine medicine must be structural rather than intellectual. On the other hand, we continue (or, perhaps, continued through 1/19/2025) to lead the world in advanced biochemical and biogenetic technology, providing tools which, if aggressively developed, can improve longevity and disease suppression. Where we appear to be falling short is: community health, broad-based appreciation for rigorous research instead of hunches, snake oil cures, and universal access to care. The public needs to be educated, both in K-12 and later in life, of the success of scientific medicine and how scientific

understanding of folk remedies leads to improvements over holistic or alternative approaches. Favoring our current insurance structure over single-payer coverage appears to be correlated with our high costs and reduced longevity. Alas, a significant fraction of the populace believes otherwise. If the statistics are lying, someone needs to provide an alternative explanation that stands up to critical review. "The way we've always done it" is the worst excuse for doing almost anything. We also need to rebuild the wall between religious preferences and medical practice. If someone wishes to forego medical treatment on religious grounds, there are only limited cases where it may be justified to override that preference. However, having one person's preferences override another's (as is happening in the abortion wars) seems antithetical to freedom.

8. Other Areas: Science thrived from the Second World War through the lunar landings. Thereafter, there has been a gradual drift to lower support by State governments of universities, greater paperwork burdens on proposals, less flexibility in carrying out research, and greater political interference in choosing and executing projects. Some of this is because of the great burden of medical costs on States so that fewer resources are available for education. Some is due to longer lifespans so that pensions consume more resources than in prior decades. Politicians in a hurry for results when more fundamental science is needed is also a concern. Nixon's "War on Cancer" was decades premature. As understanding of biochemistry has progressed, the time for that war is likely now -- except NIH and CDC have been radically resectioned and their momentum broken. Just as Germany had a brain drain in the 1930's that initiated US scientific dominance, current political currents threaten that the US will hemorrhage talent to Europe and East Asia. It is easy to destroy institutions and research groups. It takes decades to recover. Research cannot be turned on and off like a light switch. Bringing a graduate student from basic scientific literacy to the point when research progress is perceptible can take 2-3 years. Getting an independent laboratory to productivity may take a similar amount of time. Fully funding science in 2026 would not result in a return to full productivity until 2029 at the earliest. There are two (or more) election cycles in this time. Unless the society as a whole backs science adequately, continuously, and with minimal interference. the future belongs to other countries that will.

I am responding: On behalf of myself

Name: Chris Batich

Name of Organization: U Florida

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/26/2026

1. Rigor and Reproducibility: Every proposal should have a brief paragraph (half-page) estimating the financial and lifespan benefit if the work is successful. Dialysis for kidney failure is prime example. If one could grow a kidney from a decellularized pig scaffold, that would have a major impact on healthcare costs. When such projects are funded and give positive results, they should be checked by an independent lab. The book series "Organic Synthesis" had a system which worked well. Upon submission (of a funded project), a proposal was offered to an anonymous and independent lab to repeat the work. If successfully replicated, the reviewers would be identified in print. After reading the book "Doctored", I believe that about half of the high impact results are fabricated. They only identified those with 2D-gels from the images. Some consequences should result (loss of funding at least).

2. Data, Software, and Model Sharing: NIH used to have "Consensus Conferences" which did this very nicely. Bring them back?

3. Training and Mentorship: Allow more local authority to distribute some funds. Give grants to institutions and allow departmental chairs to allocate funds. Monitor results, not promises.

4. Collaboration: When I worked for DuPont's Central Research Department, we formed teams based on identified problems and needs. An announcement was made about a problem or need and all were invited to attend if interested. About 30 people usually showed up for a presentation and discussion. Various ideas were suggested and small groups of about 3 to 5 people met to plan how to test solutions. Sometimes additional people were invited to join based on needed skills. Testing for feasibility was developed and carried out. Very successful process. Needs a collegial group or a strong moderator to get everyone's opinion expressed and to keep the louder mouths restrained.

5. Entrepreneurship and Translation: Someone from CMS should add their opinion as to whether the approach proposed would be reimbursed if successful eventually... and what it would take to demonstrate clinical readiness.

6. Foundational Scientific Exploration: Joint NSF-NIH funding and good funding for engineering departments as well as science.

7. Public Impact: Regain trust by getting rid of the fake results and author sharing ("I will add you, if you add me")

8. Other Areas: Keep up the good work and don't get discouraged. You all are the best hope for better lives ahead!

6. Foundational Scientific Exploration: I would recommend broadening the scope of what the NIH considers to be human health research. Grant funding should integrate health outcomes with both financial mechanisms and ecological systems into the scope of work. Our medical research cannot continue to look at findings only in terms of human health.

To elaborate, financial mechanisms need to be in place which can make translational research to practice be financially viable after a grant is completed. Health care system economists, medical billing experts, and other health care systems analysts need to start being part of research teams. Billing, in particular, needs to be an intrinsic part of how an intervention would be put in place. This would help deliver innovations to the people who need them in a much more expedited fashion.

Regarding ecological systems, with meteorological events becoming more intense and more frequent we cannot afford to operate as if human innovation is separate from natural ecosystems. Grant funding needs to include how an intervention will affect ecosystems and how it anticipates upcoming changes in global ecological conditions as well as how intends to off set carbon emissions.

An example would be any program which involves nutrition. What would be the carbon foot print of a nutrition intervention, how would a nutrition intervention improve sustainability in light of increasing droughts, increasing food prices, and decreasing nutritional value in foods due to an increase in atmospheric carbon dioxide levels. All of these factors are critical to incorporate into any true research innovation.

I know this will involve much work for researchers, NIH staff, and cut into research funding but ignoring these factors in research criteria is, in the long run, invalidating the existing research being done.

7. Public Impact: I would recommend including a requirement , as part of the grant and include funding to be able to disseminate findings more thoroughly. This should be included as criteria for reviewers as well. I would recommend not only messaging to the communities affected or participating in the research but also members of our U.S. community who traditionally don't receive any messaging about what research is occurring NIH. Making it a requirement for instance to present findings to members of rural communities , church communities, radio and television. The NIH is doing wonder work but their is huge disconnect between the research community and those who are voting and electing people to office who are not getting enough exposure to the findings.

8. Other Areas: N/A

Description: Discusses Broadening the scope of research funding and widening the dissemination of the findings.

1. Rigor and Reproducibility: The current incentive structure rewards the first report of a finding far more than its confirmation, even though confirmation is what converts an interesting result into a reliable one. NIH could correct this issue by creating a distinct, citable funding and publication category for replication studies, and by explicitly crediting replication work in grant applications' biosketches and progress reports. For example, there could be a structured field for "independent replications of [investigator]'s findings by other groups," which currently has no home in the application or progress report and is therefore invisible to study sections. This adjustment should not come at the expense of novelty: replication and discovery are complementary, not competing, goods, and NIH's portfolio and review criteria should continue to prioritize and reward genuinely novel, innovative work even as it builds new pathways to credit replication. A field that rewarded only confirmation of existing findings would be just as distorting as one that rewards only novelty.

A second, underappreciated rigor problem is definitional: "causal research" is used loosely across disciplines that differ enormously in what counts as causal evidence – a randomized clinical trial, a Mendelian randomization analysis, and a genetic knockout in a mouse model all claim causality but carry very different epistemic weight. NIH should avoid a single causal-inference standard and instead ask applicants and reviewers to state explicitly which causal framework applies (interventional, quasi-experimental, or mechanistic) and what assumptions that framework requires. This would do more for rigor than a generic "is this causal?" checkbox.

From my own experience developing genetic mouse models to test causal mechanisms in lung injury and then testing the resulting hypotheses in patients, replication is genuinely difficult at every stage, just in different ways. Genetic and mechanistic experiments are constrained by defined alleles and protocols, which makes them somewhat more tractable to replicate than clinical studies, but they remain vulnerable to irreproducibility from genetic background effects, microbiome and vivarium differences across institutions, and subtle variation in technique that rarely makes it into a methods section. Mid-scale translational studies add a further layer of difficulty because they also depend on clinical phenotyping decisions (cohort definitions, timing of sample collection, outcome adjudication) that are even less standardized and even more rarely specified in enough detail to be replicated. NIH could require, as a condition of funding for clinical and translational R01/U01 awards, a structured "phenotyping and replication appendix" specifying these decisions in advance; a lighter-weight analogous requirement for mechanistic awards—specifying genetic background, husbandry conditions,

and reagent sources in a structured, searchable format—would make replication funding proposals easier for others to scope and justify across both domains.

2. Data, Software, and Model Sharing: Data-sharing mandates have so far rewarded the existence of a deposited dataset far more than its actual reuse, which creates an incentive to deposit the minimum compliant dataset rather than a maximally usable one. NIH should track and reward downstream reuse—for example, citation of a dataset's accession number in subsequent papers by other groups—as a distinct, fundable metric, the way citation of a paper is tracked today. This approach is already technically feasible through dbGaP, SRA, and GEO accession tracking and would shift the incentive from compliance to usefulness.

I have directed a multi-site, multi-investigator cohort study of patients with severe lung disease that generates genomics/transcriptomics sequencing data and clinical phenotype data intended for reuse by the broader research community. The single largest barrier to making those data maximally reusable has not been the sequencing or the deposition itself, but the unfunded, ongoing curation work: harmonizing clinical metadata across collecting sites, maintaining computational pipelines as reference databases and tools evolve, and fielding outside investigators' questions about the dataset. None of this work currently has a grant mechanism, a publication outlet, or a credit line. NIH could create a dedicated, renewable "data resource maintenance" supplement or small mechanism (analogous to existing administrative supplements) specifically to fund this curation labor, with progress reports structured around reuse metrics rather than new findings.

For software and analytical tools developed within R01-funded mechanistic work (e.g., pipelines for genomics/transcriptomics/epigenomics, including single-cell analysis), there is currently no NIH mechanism that funds the maintenance of a tool after its first publication, even though tool abandonment after publication is one of the most common and most damaging reproducibility failures in biomedical research. A renewable, lightweight "tool maintenance" supplement, awarded competitively based on evidence of community use (GitHub forks, downloads, or citations of the tool itself rather than the original paper), would address this issue directly and is something program staff could administer with existing infrastructure.

3. Training and Mentorship: After nine years directing a departmental Physician-Scientist Training Program spanning multiple T32 mechanisms, the metric I find most absent from current NIH accounting is mentorship's effect on trainee independence, as distinct from trainee productivity. A T32 progress report today asks how many papers and grants trainees produced; it does not systematically ask whether trainees who left the program went on to obtain independent R-level funding, and on what timeline relative to peers. NIH's own training-grant outcome data could be linked longitudinally to RePORTER funding histories to generate this metric automatically, without adding any new reporting burden on program directors. These data already exist across NIH's own systems.

Mentorship that produces co-senior authorship (i.e., where a mentor steps back from first or sole senior authorship specifically to establish a trainee's standing as an independent investigator) is one of the clearest behavioral signals of investment in the next generation, yet it is invisible in current bibliometric accounting, which simply counts the mentor's overall publication record without distinguishing this kind of deliberate credit-sharing. I have done this deliberately with departing trainees moving to faculty

positions, and there is no field in the biosketch or progress report that captures or rewards it; if anything, current author-order conventions can make a generous mentor's CV look less productive by senior-authorship counts. NIH could add a structured "mentee transition to independence" field to the biosketch, listing trainees, their current positions, and authorship roles a mentor ceded along the way.

Editorial service is similarly undercounted: time spent training the field's reviewers and authors—for example, the substantial editorial labor of triaging and shepherding hundreds of manuscripts through peer review—functions as field-wide mentorship but receives no NIH recognition mechanism comparable to the credit given for formal training grant roles.

4. Collaboration: Team science is currently evaluated almost entirely through the lens of individual attribution (author order, percent effort, role on the award), which forces collaborative contributions into a single-investigator accounting framework that does not fit how the work is actually done. Multi-PI awards, P01 program projects, and large cooperative agreements (U01s, UM1s) already exist as funding mechanisms, but study sections and tenure committees still tend to discount a PI's role on these awards relative to a comparably sized R01, even when the multi-PI award required more coordination, not less. NIH could address this issue directly within its own peer review guidance by instructing reviewers to evaluate multi-PI and program-project contributions on their own terms (e.g., coordination, integration across cores, and scientific leadership of a sub-project) rather than as a diluted version of single-PI productivity.

In assembling and contributing to multidisciplinary proposals—for example, project teams spanning immunology, synthetic biology, and engineering for translational technology development—the highest-friction part of team science is rarely the science itself but the absence of any shared NIH-recognized format for documenting who is responsible for what within a team, beyond the brief "role on project" line in a biosketch. A standardized, structured contribution statement (modeled on the CRediT taxonomy already used by many journals) adopted for NIH biosketches and progress reports would let teams document specific contributions (e.g., study design, data curation, mechanistic interpretation, clinical translation) in a way that travels with the investigator across applications and gives study sections something more substantive than author order to evaluate.

Center grants and large cooperative agreements should also be explicitly exempted from any future per-PI funding caps or productivity benchmarks calibrated to single-PI awards, since these mechanisms are structurally built to require multiple concurrent PI roles.

5. Entrepreneurship and Translation: The single biggest disincentive to translation in my own field is timing: the metrics that determine a mechanistic researcher's success (publications, grant renewals) operate on a one-to-three-year cycle, while translating a finding into a clinical trial or product realistically takes five to ten years and often does not yield a publishable result until very late in that process. A study section reviewing a competing renewal five years into translational work will frequently see "fewer papers" relative to a comparably funded purely mechanistic lab, even when the translational lab has done more total work. NIH could address this by explicitly instructing study sections, in review guidance, to weigh translational progress milestones (IND filings, trial initiation, regulatory interactions) as equivalent evidence of productivity to publications when evaluating renewals of awards with a stated translational aim.

Moving findings from genetic mouse models toward interventional trials in patients has also exposed how little institutional or NIH credit exists for the specific skill of translating a mechanistic finding into a trial-ready hypothesis, which is distinct from either basic discovery or clinical trial execution. This intermediate translational step, often the niche of physician-scientists, currently has no natural funding home (it is often “too applied” for basic mechanism review and “too early” for clinical trial mechanisms) and no natural reward in promotion or tenure review, which tends to recognize either basic-science productivity or trial leadership but not the connective work between them. A dedicated, lower-barrier translational bridge mechanism would fill a real gap and create a citable, fundable category for this work.

6. Foundational Scientific Exploration: High-risk, high-reward and purely mechanistic work is disadvantaged by any metric that rewards near-term, predictable output, because the work that most needs protection is, by definition, the work where a negative or null result is a real and informative possibility. NIH’s existing high-risk mechanisms (e.g., the Pioneer and New Innovator awards) are valuable but small in number and concentrated among a small set of awardees; the cultural problem is broader and affects ordinary R01 renewals, where reviewers often penalize an honestly reported pivot away from a hypothesis that did not pan out.

The clearest fix available without new mechanisms is in review guidance: instruct study sections explicitly that a well-justified pivot away from a non-productive hypothesis, accompanied by rigorous evidence for why the original hypothesis was abandoned, should be scored as evidence of rigor and scientific maturity rather than as a productivity shortfall. This single change in how renewals are read would do more to protect foundational exploration across the entire R01 portfolio than any expansion of dedicated high-risk mechanisms, which by design reach only a small number of investigators.

NIH should also resist the temptation to make “translational potential” an implicit scoring criterion for basic mechanistic R01s reviewed in study sections nominally focused on fundamental biology; the pressure to gesture at downstream clinical relevance in basic science aims pages, even when premature, distorts the foundational work the RFI itself identifies as worth protecting.

7. Public Impact: Public impact is hard to measure well, and NIH should be cautious about adopting metrics that are easy to game (social media mentions, news coverage) rather than metrics that track durable change in practice or policy. A more defensible approach: track and credit specific, attributable downstream uses of NIH-funded findings: citation in a clinical practice guideline, incorporation into an FDA label or guidance document, use in a CDC or WHO recommendation, or adoption in a clinical decision-support tool. These are discrete, verifiable events that already exist in public documents and could be linked to the underlying grant through existing citation-tracking infrastructure, without requiring investigators to self-report soft impact claims.

From my involvement in interventional trials in critically ill patients, the public impact that matters most to me—measurable changes in mortality or recovery time in a defined patient population—is exactly the kind of outcome that does not show up in citation counts or h-indices at all, and is currently recognized, if at all, only informally in narrative biosketch sections that reviewers may or may not weight consistently. NIH could add a structured, optional field to the biosketch for “downstream clinical or policy adoption of NIH-funded findings,” analogous to the existing personal statement, specifically inviting this

kind of concrete, externally verifiable impact claim rather than leaving it to be buried in prose.

Public trust should be treated as a public impact outcome. Transparent, accessible reporting of negative and null results, which currently have almost no path to publication or credit, would do as much for public trust in science as some positive findings.

8. Other Areas: Across the seven areas above, the common thread is that NIH already collects much of the data needed to credit these activities — training outcomes via RePORTER, dataset reuse via repository accession tracking, downstream citation via iCite — but does not yet route that data into the review, renewal, and promotion processes that shape investigator behavior. The highest-leverage changes available to NIH are not new awards or new infrastructure, but explicit instructions to study sections about what to credit, and structured fields in existing documents (the biosketch, the progress report) that make currently invisible contributions visible and fundable.

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Not Applicable

Role: Member of the Public

Date Submitted: 6/29/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: Research should be publicly available and include a short lay summary.

3. Training and Mentorship: N/A

4. Collaboration: Teams should include professionals in the field as well as those focused solely on research as to promote benefits of research reaching the public.

5. Entrepreneurship and Translation: Universities have startup incubators. Partner with these organizations to encourage discovery. Grants should specify that the technologies are affordable to the public. Many drugs or technologies though helpful, are cost prohibitive. Example: medications without generics

6. Foundational Scientific Exploration: Reduce bureaucracy surrounding guidelines, reporting, etc. In the past two years more guidelines have been implemented (ex research security) that have increased the administrative burden of doing research. This takes time away from scientific discovery and shifts it to paperwork. The unstable environment with layoffs, shut down (in ability to ask questions to NIH staff) and policy changes results in re-work for administrators due to unclear or revised instructions. Clear, straightforward, bi-partisan policy is needed.

7. Public Impact: Focus is needed on comprehensive women's health and how a woman's unique body impacts other health concerns. For example, conditions such as migraine can be influenced by hormone changes during menstruation and this may not be the specialty of a primary care doctor, neurologist, or gynecologist, leaving women guessing about their health. Additionally, research is needed about stroke and pregnancy, endometriosis, PCOS, infertility issues, perimenopause, and many other concerns for women. Diverse populations should be studied including by race, ethnicity and socio-economic status to obtain the best results.

8. Other Areas: N/A

69. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/30/2026

1. Rigor and Reproducibility: All science needs to be evaluated for reproducibility. We need to fund reproducibility studies and publish them. Independent reproduction of key experiments by (ideally) another lab needs to be incorporated into all project plans and publications. This used to be done. But as science has become more competitive and driven towards unrealistic publication counts as the only metric for career advancement and grant funding, best practices for sound science have been lost. Publication counts should no longer be part of grant funding decisions. Ideally, grants should be evaluated in a blinded fashion so that only the science is evaluated, not how many publications a researcher has gotten, how prestigious the PI is, or who their friends are on the review committee. The best scientists publish fewer papers than the sloppiest scientist. But the system for evaluating success in science are broken, and we are rewarding bad scientific practices in the current system. One sloppy practice that has begun infiltrating scientific publications is the presentation and statistical analysis of technical replicates rather than independent experimental repeats. Far too many articles now show "one representative experiment" instead of aggregating the independent experimental repeats. Thus, the scientific literature is now clogged with statistical validation of experimental approaches rather than measurements of biological variability. This must stop!

2. Data, Software, and Model Sharing: This is already a requirement for grant funding, and many journals require it as a condition for publication. I do not see this as a problem that needs to be solved.

3. Training and Mentorship: This is another area of significant problems in academic science. Mentors are basically able to treat their mentees however they want. Sadly, too many PIs treat post-docs as indentured servants rather than PIs in training. I was in a toxic lab environment, and it took me 2 years to transition into another, more supportive lab. Those 2 years counted against me, and led to me not being eligible for K99/R00 awards, which would have been a big boost for my research career. Stop punishing trainees for time lost due to bad mentors. We also need more effective metrics of success for promotion to faculty. It all comes down to publication counts, and that rewards sloppy science. And one of the most important components of promotion is your mentor championing you for promotion. An apathetic mentor or one with inherent bias (often against women, parents, people of color, etc.) can hamper the career advancement of trainees. It is difficult to assess the quality and impact of mentorship. One way would be to ask the mentees if they are getting what they need to advance their training in a supportive environment. But that would need to be done in a way that doesn't threaten their relationship with their mentor. Can there be mentorship committees that have clout and the responsibility to help transition the mentee out of a bad environment without disrupting their career advancement? Can we stop using

publication counts as the metric of success for promotion and instead use reproducibility and sound science instead? Can we reduce bias in grant evaluation through blinding to the identity of the applicant? The quality of mentorship absolutely cannot be based on scientific publication counts or grant funds awarded, as we know both of these metrics are biased, and publication counts rewards sloppy science. Can we instead measure opportunities for advancement through things like (1) designing one's own scientific program with support rather than having projects and experiments assigned by mentor, (2) attending scientific conferences, (3) presenting at scientific conferences, (4) having protected time to complete advanced coursework, (5) having access to support staff like technicians or graduate students or undergraduate research assistants? Can we somehow measure a mentor championing their trainee? Can we measure trainee mental health? It has been known for a long time that academic researchers have higher rates of depression and anxiety than the general public. This must be addressed. Can we begin recognizing post docs as experienced researchers rather than perpetual trainees? Can we begin providing retirement funds to graduate students and post docs? Can we stop financially punishing academic trainees? A major cultural shift needs to occur and how we think about trainees and the academic pipeline's responsibility towards them. If we are going to call them trainees, then we need to train them not exploit them as cheap labor.

4. Collaboration: Reduce emphasis on first- and senior-author positions in publications. Anything else would likely just create more work for the underlings in the lab that are already overwhelmed.

5. Entrepreneurship and Translation: This is an unrealistic expectation for academic researchers at this time. The system is not designed for this, and many academic departments punish researchers for entrepreneurship. Furthermore, academic researchers are already doing multiple jobs and are already burnt out. It is not realistic to expect academic researchers to take on the tremendous responsibility of building a company. For this to work, the entire academic system needs a major overhaul that provides researchers of all levels with an appropriate work-life balance and protected time for additional pursuits, such as entrepreneurship. Academic culture needs to change to see the value in entrepreneurship and support it. Academic researchers also lack the training and support necessary to successfully build companies. This infrastructure needs to first be created.

6. Foundational Scientific Exploration: Yes! Start funding them, then! It is common knowledge that you can only get a grant for something you've already done. Change the mindset at the NIH if you want to see this happen.

7. Public Impact: Yes! Remove political influence from scientific evaluations and awards if you want this to happen.

8. Other Areas: Academic research is broken. Researchers are burnt out and depressed. The system rewards sloppy science. The system pushes out parents, women, and minorities of all kinds. You have to fix the system first. Work–life balance, appropriate financial compensation, and protection from toxic work environments must be built into this system. Publication counts need to stop being a metric used to evaluates one's contribution to science. Instead, the quality of the science—for example, it's rigger and reproducibility, appropriate hypothesis testing and statistical methodology, the innovation and impact—need to be what matters. As the biggest awarder of grants in the US, you hold the purse strings. This gives you tremendous power to shape how we evaluate and reward science and scientists. Use that to transform the system into something sustainable and effective rather than maintaining the status quo that churns out an overwhelming volume of poor scientific quality publications.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: In science, collaborations should be basically encouraged. Wide and flat restrictions of individual collaborations based on non-scientific reasons can severely discourage scientists and thereby damage science. Specific concerns, like international conflicts and tax money appropriacies, should be carefully evaluated case-by-case. NIH should remain scientist-centric institute and stay away from politician's playground. Collaborations at NIH may be individually assessed in a manner similar to the ongoing ethics evaluation in NIH.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: Foundational scientific exploration is the core of science. It is a beautiful treasure of humankind, thanks to humanity's long and winding history. It is so delicate and vulnerable. It should therefore be evaluated carefully one-by-one by a group of scientific experts, like the site visits at NIH and the manuscript reviews for journal editors. It is important to be aware that a single evaluation can be wrong, so that it is important to install a failsafe mechanism to evaluate and correct, if needed, any prior evaluation. This basic aspect of science should never be evaluated based on fashion-based metrics including journal metrics, which was originally designed for librarians (not at all for individual papers). Honjo's Nobel-prize-winning discovery of PD-1 was published in EMBO Journal, Ohsumi's Nobel-prize-winning discovery of autophagy was published in FEBS Leeters, and Tonegawa's Nobel-prize-winning discovery of V(D)J recombination was published in PNAS. These journals are scientifically well-appreciated journals, but not fashionable journals like Nature, Science, and Cell.

7. Public Impact: N/A

72. Ana-Maria Vranceanu

I am responding: On behalf of myself

Name: Ana-Maria Vranceanu

Name of Organization: Mass General Hospital

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 6/30/2026

1. Rigor and Reproducibility: Release PARs or RFAs specifically designed for replication of prior trials by different research teams.

2. Data, Software, and Model Sharing: All data for all projects should be openly shared, alongside code.

3. Training and Mentorship: For all training and mentoring grants (K24, K12, T32, R25, etc), there should be clear metrics for success that are objective and measurable and collected long term. These should be set out at grant award and submitted at renewal. Things like: 1) nr of mentees with K and R grants; 2) diversity of mentees; 3) mentees who become mentors themselves should be priorities vs papers and conference presentations. Further, unique accomplishments of trainees vs copies of mentors work should be accounted for.

4. Collaboration: Collaborations are going to decrease if the number of grants we can submit or hold as PI or MPI will decrease. Even wit 6 submission, I am now considering single vs MPI grants. Removing restrictions of nr of grants will facilitate collaboration. In addition, developing PARs and RFAs that require MPIs from different disciplines working together on projects will enhance collaboration. Further, funding training programs that are interdisciplinary will also help. One challenge is balancing collaboration with independence. Academic promotion does not incentivize <MPI grants and collaboration. At top university one has to have grants as single PI in order to be promoted.

5. Entrepreneurship and Translation: Developing opportunities for renewal of grants to avoid gaps with new submissions.

6. Foundational Scientific Exploration: NA

7. Public Impact: Mandating return to results and developing protocols for how to do that well will help.

8. Other Areas: Please do not limit nr of grants people can have as PIs. This will destroy collaborations and good science. There will be no incentive to split effort and serve as MPIs. Many of us are 100% in soft money environments and 4 R01s are not enough even as single PI to keep a lab alive and mentor scientists.

73. Peter Gyarmati

I am responding: On behalf of myself

Name: Peter Gyarmati

Name of Organization: University of South Carolina

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 7/1/2026

1. Rigor and Reproducibility: Any publication should require that the findings are repeated in at least 2 other independent labs.

2. Data, Software, and Model Sharing: It would only make sense if there is a thorough normalization of data to begin with. There is such a broad range of procedures that data/software/model sharing alone would not solve anything.

3. Training and Mentorship: Increased financial support for trainees, number of trainees should be as relevant as eg number of publications. Would require documentation, and a rigorous set of criteria for what a trainee/mentee is

4. Collaboration: Collaboration alone is neutral, does not necessarily mean beneficial therefore shall not be rewarded.

5. Entrepreneurship and Translation: Should be one of the most important criteria when deciding funding. NIH lags behind in funding diagnostic methods/tools. NIH prioritized 'mechanistic research' for decades, this shall end, and practicality, translatability should be prioritized.

6. Foundational Scientific Exploration: More important would be: 'Does this research address a real question?' If NIH really want paradigm-shifting breakthroughs, it would require blank funding of investigators with proven translational potential for a decade.

7. Public Impact: For that, it would be necessary to investigate and evaluate NIH practices in the last several decades, and publish findings.

8. Other Areas: Simplify the grant application processes. PIs spend most of their times on writing applications with a ~12% success rate.

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

8. Other Areas: It would appear from the scientific review panel that the only metric that the NIH appears to use to measure productivity is the number of published papers. This is an extremely faulty metric that leads to the same people getting more and more funding, being incentivized to produce bad science that gets published in terrible journals. It has no real impact on patient care, but they can state that a grant led to 200 publications, and that's all the review panel looks at. If nothing else is changed, and even if that can be changed, the NIH review and what we invest in will be better.

1. Rigor and Reproducibility: Journal reputation is a measure of scientific impact that is seriously underutilized by the NIH. The measure is imperfect but superior to other measures that have been suggested or tried.

Journals build their reputation over time primarily based on the impact of the studies that they publish. Rigor and reproducibility have always been critical to scientific impact over time.

NIH should encourage, recognize, and incentivize publishing in highly reputable journals. Journal reputation can be assessed by a combination of citation metrics (e.g., impact factor) and surveys of scientists (e.g., Nature Index) and other informed users of science.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: Collaboration is a means to an end. NIH evaluation should focus on the end (scientific impact), not on the means.

5. Entrepreneurship and Translation: Journal reputation is a measure of scientific impact that is seriously underutilized by the NIH. The measure is imperfect but superior to other measures that have been suggested or tried.

Journals build their reputation over time primarily based on the impact of the studies that they publish. Translation into products is part of the scientific impact that enhances journal reputation over time.

NIH should encourage, recognize, and incentivize publishing in highly reputable journals. Journal reputation can be assessed by a combination of citation metrics (e.g., impact factor) and surveys of scientists (e.g., Nature Index) and other informed users of science.

6. Foundational Scientific Exploration: Journal reputation is a measure of scientific impact that is seriously underutilized by the NIH. The measure is imperfect but superior to other measures that have been suggested or tried.

Journals build their reputation over time primarily based on the impact of the studies that they publish.

Foundational scientific breakthroughs are already key elements of scientific impact and journal reputation over time.

NIH should encourage, recognize, and incentivize publishing in highly reputable journals. Journal reputation can be assessed by a combination of citation metrics (e.g., impact factor) and surveys of scientists (e.g., Nature Index) and other informed users of science.

7. Public Impact: Journal reputation is a measure of scientific impact that is seriously underutilized by the NIH. The measure is imperfect but superior to other measures that have been suggested or tried.

Journals build their reputation over time primarily based on the impact of the studies that they publish. Public impact is already part of the scientific impact that enhances journal reputation over time.

NIH should encourage, recognize, and incentivize publishing in highly reputable journals. Journal reputation can be assessed by a combination of citation metrics (e.g., impact factor) and surveys of scientists (e.g., Nature Index) and other informed users of science.

8. Other Areas: N/A

76. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Non-Profit Research Organization

Role: Investigator/Researcher

Date Submitted: 7/2/2026

1. Rigor and Reproducibility: Ideas:
1) create a branch of the NIH who's only responsibility is replicating study findings that are a) replicable, b) most likely to have public health impact, c) contradictory to established literature, or d) new. The work may be done by staff scientists or contracted out to other sites. The prior NIH-funded investigative team must comply with the branch to ensure completion. Publish results with a specific identifier in the title or abstract.
2) increase the quality of scientific review such that methodological details and results are provided clearly so studies can be reproduced--this is too big of a problem for the NIH to tackle, but it's a genuine problem.

2. Data, Software, and Model Sharing: This takes times and not everyone knows how to do this well, especially at smaller institutions or non-academic universities where there is not as much administrative support or specialization. Consider having NIH staff experts assigned who's only job is to help virtually on on-site to ensure this happens.

3. Training and Mentorship: N/A

4. Collaboration: It can be hard for new researchers or institutions to break into this space, especially when it's dominated by larger universities and/or richer institutions that can send their researchers to more conferences. It's also hard to know who what specific expertise, equipment, grad students to support execution or creating collaborations--which are harder when they're outside your organization. Finding and curating solid collaborations also take time. In general, the field often knows what those really important studies that should be done but seem impossible due to funding restrictions or difficulty recruiting enough participants. We need to find a way to expedite the logistical and bureaucratic hurdles. Besides compensation for a site's time in recruiting for a study, perhaps there should be a formal CV-worthy acknowledgment besides authorship that still incentives sites to contribute.

5. Entrepreneurship and Translation: This is NIH's greatest weakness, in my opinion. I've been part of review sessions where discussed grants in the top half (now top third), including those that score well, feel like research for research sake. Too much is incentivized when some technology sounds cool or will gather all types of information. Often it's done with such expensive equipment or by people with such specific, non-scalable processes that it'll never be implementing into real life. And so many grants are funded that are simply correlational. Many researchers don't have training in causality, at least from

observational data. Covariates or confounders are rarely fully identified by the grant submitters and grant reviewers rarely ask for them. Or the Significance section might mention A, B, and C are all related to outcome Y but no specifics are given or required to make it clear that maybe A explains 50% of the variance and factors B and C only explain 5% each and this study wants to study factors B and C but not model A in their statistics. It inflates the importance of B and C in the scheme of public health and doesn't provide a clear picture on intervening on which factor gives the best ROI. Repeatability or measurement error is often not acknowledged sufficiently with people providing ICCs rather than absolute reliability/agreement metrics.
The NIH should create a team follows up with funded researchers each year for up to 10 years to see if and how their research has been implemented/translated--this is a hard metric(s) to quantify, I get. A public report should be created. Simple language. Not "how many times was your paper cited". The NIH should be more like PCORI who funds Implementation projects after solid, large-scale CER studies. If it's clinical practice or public policy/health that needs to be changed as a result of scientific findings, that takes a long time and a lot of money. The NIH needs to do a better job of funding good science from the start, independently reproducing it, then ensuring its implementation. I think the NIH needs to play a more authoritative role in telling researchers what metrics are important. It's not just manuscripts or publishing something with little impact because an RPPR.

6. Foundational Scientific Exploration: This is challenging because I agree but who gets funded seems biased in favor of researchers or students from prestigious universities or a strong track record. Maybe the NIH needs to be more involved and check in more quickly and be able to decide to pull funding sooner if a project doesn't seem to be yielding results.

7. Public Impact: Share the public benefit publicly! I'm a researcher and fully believe it in, but I agree that the ROI isn't clear. I've reviewed too many grants and too many journal manuscripts (not necessarily NIH-funded) that are just crappy or minimally useful science and/or with unclear or minimal clinical/public health impact. Researchers need to stop trying to oversell the importance or impact of their results if their study is only n=10 and cross-sectional, for instance. Uncertainty/confidence intervals need to be clearly communicated.

I think the NIH needs to drive more of the questions researchers ask -- e.g., health dollars spent, unmet public needs (e.g., mental health), premature death, health disparities.

8. Other Areas: The NIH needs to switch to a 2-phased scientific review: Phase 1: review a 1pg letter of intent. Phase 2: only invited LOIs submit a full application. This will save investigators (and grant reviewers) a lot of time and less burn out and stress and false hope. It will likely also save the NIH money.

77. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Healthcare Institution

Role: Investigator/Researcher

Date Submitted: 7/2/2026

1. Rigor and Reproducibility: Funding is needed to conduct investigations that reproduce or replicate the work of other investigators. However, the peer-review system rewards innovation, so obtaining funding to repeat the work of others is unlikely. It would also be exorbitantly expensive to repeat every investigation. I recommend that special funding opportunities be created to repeat work that is of particularly high impact - such as the discovery of a new drug or technology with large health consequences. This would require vetting scientific discoveries and selecting those with the highest impact, and perhaps more modest data/evidence that merit replication.

Also, repeating the work of others can be expedited (and hence cost less) if the original data are available. However, archiving and curating data costs money. Thus, funding needs to be available to support the data sharing and management mandates.

2. Data, Software, and Model Sharing: The costs associated with these activities can be significant, and with across-the-board budget cuts, investigators are forced to choose between conducting their proposed research plan to generate new knowledge or managing and sharing data. Free archive infrastructure need to be readily available to make sure data sharing can happen efficiently.

3. Training and Mentorship: Gathering data on how many trainees go on to participate in the biomedical research community is an important way to assess the impact of training efforts. Trainees/mentees who go on to participate in research and development within an industry setting need to be acknowledged, in addition to those who pursue traditional academic routes.

4. Collaboration: Assessing the number of disciplines involved in a project is one metric for team science, though successful programs built around a single discipline should not be penalized if the work can be conducted effectively without an interdisciplinary team.

5. Entrepreneurship and Translation: More credit should be given to patents, especially those that are licensed to commercial entities. Getting new technology into the commercial sector is key to having a dramatic impact on public health.

6. Foundational Scientific Exploration: Journal editors are not keen on publishing many negative findings. So, even though knowing what doesn't work is valuable to the scientific community, programs that experience failure in a high-risk activity have more difficulty in getting their work published in

leading journals, if at all. A culture change is needed to allow short communications of negative findings in the peer-reviewed literature.

7. Public Impact: Rewarding the grants that produce drugs or devices that are translated into clinical practice is essential to ensuring that discoveries impact human health. Measures of health outcomes on a population scale is thus essential. Secondary measures, such as economic growth resulting from discoveries, also help to measure societal impact.

8. Other Areas: The traditional metrics for scientific productivity should not be abandoned, but rather supplemented with metrics that measure commercialization success, translation into clinical practice, and impact on health outcomes for the target disease.

78. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 7/2/2026

1. Rigor and Reproducibility: As a requirement of NIH awards, authors should be required to include in their acknowledgements the PMIDs of papers with data replicated or data sets used in the new study. NIH could then link these PMIDs to the grants acknowledged in the referenced prior papers, serving as a measure of reproducibility

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: As it stands, there is not a perfect mechanism for tracking collaborations between NIH-funded investigators supported by different awards. Typically, productivity is tracked by publications, which are associated with grants by award identifiers. But often, a collaborating investigator will perform a key experiment that falls outside of the scope of their own grants and is thus not funded by the NIH or attributed to the NIH in the publication. Thus, RPPRs are blind to this collaboration.

NIH should create a formal mechanism to track and reward general collaborative activity between its funded investigators, even if it falls outside the scope of NIH-supported work. For NIH-supported investigators, they should have two categories of research products to report. The current class of research products funded by the NIH award, plus a new class of general collaborative manuscripts not supported by the award. This would allow NIH to capture the grey area of collaboration not directly funded by NIH awards, the bulk of which is currently missed.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

8. Other Areas: N/A

79. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Role: Investigator/Researcher

Date Submitted: 7/3/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: Recently, NIH appears to be pulling back from supporting infrastructure such as the model organism databases that have been critical to integrating datasets generated by different groups and making the data readily accessible to all researchers in the field (as well as anyone in the public who would be interested in accessing the data). Rather than ceasing this support, I believe NIH should expand its support to ensure that such databases are well-designed, well-functioning, and appropriately curated by experts in the field. To enhance transparency, data within the databases should be readily traceable to its origin. NIH funding to support the databases can require/reward adherence to best practices for making sure the data are accessible, transparent, and freely available. Large-scale data generation projects can be tied to additional funding appropriate for supporting this dissemination.
For those whose research focuses on method generation, key metrics of success should include not only publication but also adoption of methods by the community over time to analyze data, not simply compare to other methods.

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: It should be easier to obtain a small amount of seed funding for new approaches or to expand a lab's research into a new scientific area. Review of such proposals should truly be independent of preliminary data, but instead be based on novelty, rigor of the approach, and potential for real innovation. Early investigators, early-mid career investigators, and small labs should be prioritized for receiving such funding.

7. Public Impact: N/A

8. Other Areas: N/A

80. Gregory Edward Cox

I am responding: On behalf of myself

Name: Gregory Edward Cox

Name of Organization:

Type of Organization: Not Applicable

Role: Investigator/Researcher

Date Submitted: 7/6/2026

1. Rigor and Reproducibility: Historically, NIH has prioritized novelty when evaluating proposals, but criteria could be amended to explicitly include replication and production of new research tools as sources of intellectual merit for proposals. Note that I am not advocating for new categories of grants. Rather, I'm saying that a proposal that includes an Aim to replicate a prior result---along with a clear rationale for doing so---should be counted as having equivalent intellectual merit to a proposal that includes an Aim to test a novel hypothesis (again, assuming there is a clear rationale for doing so). Similarly for grants including an Aim to develop a new research tool, method, or material.

2. Data, Software, and Model Sharing: Part of the budget granted by NIH funded proposals could be explicitly allocated to costs associated with sharing materials. For example, NIH funds should be able to be used to support open-access publishing, public data repositories, and other mechanisms that enable the sharing of data and software.

3. Training and Mentorship: NIH should support students from a broad range of backgrounds, particularly those underrepresented in STEM fields. Doing so increases the intellectual strength of our scientific workforce because the greater the variety of perspectives and skills within the community, the greater the chance for innovation and discovery. It also fosters transparency and openness, and therefore public trust, by increasing access to scientific knowledge and skills beyond an elite few.

4. Collaboration: N/A

5. Entrepreneurship and Translation: As a federal agency funded by taxpayer dollars, the best function the NIH can serve is to build a robust body of knowledge that can then be rapidly iterated on and applied by private corporations and nonprofit entities. The NIH plays the long game.

6. Foundational Scientific Exploration: Because the NIH does not need to turn a profit, it is ideally situated to support basic research and potentially risky proposals. These should be accorded higher funding priority than proposals that seek to translate existing knowledge into products, since other entities are better suited to accomplish that goal.

7. Public Impact: The NIH makes its public impact known through the research it supports. Therefore, supporting a broad array of initiatives focusing on training new scientists and developing basic knowledge and techniques will ultimately produce the greatest public impact, through new knowledge,

through expanding representation in the sciences, and through the public-facing applications of the research supported by NIH.

8. Other Areas: N/A

1. Rigor and Reproducibility: Reproducibility requires funding of larger studies with greater hetereogeneity in settings and populations, which has higher costs. More funding mechanisms to support large, multi-site studies are needed.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: Funding opportunities that require both bench and clinical aims will incentivize basic and clinical scientists to collaborate, accelerating the maturation of discoveries.

6. Foundational Scientific Exploration: N/A

7. Public Impact: Funding opportunities to conduct systematic reviews and meta-analyses will incentivize scientists to focus on synthesis of research that leads to practice statements and clinical guidelines. Rather than simple metrics of total publication counts and citation metrics, counts of publications that are cited in systematic reviews, meta-analyses,, practice statements, and clinical guidelines will reveal which publications are most impactful. Counts of publications that are cited in grant applications also captures the nearer term influence of published work (as opposed to the ultimate publication from completed study that cites papers published before it was funded).

1. Rigor and Reproducibility: The reliability (reproducibility and replicability) of scientific findings is critical for innovation and for public confidence in science and medicine. There are many potential causes of unreliable scientific findings, and many solutions have been proposed over the past two decades. Incentives from federal funding agencies for research initiatives should be defined by the priorities of the funding agency, e.g., as currently expressed by priority scores. Priorities for funding projects can be based (primarily) on the potential scientific significance (including scientific rigor) of the research findings and the experimental design of the proposed study. One broad framework related to experimental design would be to classify proposed studies as: 1. Controlled Experiments or 2. Exploratory Studies. Controlled experiments should have priority over Exploratory Studies because they directly test cause-and-effect relationships. Controlled Experiments should compare two or more interventions (treatment arms), often including a control group, with adequate statistical power to test an explicitly stated experimental hypothesis or primary aim. Controlled Experiments should (ideally) randomly assign participants to treatment arms. Controlled Experiments could include traditional randomized controlled trials (RCTs) as well as quasi-experimental Real-World studies such as case-controlled studies that are often used in econometric research where randomization of participants to interventions is not possible for logistical or ethical reasons. Exploratory Studies typically use correlation designs, which include long-term observational studies and cross-sectional studies. Exploratory Studies can be viewed as having a primary function of generating hypotheses that can then be tested using Controlled Experiments. Cross-validation of the findings of Exploratory Studies could strengthen decisions to progress from Exploratory Studies to Controlled Experiments. There is need for both basic research and applied research, with applied research having priority for NIH. Coordination with the National Science Foundation would facilitate crosstalk and strategic planning for the translation of basic research to tests of practical application. Priority can be provided for proposed studies that replicate (or reproduce) and extend previous findings from controlled experiments. To compare findings across studies, reporting standardized effects sizes for all results should be made mandatory. Publishing the null results of well-designed experiments can also be encouraged. Findings of weak or null effect sizes can facilitate an understanding of failures of replication. The reliability (replicability/reproducibility) of results from a series of studies can be tested via meta-analysis and/or systematic reviews. Utilization of the concept of a fail-safe number of null results could be encouraged to operationally define unreliable findings.

2. Data, Software, and Model Sharing: Sharing data, software, and previous data analysis can be made mandatory for federal funding of research. Priority for clear descriptions of this shared data capacity can be made explicit in NIH policies. Also, explicit descriptions of independent (intervention/control) and dependent (outcome) variables can be prioritized, including specification of the reliability and validity of outcome/dependent measures. To facilitate data sharing and transparency across studies, NIH might seek competitively funded data coordinating centers (DCCs) that could be utilized by independent investigators or multi-site investigations (e.g., DPP Research Group, 2002; Look AHEAD Research Group, 2013). These DCCs can be conceptualized as centers of excellence for experimental expertise ranging from genotyping and phenotyping to measures of behavioral adherence (e.g., Williamson et al, 2010). DCCs could assist in data collection, storage, and data sharing. Making DCCs available to all interested investigators should facilitate collaboration and enhance the likelihood of testing for replication and extension of original findings. It could also reduce the overall costs of conducting scientific research and enhance the transparency of scientific rigor. One of the mandates of DCCs might be to plan studies that facilitate making causal inferences among variables using controlled experimental methods.

3. Training and Mentorship: Funding support for junior investigators should be a continuing priority for NIH. Within each of the NIH Institutes, an executive committee could be formed to establish a long-term strategy for priorities and for the process of attaining objectives related to mentoring. One part of this strategy would be to establish a vision for mentorship of junior scientists and support institutions that will ensure a non-interrupted pipeline of high-quality research and researchers that can be supported by government, foundation, and private sources. This plan could include funding for promising post-doctoral fellows who might later be granted funding as junior investigators. The infrastructure of long-term mentorship should be flexible, including regular meta-science evaluation of the success of the mentoring program using objective measures, e.g., per cent of funded post-doctoral fellows who receive future funding. NIH can also facilitate the training of early career scientists by providing virtual and in-person training related to the design of Controlled Experiments, philosophy of science, and the optimal data analytic strategies for testing a diversity of hypotheses. This training can emphasize the importance of the nuances of experimental design, e.g., the importance of external controls such as control groups or putative mediators. Also, the training could emphasize the significance of internal control methods, e.g., blinding investigators regarding treatment arm assignment of participants, the reliability and validity of outcome measures, the impact of repeated measurement, and the requirements for using multivariate statistical analyses.

4. Collaboration: Current research initiatives are often complex and require considerable scale, e.g., large sample sizes. These factors are especially relevant for Controlled Experiments that address significant health concerns of a population. For these reasons, priority for highly qualified multi-disciplinary teams of scientists is important. Peer review panels could evaluate research teams, research support institutions, and proposed research plans, utilizing the principles of priority that have been described. These review panels could include senior and mid-career scientists as well as public information advocates that can address the public response to the program of study and its hypothesized results. In some areas of health-related research, the body of knowledge may be quite advanced. In such cases, the need for large-scale, national scope, multi-site studies can be prioritized, Funding for such multi-site projects can be “carved-out” of the overall budget of an NIH Institute so that investigators will be motivated to establish collaborative networks that are likely of work together in a cooperative manner (e.g., DPP Research Group, 2002; Look AHEAD Research Group, 2013). In such

studies, priority should be given to studies that test an explicit mechanism of action. Such experimental tests might be guided by the precision of experimental design, e.g., the design of intervention and control arms, or using mediation analysis (e.g., Williamson et al, 2009) that tests for covariation within and across intervention/control arms. Such mediation analysis might hypothesize genotypic or phenotypic variables, that include factors such as adherence to the intervention. Identification of primary mechanisms of action from meditation analyses can inform the development of hypotheses for future basic or applied controlled experiments.

5. Entrepreneurship and Translation: In addition to promoting Controlled Experiments, NIH could prioritize applied health-related research. Collaboration with NSF and other public and private institutions could involve strategic planning to link basic health-related research and applied research. The long-term strategy for applied research projects would include proof-of-concept studies, scaled-up Real-World Experiments (e.g., Horstmann et al, 2021), and innovative research development projects that are likely to yield commercially viable health enhancement programs. This pipeline of applied research could include pharmacological and non-pharmacological interventions. In this context, technological innovations such as artificial intelligence (AI) and social media could be viewed as tools for delivering/disseminating specific health enhancement interventions, e.g., how the internet and streaming media were tested as innovative delivery strategies in the first two decades of this century. From this perspective, the benefits and harms of these tools could be evaluated in terms of specific objectives, e.g., prevention of type 2 diabetes or suicide, and unintended negative consequences could be objectively studied using experimental controls. For example, a control group could be used to evaluate the natural historical occurrence of adverse events associated with or without AI or social media delivery strategies. If studies used similar research designs, e.g., RCTs, and comparable interventions and outcome measures, meta-analyses and systematic literature reviews could confidently test the reliability, reproducibility, and strength of the benefits and harms of innovative interventions. It may be necessary to establish NIH-supported Centers of Excellence across research domains to systematically collate such data for meaningful results from meta-analysis and reviews and to explain the significance of the conclusions to the public. Centers of Excellence could enhance the likelihood that null results of well-designed RCTs were available for inclusion in meta-analyses. This comprehensive strategy would enhance the probability that innovative health-related interventions were empirically proven to be effective, safe, and available to the public. This process could be illuminated by public health advocates so that public trust in science and medicine can be restored.

6. Foundational Scientific Exploration: There can be no doubt that basic research and exploratory research forms the foundation for high-quality applied research. For this reason, prioritized funding for basic and exploration research should be maintained. A question for NIH is who the primary source of funding for basic research might be. There are many potential funding sources for different types of research, ranging from NSF, USDA, DOD, foundations, and private institutions. Coordination among these public and private agencies will be critical to produce streamlined coordination and relative lack of overlap. Another potential solution might be to plan critical basic and exploration research in the internal laboratories of NIH Institutes. For example, the hypothesized targets of interventions to prevent/delay the onset of cognitive impairment of senior citizens might originate from the National Institute of Aging. The Centers of Excellence may also play a role in the planning and development of such research.

7. Public Impact: Translation of proof-of-concept research into population-based Real-World strategies that enhance the health of entire communities will be essential to ensure maximal public impact and a widespread trust in the integrity and utility of federally funded research initiatives. One strategy to attain this objective will be to carve out and prioritize Real-World quasi-experimental studies such as case-controlled trials that are common in economics, climatology, and other fields with practical constraints on randomization of participants to treatment arms. To preserve data analytic integrity, such studies must be careful to utilize cluster randomization strategies when individuals are naturally grouped together (e.g., students in a school or patients in a clinic). Public education about the strengths and weaknesses of different types of experimental designs and the implication of weak effect sizes is badly needed to disentangle confusion about what is often interpreted by experts and the public as conflicting results. There is need for continuing public education about complex scientific concepts, e.g., the probabilistic nature of empirical knowledge. Good targets for scientific education include making logical errors, e.g., making causal inferences from correlations, significance of standardized effect sizes, and the limitations of statistical controls. Another important educational distinction will be to differentiate scientific results that are based on empirical observations versus results that are based on statistical modelling of future events. Such statistical modelling should be viewed as Exploratory Studies that generate hypotheses that can be tested using Controlled Experiments. For maximal public impact, there is a need to systematically evaluate and collate a research base using unbiased methodology. Over the past two decades great strides in objectively grading the quality of research using consensus-based rules for judging the quality and bias of research studies. These grading systems often yield a letter grading format, e.g., A to F, that is easily understood by the public. This type of evaluation could be managed by Centers of Excellence or other expert panels that include public information advocates. If these strategies could be systematically employed, public trust in science and health care could benefit.

8. Other Areas: Generalization of the results of Controlled Experiments to the general population is very important. The experimental design of prioritized experiments should include internal control protocols for recruitment of participants that are representative of the population of interest. These methods do not necessarily assume a uniform response to interventions across individuals or sub-groups of people. Large-scale studies can be designed to test the relative efficacy and safety of an intervention for different types of people by inclusion of planned evaluations of the impact of the intervention on specified sub-groups, Sub-group analyses must be planned from participant recruitment through the intervention phase(s) to ensure that adequate numbers of sub-group members are recruited and retained. Statistical power analysis for sub-group studies can be used to guide this effort. Priority can be given to proposals that plan to study demographic and non-demographic variables. Ideally, these non-demographic variables can be operationally defined as dimensions, i.e., not categories. Sub-groups can be viewed as moderator variables in the overall analysis of benefits and harms of an intervention. Examples of different moderators include genotypes and phenotypes as well as behavioral factors, and social factors, e.g., level of education. Evaluation of protocols should include protection of human subjects, e.g., safety, privacy, and ethics.

Cardiovascular Effects of Intensive Lifestyle Intervention in Type 2 Diabetes

The Look AHEAD Research Group

Abstract

BACKGROUND—Weight loss is recommended for overweight and obese individuals with type 2 diabetes based on short-term studies, but long-term effects on cardiovascular disease remain unknown. We examined whether intensive lifestyle intervention for weight loss decreased cardiovascular morbidity and mortality in overweight or obese adults with type 2 diabetes.

METHODS—We randomly assigned 5,145 overweight or obese individuals with type 2 diabetes recruited at 16 US centers to intensive lifestyle intervention (the intervention group), which promoted weight loss through decreased calorie intake and increased physical activity, or diabetes support and education (the control group). The primary outcome was the first post-randomization occurrence of a composite cardiovascular outcome (cardiovascular death, non-fatal myocardial infarction, non-fatal stroke, or hospitalized angina) over a planned maximum follow-up of 13.5 years.

RESULTS—The trial was stopped early based on a futility analysis when median follow-up was 9.6 years. Weight loss was greater in the intervention group than the control group throughout (8.6% vs. 0.7% at 1 year; 6.0% vs. 3.5% at study end). Intensive lifestyle intervention also produced greater reductions in hemoglobin A1c and greater initial improvements in fitness and all cardiovascular risk factors, except LDL cholesterol. The primary outcome occurred in 403 patients in the intervention group and in 418 in the control group (1.83/100 person-years and 1.92/100 person-years, respectively; hazard ratio 0.95; 95% CI 0.83 to 1.09, p=0.505).

CONCLUSION—In our study, intensive lifestyle intervention focused on weight loss did not reduce cardiovascular events in overweight or obese adults with type 2 diabetes. (Funded by the Department of Health and Human Services and others; ClinicalTrials.gov number, NCT00017953.)

Weight loss is recommended for overweight and obese individuals with type 2 diabetes.[1] This recommendation is based on short-term studies showing numerous benefits of weight loss, including improvements in glycemic control, cardiovascular disease risk factors, quality of life and other obesity-related comorbidities.[2] However, it is unknown whether weight loss reduces the risk of cardiovascular morbidity and mortality in individuals with type 2 diabetes. Epidemiological studies in individuals with diabetes provide conflicting results, perhaps due to confounding from unintentional weight loss.[3] A recent meta-analysis[4] of cohort studies concluded that moderate intentional weight loss was associated with reduced mortality in “unhealthy” individuals, which included individuals with diabetes. The Swedish Obesity Subjects (SOS) study (ClinicalTrials.gov number NCT01479452) reported lower cardiovascular event rates over a mean follow-up of 13.3 years in patients with type 2 diabetes who underwent bariatric surgery;[5] however, this was a non-randomized study, and the results achieved through surgery cannot be generalized to other approaches to weight loss.

Thus, a critical question remains: Does an intensive lifestyle intervention designed to produce weight loss through caloric restriction and increased physical activity decrease cardiovascular morbidity and mortality in overweight and obese adults with type 2 diabetes?

Look AHEAD (Action for Health in Diabetes) addressed this question in a multicenter randomized clinical trial.

METHODS

Study Design

The study methods have been published previously.[6, 7] Look AHEAD was a randomized trial conducted at 16 clinical sites in the United States (see the Supplementary Appendix). The trial was designed and conducted by the authors, and all analyses were completed by the coordinating center. The study was approved by institutional review boards at each center. The trial was not blinded, but clinical assessors and end point adjudicators were masked to treatment assignment. The authors vouch for the accuracy and completeness of the data and all analyses and for the fidelity of this report to the trial protocol, which is available with the full text of this article at NEJM.org.

The study was sponsored by the National Institutes of Health, with additional support from other federal partners and the clinical research centers of several participating institutions. Major contributions were provided by the FedEx Corporation; Health Management Resources; LifeScan, Inc., a Johnson & Johnson Company; Nestle HealthCare Nutrition, Inc.; Hoffmann-La Roche Inc.; Abbott Nutrition; and Unilever North America. None of the corporate sponsors had any role in the trial design, data analysis, or reporting of results.

Participants

To be eligible for participation in the trial, volunteers were required to be 45 to 76 years of age and to have all of the following: self-reported type 2 diabetes verified by use of glucose-lowering medication, physician report, or glucose levels; body-mass index (BMI) of 25.0 kg/m^2 or greater (27 kg/m^2 or greater in individuals taking insulin); hemoglobin A1c less than 11%; systolic blood pressure less than 160 mmHg; diastolic blood pressure less than 100 mmHg; triglycerides less than 600 mg/dl; ability to complete a valid maximal exercise test suggesting it was safe to exercise; and a primary care provider. Participants could be using any type of glucose-lowering medication, but the percentage of participants using insulin was limited to less than 30%. Participants with and without a history of cardiovascular disease were included to increase generalizeability of results. Additional eligibility criteria are described elsewhere [6] and in the Supplementary Appendix.

Interventions

Eligible individuals were randomized to either an intensive lifestyle intervention (the intervention group) or diabetes support and education (the control group); randomization was stratified by clinical site. Curricula for both treatment arms were developed centrally and have been described in detail [6, 8] (see the Supplementary Appendix). Intensive lifestyle intervention aimed at achieving and maintaining at least a 7% weight loss by focusing on reduced caloric intake and increased physical activity. The program included both group and individual counseling sessions, occurring weekly during the first six months, with decreasing frequency over the course of the trial. Specific intervention strategies included a calorie goal of 1200 to 1800 kcal/day (with less than 30% of calories from fat and more than 15% from protein), use of meal replacement products, and at least 175 minutes per week of moderate intensity physical activity. A toolbox of strategies was available for participants having difficulty achieving the weight loss goals.

Diabetes support and education featured three group sessions per year focused on diet, exercise, and social support during years 1 to 4. In subsequent years the frequency was reduced to one session annually.

NIH-PA Author Manuscript

NIH-PA Author Manuscript

NIH-PA Author Manuscript

All medication adjustments were made by the participant's health care provider, with the exception of temporary changes in glucose-lowering medications made by study staff to reduce the risk of hypoglycemia in the intensive lifestyle intervention group. Participants and their health care providers received annual reports on the participants' updated cardiovascular risk factors and the goals recommended by the American Diabetes Association.[1]

Assessments and Outcomes

Certified staff, masked to participants' intervention assignment, measured weight, waist circumference and blood pressure, assessed medication use, and obtained blood for analysis at the central laboratory annually.[6] Maximal exercise tests were performed on the full cohort prior to randomization. Submaximal exercise tests were performed on the full cohort at years 1 and 4 and on a subset at year 2.

During annual visits and 6-month phone calls, participants were queried by staff masked to treatment assignment about all medical events and hospitalizations. These queries were augmented with searches of national databases on deaths. Hospital and other records were obtained for potential cardiovascular events and adjudicated according to standard criteria by reviewers masked to intervention assignment (see Supplementary Appendix).

The primary end point was the first post-randomization occurrence of a composite cardiovascular outcome. Initially, the composite cardiovascular outcome included cardiovascular death, nonfatal myocardial infarction, and nonfatal stroke, and the anticipated maximal follow-up interval was 11.5 years. During the first two years of the trial, the primary event rate in the control group was lower than expected.[9] Therefore, hospitalized angina was added to the primary outcome and planned follow-up was extended to a maximum of 13.5 years. Three composite secondary cardiovascular outcomes were also examined: cardiovascular death, myocardial infarction, or stroke (the original primary outcome); death (all causes), myocardial infarction, stroke, or hospitalized angina; and death (all causes), myocardial infarction, stroke, hospitalized angina, coronary artery bypass grafting, percutaneous coronary angioplasty, hospitalization for heart failure, or peripheral vascular disease.

Statistical Analyses

With a planned sample size of 5000 participants, Look AHEAD had greater than 80% probability of detecting an 18% difference in major cardiovascular events between the two groups, assuming a two-sided alpha level of 0.05, a primary outcome rate of 2% per year in the control group, and a planned maximum follow-up of 13.5 years. The 18% difference was chosen based on reductions in mortality in individuals with type 2 diabetes with voluntary weight loss in an observational study,[10] effect sizes chosen for trials with similar outcomes,[11] feasibility, and public health significance.

On September 14, 2012, Look AHEAD's primary sponsors, based on futility analysis and recommendation of the data and safety monitoring board, instructed the study investigators to terminate the intervention. All data analyses extend to this date. At that time, the probability of observing a significant positive result at planned end of follow-up, assuming the actual hazard ratio to be 0.82, was estimated to be 1%.

Baseline characteristics and key safety outcomes were compared between study groups using chi-square, Fisher's exact, Wilcoxon rank-sum, two-sample t-tests and Poisson regression. Physical and laboratory measurements and medication use from baseline through 10 years were modeled with generalized linear regression and generalized estimating equations. Center was included as a covariate, covariance was unstructured, and linear

NIH-PA Author Manuscript

NIH-PA Author Manuscript

NIH-PA Author Manuscript

contrasts were used to compare groups throughout post-baseline follow-up and at annual visits. Analyses of primary and secondary outcomes were performed using time-to-event methods according to the intention-to-treat principle as pre-specified in the protocol. Kaplan–Meier estimates were used to calculate the proportion of participants who had an event over time. First occurrences of primary and secondary outcomes in the two groups were compared with hazard ratios and 95% confidence intervals. Two-sided p-values were calculated with likelihood-ratio tests from Cox proportional-hazards regression, with models containing terms for clinical site, history of cardiovascular disease, and intervention assignment. The consistency of intervention effects on the primary outcome among three pre-specified subgroups (sex, race or ethnicity and history of cardiovascular disease) was evaluated using interaction tests. Results were not adjusted for multiple comparisons and $p<0.05$ was used. Statistical analyses were conducted using S-Plus software, version 8.0 (Insightful) or SAS software, and version 9.1 (SAS Institute).

RESULTS

Study Participants

Between August 2001 and April 2004, a total of 5145 participants were enrolled and randomly assigned to intensive lifestyle intervention (N=2,570) or to diabetes support and education (N=2,575) (Supplementary Appendix Fig. S1). Groups were similar at baseline (Table 1). The average age was 58.7 years, 59% were women, and the mean BMI was 36.0 kg/m^2. The median duration of diabetes was 5 years, and 14% reported a history of cardiovascular disease. Additional baseline data have been published previously.[12]

When the intervention was stopped on September 14, 2012, the median follow-up was 9.6 years (interquartile range 8.9 to 10.3) and fewer than 4% of all randomized participants had been lost to follow-up.

Weight, Waist Circumference and Fitness

Intensive lifestyle intervention produced significantly greater changes than diabetes support and education in weight, waist circumference and fitness (Fig. 1A-C) and Supplementary Appendix Table S1). Differences in mean weight loss were greatest at 1 year (8.6% in the intervention group vs. 0.7% in the control group) but remained statistically significant throughout the trial. When intervention ended, mean weight loss from baseline was 6.0% in the intervention group compared with 3.5% in the control group.

Cardiovascular Disease Risk Factors

During the first year of follow-up, intensive lifestyle intervention produced greater improvements than diabetes support and education in all measured cardiovascular risk factors except low-density lipoprotein (LDL) cholesterol (Fig. 1D and Supplementary Appendix Fig. S2 and Table S1). The difference in cardiovascular risk factors between intervention groups diminished over time, with hemoglobin A1c and systolic blood pressure showing the most sustained differences. LDL cholesterol levels were lower in the control group than the intervention group (mean difference of 1.6 mg/dl over the 10 years). Use of antihypertensive medications, statins and insulin was lower in the intervention group than in the control group (Supplementary Appendix Fig. S2 and Fig. S3 and Table S1).

Clinical Outcomes

The composite primary outcome of the first occurrence of hospitalized angina, nonfatal myocardial infarction, nonfatal stroke, or death from cardiovascular causes occurred in 821 participants (403 in the intensive lifestyle intervention group and 418 in the diabetes support and education group). Rates were not different between groups (1.83/100 person-years and

NIH-PA Author Manuscript

NIH-PA Author Manuscript

NIH-PA Author Manuscript

1.92/100 person-years, respectively; hazard ratio =0.95; 95% CI 0.83 to 1.09, p=0.505) (Table 2 and Fig. 2). There were also no significant differences between the two trial groups with respect to the pre-specified composite secondary outcomes or any of the individual cardiovascular events making up the composite outcomes (Table 2). There were no significant interactions among the pre-specified subgroups (Fig. 3).

Adverse Events

Severe hypoglycemia, gallstones, fractures, amputations and congestive heart failure were monitored, as plausibly being affected by intensive lifestyle intervention. Although the rate of self-reported fractures differed significantly between groups (2.16/100 person-years in the control group versus 2.51/100 person-years in the intervention group; p=0.011), the incidence rate for adjudicated fractures did not (1.64/100 person-years and 1.66/100 person-years, respectively; p=0.833) (Supplementary Appendix Table S2).

DISCUSSION

The Look AHEAD trial compared the effect of an intensive lifestyle intervention with a control regimen of diabetes support and education in overweight and obese participants with type 2 diabetes. At a median follow-up of almost 10 years, there was no significant difference between the two groups in cardiovascular morbidity and mortality.

Look AHEAD showed that overweight and obese adults with type 2 diabetes can lose weight and maintain modest weight losses over 10 years. Multi-component lifestyle interventions in clinical trial settings typically produce initial weight losses of 7 to 10%;[13, 14] with maximal weight loss at 1 year, followed by gradual regain.[13-15] However, few studies have provided ongoing intervention for an extended time.[16] In our trial, the initial mean weight loss in the intensive lifestyle intervention group was 8.6%. This was followed by weight regain through year 5 and then a subsequent gradual decrease in weight, resulting in an average weight loss of 6.0% at the end of the trial. The control group experienced a gradual but consistent weight loss throughout the study, resulting in an average weight loss of 3.5% at end of the trial. The intervention group also had greater improvements in fitness, particularly at 1 year.

We have considered several possible explanations for the lack of a significant difference in the cardiovascular event rates between groups. One possibility is that the study lacked sufficient power. We do not feel this explains the negative result; the 95% confidence interval for the primary outcome excluded the benefit of 18% or more targeted in the trial's design. Another possibility is that sustained weight losses larger than those achieved in Look AHEAD may be required to reduce the risk of cardiovascular disease. In this regard, it is noteworthy that the differential weight loss between the two trial groups averaged 4% over the course of the study but only 2.5% at the end. However, our trial was planned to test the effects of intensive lifestyle intervention and the weight losses achieved in the intervention group are representative of the best that has been achieved with current lifestyle approaches. Third, educational sessions provided to the control group assigned to diabetes support and education, the greater use of statinsin the control group, and the overall intensification of medical management of cardiovascular risk factors[17] may have made a relative benefit of intensive lifestyle intervention more difficult to demonstrate. The intervention may also have had different effects in different subgroups. Although none of the interactions with subgroups were statistically significant, our data suggest that the event rate for the primary outcome was non-significantly lower in ILI than in DSE among individuals with no history of CVD at baseline, but non-significantly higher in ILI than in DSE among individuals with CVD at baseline.

NIH-PA Author Manuscript

NIH-PA Author Manuscript

NIH-PA Author Manuscript

There are several limitations to these findings. We used a specific lifestyle intervention that focused on achieving weight loss through caloric restriction and increased physical activity. It is unclear whether an intervention focused on changes in dietary composition, for example the Mediterranean diet,[18] might yield different outcomes. In addition, Look AHEAD recruited participants with type 2 diabetes who were motivated to lose weight through lifestyle intervention and who could successfully complete a maximal fitness test at baseline. Thus, the results cannot be generalized to all individuals with type 2 diabetes.

The finding that intensive lifestyle intervention, compared with diabetes support and education, did not reduce the risk of cardiovascular morbidity and mortality must be considered within the context of other positive effects observed with this intervention. Intensive lifestyle intervention produced clinically meaningful improvements in hemoglobin A1c, especially over the first year of the intervention, that were at least partly sustained throughout follow-up. This positive effect is noteworthy since it may explain why participants in the intervention group were less likely to be treated with insulin over this period. Further, we recently reported that individuals in the intervention group of Look AHEAD were more likely to experience partial diabetes remission during the first four years of the trial.[19] Other benefits identified during the early years of the trial have included improvements in urinary incontinence,[20] sleep apnea,[21] depression,[22] quality of life,[23] physical function,[24] and mobility. Intensive lifestyle intervention has also been shown to prevent or delay the development of type 2 diabetes in other studies.[15, 26]

In conclusion, the Look AHEAD trial found that intensive lifestyle intervention did not reduce the risk of cardiovascular morbidity or mortality compared with a control program of diabetes support and education in overweight and obese participants with type 2 diabetes.

Look AHEAD Funding and Support

This study is supported by the Department of Health and Human Services through the following cooperative agreements from the National Institutes of Health: DK57136, DK57149, DK56990, DK57177, DK57171, DK57151, DK57182, DK57131, DK57002, DK57078, DK57154, DK57178, DK57219, DK57008, DK57135, and DK56992. The following federal agencies have contributed support: National Institute of Diabetes and Digestive and Kidney Diseases; National Heart, Lung, and Blood Institute; National Institute of Nursing Research; National Center on Minority Health and Health Disparities; NIH Office of Research on Women's Health; and the Centers for Disease Control and Prevention. This research was supported in part by the Intramural Research Program of the National Institute of Diabetes and Digestive and Kidney Diseases. The Indian Health Service (I.H.S.) provided personnel, medical oversight, and use of facilities. The opinions expressed in this paper are those of the authors and do not necessarily reflect the views of the I.H.S. or other funding sources.

Additional support was received from The Johns Hopkins Medical Institutions Bayview General Clinical Research Center (M01RR02719); the Massachusetts General Hospital Mallinckrodt General Clinical Research Center and the Massachusetts Institute of Technology General Clinical Research Center (M01RR01066); the University of Colorado Health Sciences Center General Clinical Research Center (M01RR00051) and Clinical Nutrition Research Unit (P30 DK48520); the University of Tennessee at Memphis General Clinical Research Center (M01RR0021140); the University of Pittsburgh General Clinical Research Center (GCRC) (M01RR000056), the Clinical Translational Research Center (CTRC) funded by the Clinical & Translational Science Award (UL1 RR 024153) and NIH grant (DK 046204); the VA Puget Sound Health Care System Medical Research Service, Department of Veterans Affairs; and the Frederic C. Bartter General Clinical Research Center (M01RR01346).

The following organizations have committed to make major contributions to Look AHEAD: FedEx Corporation; Health Management Resources; LifeScan, Inc., a Johnson & Johnson Company; OPTIFAST® of Nestle HealthCare Nutrition, Inc.; Hoffmann-La Roche Inc.; Abbott Nutrition; and Slim-Fast Brand of Unilever North America.

Some of the information contained herein was derived from data provided by the Bureau of Vital Statistics, New York City Department of Health and Mental Hygiene.

1. Rigor and Reproducibility: The AI gold rush has created conflicted reviewers across public, private and academic organizations. These reviewers may be economically, academically or emotionally conflicted. They may be indirectly conflicted by the investments in their 401k.

Leading institutions in AI have long histories of anti-competitive behavior as well and the circular economy which represents half of stock market value is well documented. As AI represents the only growing area of the US economy, our government has clearly chosen to look the other way on issues that should have been brought to the DOJ which included reviewer supply chain collusion.

Although WEO 14110 ordered NIH to cease collusion with major technology companies and foster innovation by small businesses, the order was clearly ignored by NIH and GAO. In this environment, it has been all but impossible for small businesses to introduce non AI innovations that are safer (even if preferred by the FDA), more powerful and more efficient/environmentally friendly. Compounding the problem is that many reviewers with clinical research background seem to know the language of AI but not actually what the words mean. Reviewers with computationally background are the most hostile to non AI approaches because they know that AI is a poor option for certain applications like chaotic time series observation.

The greed, dysfunction, misinformation and just plain stupidity is unprecedented in US history. Current resource allocation away from "real science" and to AI pretty well assures that AI will always be needed. However, to use AI, when a physics based model is possible, is to be artificially stupid and not old fashioned. This corruption of scientific process and fiduciary responsibility is not in the best interest of healthcare, science or the American people.

AI is useful when there are no real science alternatives but not as a replacement for real science or math. Our goal should be to replace AI with superior knowledge and not the reverse. I suggest that NIH at least consider DARPA documentation on this topic because they focus on what works and not what makes money for powerful stakeholders. They do not persecute innovators with potentially game changing new ideas.

Perhaps the greatest travesty with AI stakeholders holding all the cards is that it is in their best interest to improve real science to to the point where AI can perform better but not to the point that AI is obsoleted and that is what the future brings.

Date Submitted: 7/8/2026

1. Rigor and Reproducibility: The best way to test for replication and reproducibility, is to make sure that there is sufficient funding for it. But this should be in-addition to existing funding, not taking away from other scientists.

2. Data, Software, and Model Sharing: Sure, as long as data is secure and analyzed by experts.

3. Training and Mentorship: I think you need to let mentors mentor, and trainees be trained. You're looking to trim a brisket that's already lean enough.

4. Collaboration: Collaboration is important, as long as it is done by those who are trained and familiar within their fields.

5. Entrepreneurship and Translation: Translational research is important, as long as we're using a scientific and rigorous approach.

6. Foundational Scientific Exploration: High-risk high reward makes sense when there is knowledge and appropriate scientific background. Otherwise you just get a Theranos case.

7. Public Impact: If you care about public trust, please do not allow anti-vaxxer quacks into the high ranks of our scientific leadership. That would really help.

8. Other Areas: N/A

1. Rigor and Reproducibility: PREMISE

A 2014 Student Growth Screening Survey indicates about 42% of Ketchikan district students, pre-kindergarten through 9th grade, are either overweight or obese. An additional 6.5% of the student population is ranked as severely obese (MORBID OBESITY.) That totals 48.5%. Barbara McCarthy was the Ketchikan School District's Wellness Coordinator and said "….with parental permission, 88 percent of all students enrolled in the Ketchikan School District participated in the survey."

According to the most recent Behavioral Risk Factor Surveillance System (BRFSS) data, adult obesity rates now exceed 35% in 23 states. West Virginia has the highest adult obesity rate at 41.2% and the District of Columbia (D.C.) has the lowest at 23.5%. Between 2022 and 2023, three states experienced statistically significant increases in their adult obesity rate: Alaska, Arkansas, and Oregon. No state experienced a decline. (Assumed fact- "Many Overweight students will become obese adults.")

"Consistently studies show that students who eat well and students who are active will perform better academically, they are more likely to go on to higher education and they have fewer classroom behavior issues" according to McCarthy.

In 2011–2012, approximately 1 in 6 (17.7%) US children aged 6 to 11 were obese. Compared with their non-obese peers, these children are more likely to experience low self-esteem and depression, discrimination by other children, and academic struggles; they are also more likely to become obese adults. The ability to monitor childhood obesity prevalence at the state and local levels is critical for state public health programs to assess trends and the success or failure of interventions.
Obesity can negatively affect a student's academic learning through several pathways, including biological factors like compromised executive function and memory, indirect factors such as increased school absenteeism and bullying, and teacher bias which can lead to lower expectations and grading. This can result in lower grades, poorer test scores in reading and math, and less likelihood of graduating from college.

6.5% of Ketchikan's young students were measured as having MORBID OBESITY. Morbid obesity at an

early age can significantly reduce a child's life expectancy, with some studies suggesting it could be cut by half. This is because severe early-onset obesity is linked to developing serious health conditions like heart disease & type 2 diabetes at an earlier age, increasing the risk of mortality later in life. The impact is profound and highlights the need for early and comprehensive prevention and treatment to improve both the quality and length of life.

A childhood diagnosis of Type 2 diabetes significantly reduces life expectancy due to the long-term impact of high blood sugar, increasing the risk of early and severe complications like heart disease, stroke, and kidney disease. Studies estimate that life expectancy could be reduced by 15 to 19 years or more. Diabesity leads to Chronic Disease and Chronic Disease leads to disabilities, increased insurance claims and premature death.
pastedGraphic.png
Alaska Nutrition, Physical Activity, and Obesity Facts Report- 2025
“For over two decades, the percentage of adult and high school-aged Alaskans with obesity has continued to rise. Physical activity and healthy eating can prevent overweight, obesity, and several chronic diseases, including many cancers, heart disease, and type 2 diabetes. It can also impact mental health. Healthy eating patterns have been associated with a reduced risk of depression. The mental health benefits of physical activity—for adults and children—include better mood, sleep and focus.” ALASKA Physical Activity, Nutrition & Obesity Facts Report.

PROPOSAL
To combat Obesity amongst Alaskan School students:

At the high school and junior high/middle school levels: Reassign all P.E. & health teachers to become Health & P.E. Concierges (HPEC). Their responsibilities will include assisting students and homeroom teachers to introduce, implement and maintain each student’s individual P.E. & Health Journal (PE&HJ), in a manner similar to IEP’s for special needs students. The Journal will remain the property of the student. The monthly markers of change will be shared with each student’s concierge. The concierge along with the student will decide upon a health, diet and physical education program that meets the student where they are and plans for maintenance or improvement in weight, strength, mobility, flexibility, body-fat-%, heart rate, blood pressure, etc. all of which can be measured with a body analysis scale preferably located in each home room and each Health & P.E. Concierge’s office. These concierges will provide students with lists of foods and beverages to avoid and also lists and portions of foods and beverages to consume. This protocol could also be implemented at the elementary school level. Faculty & staff would be encouraged to participate also thus lowering the incidence and complications of chronic disease.

Activity: for 8 minutes each morning and 8 minutes each afternoon all students (& staff?) will participate in a nonstop physical activity; walking, jogging, jumping, 6 count burpee's, jumping jacks, etc. or combinations thereof agreed to by the student with the guidance of their concierge. The idea is to move for 8 minutes and work for improvement in: distance traveled, numbers of repetitions, difficulty of tasks performed, etc.

Compare this to a typical P.E. class on softball where 9 players are on the field and the pitcher and catcher are the only ones even coming close to getting any actual exercise. The OTHER half of the class is in the dugout, SITTING! Consider ever popular dodgeball where the obese slow player is sidelined only to view the athletes continue to get exercise.

Completing the PE&HJ for all four years of H.S. attendance should become the new graduation requirement, replacing the current failed health and P.E. classes requirements most districts now have. An extensive health & lifestyle bibliography could be incorporated into most other subjects of academia: math, English, science, reading, etc.

Please compare this PROPOSAL with ALL other class requirements. There is NO OTHER SUBJECT MATTER taught that has such practical application to each student's life every single day of their lives. It teaches and guides students to make informed choices on what to eat and not eat, what to drink and not drink and whether or not to take the stairs as opposed to the elevator. These are daily choices that are impacting our students multiple times per day and will, daily for the rest of their lives. District staff members should also benefit from the district's focus on health and longevity.

Concierges will enter weights & body fate % data into a spreadsheet to calculate school wide improvements, while protecting each student's identity. Please realize that this plan is subject to changes and improvements but also realize that the existing curriculum is NOT solving the problems of student obesity.

Alaska School Districts are encouraged to abandon their existing Health and P.E. curriculums and replace the present 1/2 semester each of Health & P.E. as graduation requirements with the requirement to complete 4 years of a student's PE&HJ (P.E. & HEALTH JOURNAL).

I'm suggesting that the Alaska School Boards and the Alaska Department of Education & Early Development take initial steps to address this issue and form task force committees to examine the PREMISE and thoroughly vet my PROPOSAL. I'm willing to serve.

Kindly submitted by:

Robert B. Holston Jr. "Rob" 907-617-2262 holston@kpunet.net Health & Longevity Coach
I am a volunteer :) "Willing to serve."

2. Data, Software, and Model Sharing: PREMISE

The impact is profound and highlights the need for early and comprehensive prevention and treatment to improve both the quality and length of life.

A childhood diagnosis of Type 2 diabetes significantly reduces life expectancy due to the long-term impact of high blood sugar, increasing the risk of early and severe complications like heart disease, stroke, and kidney disease. Studies estimate that life expectancy could be reduced by 15 to 19 years or more. Diabesity leads to Chronic Disease and Chronic Disease leads to disabilities, increased insurance claims and premature death.

Alaska Nutrition, Physical Activity, and Obesity Facts Report- 2025
“For over two decades, the percentage of adult and high school-aged Alaskans with obesity has continued to rise. Physical activity and healthy eating can prevent overweight, obesity, and several chronic diseases, including many cancers, heart disease, and type 2 diabetes. It can also impact mental health. Healthy eating patterns have been associated with a reduced risk of depression. The mental health benefits of physical activity—for adults and children—include better mood, sleep and focus.”
ALASKA Physical Activity, Nutrition & Obesity Facts Report.

PROPOSAL
To combat Obesity amongst Alaskan School students:

At the high school and junior high/middle school levels: Reassign all P.E. & health teachers to become Health & P.E. Concierges (HPEC). Their responsibilities will include assisting students and homeroom teachers to introduce, implement and maintain each student's individual P.E. & Health Journal (PE&HJ), in a manner similar to IEP's for special needs students. The Journal will remain the property of the student. The monthly markers of change will be shared with each student's concierge. The concierge along with the student will decide upon a health, diet and physical education program that meets the student where they are and plans for maintenance or improvement in weight, strength, mobility, flexibility, body-fat-%, heart rate, blood pressure, etc. all of which can be measured with a body analysis scale preferably located in each home room and each Health & P.E. Concierge's office. These concierges will provide students with lists of foods and beverages to avoid and also lists and portions of foods and beverages to consume. This protocol could also be implemented at the elementary school level. Faculty & staff would be encouraged to participate also thus lowering the incidence and complications of chronic disease.

Activity: for 8 minutes each morning and 8 minutes each afternoon all students (& staff?) will participate in a nonstop physical activity; walking, jogging, jumping, 6 count burpee's, jumping jacks, etc. or combinations thereof agreed to by the student with the guidance of their concierge. The idea is to move for 8 minutes and work for improvement in: distance traveled, numbers of repetitions, difficulty of tasks performed, etc.

Compare this to a typical P.E. class on softball where 9 players are on the field and the pitcher and catcher are the only ones even coming close to getting any actual exercise. The OTHER half of the class is in the dugout, SITTING! Consider ever popular dodgeball where the obese slow player is sidelined only to view the athletes continue to get exercise.

Completing the PE&HJ for all four years of H.S. attendance should become the new graduation requirement, replacing the current failed health and P.E. classes requirements most districts now have. An extensive health & lifestyle bibliography could be incorporated into most other subjects of academia: math, English, science, reading, etc.

Please compare this PROPOSAL with ALL other class requirements. There is NO OTHER SUBJECT MATTER taught that has such practical application to each student's life every single day of their lives. It teaches and guides students to make informed choices on what to eat and not eat, what to drink and not drink and whether or not to take the stairs as opposed to the elevator. These are daily choices that are impacting our students multiple times per day and will, daily for the rest of their lives. District staff members should also benefit from the district's focus on health and longevity.

Concierges will enter weights & body fate % data into a spreadsheet to calculate school wide improvements, while protecting each student's identity. Please realize that this plan is subject to changes and improvements but also realize that the existing curriculum is NOT solving the problems of student obesity.

Alaska School Districts are encouraged to abandon their existing Health and P.E. curriculums and replace the present 1/2 semester each of Health & P.E. as graduation requirements with the requirement to

complete 4 years of a student's PE&HJ (P.E. & HEALTH JOURNAL).

I'm suggesting that the Alaska School Boards and the Alaska Department of Education & Early Development take initial steps to address this issue and form task force committees to examine the PREMISE and thoroughly vet my PROPOSAL. I'm willing to serve.

Kindly submitted by:

Robert B. Holston Jr. "Rob" 907-617-2262 holston@kpunet.net Health & Longevity Coach
I am a volunteer :) "Willing to serve."

3. Training and Mentorship: PREMISE

A 2014 Student Growth Screening Survey indicates about 42% of Ketchikan district students, pre-kindergarten through 9th grade, are either overweight or obese. An additional 6.5% of the student population is ranked as severely obese (MORBID OBESITY.) That totals 48.5%. Barbara McCarthy was the Ketchikan School District's Wellness Coordinator and said "….with parental permission, 88 percent of all students enrolled in the Ketchikan School District participated in the survey."

According to the most recent Behavioral Risk Factor Surveillance System (BRFSS) data, adult obesity rates now exceed 35% in 23 states. West Virginia has the highest adult obesity rate at 41.2% and the District of Columbia (D.C.) has the lowest at 23.5%. Between 2022 and 2023, three states experienced statistically significant increases in their adult obesity rate: Alaska, Arkansas, and Oregon. No state experienced a decline. (Assumed fact- "Many Overweight students will become obese adults.")

"Consistently studies show that students who eat well and students who are active will perform better academically, they are more likely to go on to higher education and they have fewer classroom behavior issues" according to McCarthy.

In 2011–2012, approximately 1 in 6 (17.7%) US children aged 6 to 11 were obese. Compared with their non-obese peers, these children are more likely to experience low self-esteem and depression, discrimination by other children, and academic struggles; they are also more likely to become obese adults. The ability to monitor childhood obesity prevalence at the state and local levels is critical for state public health programs to assess trends and the success or failure of interventions.
Obesity can negatively affect a student's academic learning through several pathways, including biological factors like compromised executive function and memory, indirect factors such as increased school absenteeism and bullying, and teacher bias which can lead to lower expectations and grading. This can result in lower grades, poorer test scores in reading and math, and less likelihood of graduating from college.

6.5% of Ketchikan's young students were measured as having MORBID OBESITY. Morbid obesity at an early age can significantly reduce a child's life expectancy, with some studies suggesting it could be cut by half. This is because severe early-onset obesity is linked to developing serious health conditions like heart disease & type 2 diabetes at an earlier age, increasing the risk of mortality later in life. The impact is profound and highlights the need for early and comprehensive prevention and treatment to improve

both the quality and length of life.

A childhood diagnosis of Type 2 diabetes significantly reduces life expectancy due to the long-term impact of high blood sugar, increasing the risk of early and severe complications like heart disease, stroke, and kidney disease. 7. Public Impact: PREMISE

A 2014 Student Growth Screening Survey indicates about 42% of Ketchikan district students, pre-kindergarten through 9th grade, are either overweight or obese. An additional 6.5% of the student population is ranked as severely obese (MORBID OBESITY.) That totals 48.5%. Barbara McCarthy was the Ketchikan School District’s Wellness Coordinator and said “….with parental permission, 88 percent of all students enrolled in the Ketchikan School District participated in the survey.”

According to the most recent Behavioral Risk Factor Surveillance System (BRFSS) data, adult obesity rates now exceed 35% in 23 states. West Virginia has the highest adult obesity rate at 41.2% and the District of Columbia (D.C.) has the lowest at 23.5%. Between 2022 and 2023, three states experienced statistically significant increases in their adult obesity rate: Alaska, Arkansas, and Oregon. No state experienced a decline. (Assumed fact- “Many Overweight students will become obese adults.”)

“Consistently studies show that students who eat well and students who are active will perform better academically, they are more likely to go on to higher education and they have fewer classroom behavior issues” according to McCarthy.

In 2011–2012, approximately 1 in 6 (17.7%) US children aged 6 to 11 were obese. Compared with their non-obese peers, these children are more likely to experience low self-esteem and depression, discrimination by other children, and academic struggles; they are also more likely to become obese adults. The ability to monitor childhood obesity prevalence at the state and local levels is critical for state public health programs to assess trends and the success or failure of interventions.
Obesity can negatively affect a student's academic learning through several pathways, including biological factors like compromised executive function and memory, indirect factors such as increased school absenteeism and bullying, and teacher bias which can lead to lower expectations and grading. This can result in lower grades, poorer test scores in reading and math, and less likelihood of graduating from college.

6.5% of Ketchikan’s young students were measured as having MORBID OBESITY. Morbid obesity at an early age can significantly reduce a child's life expectancy, with some studies suggesting it could be cut by half. This is because severe early-onset obesity is linked to developing serious health conditions like heart disease & type 2 diabetes at an earlier age, increasing the risk of mortality later in life. The impact is profound and highlights the need for early and comprehensive prevention and treatment to improve both the quality and length of life.

A childhood diagnosis of Type 2 diabetes significantly reduces life expectancy due to the long-term impact of high blood sugar, increasing the risk of early and severe complications like heart disease, stroke, and kidney disease. Studies estimate that life expectancy could be reduced by 15 to 19 years or more. Diabesity leads to Chronic Disease and Chronic Disease leads to disabilities, increased insurance claims and premature death.

Alaska Nutrition, Physical Activity, and Obesity Facts Report- 2025
“For over two decades, the percentage of adult and high school-aged Alaskans with obesity has continued to rise. Physical activity and healthy eating can prevent overweight, obesity, and several chronic diseases, including many cancers, heart disease, and type 2 diabetes. It can also impact mental health. Healthy eating patterns have been associated with a reduced risk of depression. The mental health benefits of physical activity—for adults and children—include better mood, sleep and focus.” ALASKA Physical Activity, Nutrition & Obesity Facts Report.

PROPOSAL
To combat Obesity amongst Alaskan School students:

At the high school and junior high/middle school levels: Reassign all P.E. & health teachers to become Health & P.E. Concierges (HPEC). Their responsibilities will include assisting students and homeroom teachers to introduce, implement and maintain each student’s individual P.E. & Health Journal (PE&HJ), in a manner similar to IEP’s for special needs students. The Journal will remain the property of the student. The monthly markers of change will be shared with each student’s concierge. The concierge along with the student will decide upon a health, diet and physical education program that meets the student where they are and plans for maintenance or improvement in weight, strength, mobility, flexibility, body-fat-%, heart rate, blood pressure, etc. all of which can be measured with a body analysis scale preferably located in each home room and each Health & P.E. Concierge’s office. These concierges will provide students with lists of foods and beverages to avoid and also lists and portions of foods and beverages to consume. This protocol could also be implemented at the elementary school level. Faculty & staff would be encouraged to participate also thus lowering the incidence and complications of chronic disease.

Activity: for 8 minutes each morning and 8 minutes each afternoon all students (& staff?) will participate in a nonstop physical activity; walking, jogging, jumping, 6 count burpee's, jumping jacks, etc. or combinations thereof agreed to by the student with the guidance of their concierge. The idea is to move for 8 minutes and work for improvement in: distance traveled, numbers of repetitions, difficulty of tasks performed, etc.

Compare this to a typical P.E. class on softball where 9 players are on the field and the pitcher and catcher are the only ones even coming close to getting any actual exercise. The OTHER half of the class is in the dugout, SITTING! Consider ever popular dodgeball where the obese slow player is sidelined only to view the athletes continue to get exercise.

Completing the PE&HJ for all four years of H.S. attendance should become the new graduation requirement, replacing the current failed health and P.E. classes requirements most districts now have. An extensive health & lifestyle bibliography could be incorporated into most other subjects of academia: math, English, science, reading, etc.

Please compare this PROPOSAL with ALL other class requirements. There is NO OTHER SUBJECT MATTER taught that has such practical application to each student’s life every single day of their lives. It teaches

and guides students to make informed choices on what to eat and not eat, what to drink and not drink and whether or not to take the stairs as opposed to the elevator. These are daily choices that are impacting our students multiple times per day and will, daily for the rest of their lives. District staff members should also benefit from the district's focus on health and longevity.

Concierges will enter weights & body fate % data into a spreadsheet to calculate school wide improvements, while protecting each student's identity. Please realize that this plan is subject to changes and improvements but also realize that the existing curriculum is NOT solving the problems of student obesity.

Alaska School Districts are encouraged to abandon their existing Health and P.E. curriculums and replace the present 1/2 semester each of Health & P.E. as graduation requirements with the requirement to complete 4 years of a student's PE&HJ (P.E. & HEALTH JOURNAL).

I'm suggesting that the Alaska School Boards and the Alaska Department of Education & Early Development take initial steps to address this issue and form task force committees to examine the PREMISE and thoroughly vet my PROPOSAL. I'm willing to serve.

Kindly submitted by:

Robert B. Holston Jr. "Rob" 907-617-2262 holston@kpunet.net Health & Longevity Coach
I am a volunteer :) "Willing to serve."

8. Other Areas: PREMISE

A 2014 Student Growth Screening Survey indicates about 42% of Ketchikan district students, pre-kindergarten through 9th grade, are either overweight or obese. An additional 6.5% of the student population is ranked as severely obese (MORBID OBESITY.) That totals 48.5%. Barbara McCarthy was the Ketchikan School District's Wellness Coordinator and said "….with parental permission, 88 percent of all students enrolled in the Ketchikan School District participated in the survey."

According to the most recent Behavioral Risk Factor Surveillance System (BRFSS) data, adult obesity rates now exceed 35% in 23 states. West Virginia has the highest adult obesity rate at 41.2% and the District of Columbia (D.C.) has the lowest at 23.5%. Between 2022 and 2023, three states experienced statistically significant increases in their adult obesity rate: Alaska, Arkansas, and Oregon. No state experienced a decline. (Assumed fact- "Many Overweight students will become obese adults.")

"Consistently studies show that students who eat well and students who are active will perform better academically, they are more likely to go on to higher education and they have fewer classroom behavior issues" according to McCarthy.

Core Recommendation

NIH should explicitly recognize biosafety, biosecurity, and safety oversight as measurable leading indicators of rigorous, reproducible, transparent, and publicly responsible biomedical research.

These activities are not separate from scientific impact. They are part of the conditions that determine whether research can be interpreted, repeated, translated, and trusted. A study that uses infectious agents, recombinant or synthetic nucleic acids, biological toxins, human materials, animals, arthropods, environmental samples, or emerging biotechnologies is shaped not only by its experimental design, but also by the risk assessment, containment practices, oversight review, personnel competency, material control, and institutional systems under which the work is conducted.

NIH has an opportunity to align scientific incentives with the full research lifecycle by recognizing that gold standard science requires gold standard biosafety.

This recommendation is also consistent with NIH's ongoing modernization of the NIH Guidelines for Research Involving Recombinant or Synthetic Nucleic Acid Molecules, as directed by the NIH Biosafety Modernization Initiative and related policy updates. As NIH modernizes biosafety oversight to reflect current technologies, risk paradigms, and institutional practices, there is a parallel opportunity to ensure that these expectations are consistently applied and visible within how scientific impact is defined and rewarded.

Rationale

Scientific impact is often measured through publications, citations, journal prestige, grant productivity, patents, data sharing, and translation of scientific findings into practical application. These measures capture important dimensions of productivity and influence, but they do not fully account for whether research was conducted under conditions that support safety, security, reproducibility, transparency, and public trust. When the scientific enterprise is supported by public funding, these considerations are equally important, if not more important, to sustaining public support and maintaining international leadership in science.

Biosafety and biosecurity oversight are foundational to responsible biomedical research. Existing federal and institutional frameworks already require risk assessment, appropriate containment, training, incident

response, institutional review, and continuing oversight for many categories of life sciences research. Institutional Biosafety Committees, biosafety professionals, animal care and use programs, occupational health programs, research compliance offices, and other institutional partners collectively support the safe and responsible conduct of science. Many of these oversight processes are also required as a condition of federal funding.

Despite this, these activities are rarely visible in how scientific impact is measured. In many publications, critical safety-related methodological details are absent, inconsistently reported, or difficult to interpret. Examples include the biosafety level used, containment or facility controls, inactivation methods for materials intended for downstream use, PPE and exposure mitigation strategies, biological material traceability, institutional review status, and whether additional biosecurity or dual use review was completed when applicable. Requiring these oversight activities to be documented in research publications would not only show that lead institutions are conducting work responsibly, but also promote similar standards among collaborators and other laboratories that may replicate or build upon such work.

This gap matters because biosafety conditions can influence experimental reproducibility and interpretation. Safety considerations are embedded throughout the research process, from experimental design and risk assessment to the procedures, materials, equipment, and personnel involved in the work. Risk assessment must account not only for individual agents or materials, but also for how they interact with experimental manipulations, routes of exposure, handling practices, containment level, inactivation methods, personnel competency, equipment controls, and facility conditions. These factors may all affect the quality, reliability, and interpretability of research outputs. They also affect public confidence in federally funded research, particularly when work involves pathogens, emerging technologies, dual use potential, biological materials of concern, or research conducted under heightened public scrutiny.

Proposed Measurable Leading Indicators

NIH could incorporate biosafety, biosecurity, and safety oversight into scientific impact frameworks through tiered, risk proportionate indicators. In this context, leading indicators are evidence that appropriate risk assessment, oversight, controls, training, and accountability were in place before and during the conduct of research, rather than measures that only identify failures after they occur. This approach aligns with the direction of NIH's broader biosafety modernization efforts, which emphasize risk-based oversight, clarity of expectations, and applicability to emerging biotechnologies. These indicators should scale with the nature of the research and should rely as much as possible on existing institutional processes rather than creating duplicative administrative systems. Where applicable, reporting expectations should be standardized across research sectors so readers can interpret biosafety and biosecurity requirements consistently across studies while allowing institutional processes to remain risk proportionate and context specific. This is essential to avoid additional burden for institutions that are already stretched by existing oversight requirements.

A. Project and Protocol Level Indicators

NIH could recognize whether a project includes:

1. Documented biological risk assessment appropriate to the agents, materials, procedures, host range, routes of exposure, scale, and research setting.

2. Institutional review and approval where applicable, including IBC review, DURC or PEPP review, select agent review, animal care and use review, occupational health review, or other relevant institutional oversight.

3. Clear linkage between risk assessment and the selected controls, including containment level, engineering controls, PPE, work practices, exposure response, and decontamination or final disposition controls when materials are not intended for further use.

4. Personnel training and competency documentation for individuals performing high-consequence or specialized procedures, such as work in Biosafety Level 3 or Biosafety Level 4 laboratories.

5. Material accountability and traceability, where relevant, including biological material provenance, transfer approvals, material transfer agreements, inventory expectations, and chain of custody for materials of concern.

6. Documentation of inactivation methods when biological materials are intended for downstream analysis, transfer, storage, reuse, or removal from containment.

7. Evidence of ongoing oversight, such as post approval monitoring, biosafety inspections, corrective actions, learning from incidents, and periodic protocol updates.

B. Publication and Dissemination Indicators

A biosafety and biosecurity methods statement could be required for federally funded research outputs when the work involves biological hazards, recombinant or synthetic nucleic acids, biological toxins, animals, human specimens, or other materials subject to institutional biosafety and biosecurity review. As NIH and the broader research ecosystem move toward clearer and more consistent expectations for transparency in biosafety-relevant methodologies, standardized reporting of applicable requirements, institutional review, and oversight verification would help produce concise, interpretable statements that support rigor, reproducibility, and public trust.

This statement could be concise and risk proportionate. It might include:

1. Applicable institutional approvals, such as IBC, IACUC, DURC or PEPP, select agent, or other relevant reviews.

2. Biosafety level or containment approach used for the work, as documented through applicable institutional review or risk assessment processes.

3. Key facility, equipment, or procedural controls necessary to interpret or reproduce the work.

4. Inactivation methods for materials intended for downstream analysis, transfer, storage, reuse, or removal from containment, when those methods affect interpretation, reproducibility, or downstream application.

5. Decontamination, disinfection, sterilization, destruction, or waste treatment approaches when relevant to responsible final disposition of biological materials, without requiring disclosure of sensitive operational details.

6. Personnel training or competency expectations for specialized procedures.

7. Material transfer, provenance, or traceability information when relevant.
8. A statement that sensitive security details have been withheld when disclosure could create misuse risk.

This would be analogous in spirit to existing publication reporting expectations for animal research, clinical trials, data sharing, conflict of interest, funding acknowledgment, and author contribution statements. The purpose would not be to disclose sensitive operational details. The purpose would be to make safety relevant methodological information and oversight controls visible enough to support rigor, reproducibility, and public trust.

C. Investigator and Team Science Indicators

NIH could recognize biosafety and biosecurity contributions as part of team-based science. In many institutions, the quality of research depends on contributions from biosafety professionals, IBC administrators, veterinarians, occupational health experts, facility engineers, biocontainment staff, research security professionals, data and cyberbiosecurity experts, and compliance personnel.

Possible indicators include:

1. Evidence that investigators engaged appropriate institutional expertise early in study design.
2. Documentation that biosafety or biosecurity considerations informed experimental planning.
3. Inclusion of biosafety or biorisk management expertise in complex or higher risk projects.
4. Recognition of safety professionals and oversight contributors in acknowledgments, methods sections, grant progress reports, or contributor statements when their input significantly shaped the research.

D. Institutional Indicators

NIH could also recognize institutional commitment to biosafety and biosecurity as part of gold standard science. Potential indicators include:

1. Centralized systems for protocol review, biological material oversight, training, occupational health involvement, and incident tracking.
2. Adequate staffing and resourcing for IBC administration, biosafety programs, biosecurity review, and compliance monitoring.
3. Routine use of data and metrics to evaluate program effectiveness.
4. Processes for learning from incidents, near misses, audit findings, and corrective actions.
5. Institutional mechanisms for escalating research with higher biosafety, biosecurity, or dual use concern.
6. Systems for distinguishing and validating materials that are inactivated for downstream use from materials that are decontaminated, destroyed, or otherwise treated for final disposition.
7. Evidence that safety oversight supports research rather than merely delaying or policing it.

To address concerns that institutions with fewer biosafety resources could be disproportionately affected by the inclusion of these metrics, NIH could consider a two-tier approach. The first tier could include minimum biosafety and biosecurity reporting expectations for all institutions receiving federal funding. The second tier could be a voluntary recognition model for institutions with more mature and well-resourced systems. This approach could function as an NIH aligned gold standard biosafety recognition framework rather than a rigid accreditation requirement. Such a model could incentivize institutions to invest in safety infrastructure, improve internal coordination, strengthen public confidence in federally funded research, and continuously improve existing safety systems.

Potential Incentives

NIH could reward biosafety and biosecurity excellence without turning safety into a punitive or overly bureaucratic scoring exercise.

Potential incentives include:

1. Incorporating biosafety and biosecurity reporting into existing rigor and reproducibility expectations.
2. Adding biosafety and biosecurity methods statements to publication and public access expectations for relevant research.
3. Encouraging progress reports to describe major biosafety or biosecurity milestones for higher risk work.
4. Supporting administrative supplements or infrastructure funding for institutions seeking to strengthen biorisk management systems.
5. Recognizing investigators and institutions that model exemplary integration of safety, security, transparency, and scientific rigor.
6. Developing common reporting elements for biosafety and biosecurity, similar to other structured reporting frameworks.
7. Supporting training modules that help investigators understand how safety and security decisions affect research quality and public trust.
8. Encouraging journals and preprint servers to adopt risk proportionate biosafety reporting expectations for federally funded research.

Benefits

Recognizing biosafety, biosecurity, and safety oversight as measurable indicators of scientific impact would provide several benefits.

1. Stronger Reproducibility

Key biosafety variables, such as review of experimental conditions, risk assessment of individual components and system level issues, containment level, handling practices, inactivation methods for

materials intended for downstream use, PPE, equipment controls, and facility conditions, can affect whether a study can be accurately interpreted or repeated.

2. Greater Transparency

A concise biosafety and biosecurity methods statement would help readers understand the conditions under which research was conducted without requiring disclosure of sensitive operational details.

3. Improved Public Trust

The public is more likely to trust federally funded research when institutions can demonstrate that work was conducted under appropriate oversight, accountability, and risk management systems.

4. Better Institutional Coordination

If NIH recognizes biosafety and biosecurity as part of scientific impact, institutions will have a stronger incentive to centralize systems, appropriately size and fund oversight programs, create efficiencies, reduce facility and administrative costs, and reduce silos among research administration, safety, security, occupational health, animal care, and compliance functions.

5. Stronger Safety Culture

Rewarding safety as part of excellent science reinforces the idea that investigators, institutions, and funders share responsibility for responsible research. Beyond institutional benefits, this approach would reinforce a broader culture in which the scientific enterprise recognizes its responsibility to advance science in a manner that is safe, secure, ethical, and publicly accountable.

6. Better Support for Emerging Technologies

Fields such as synthetic biology, gene editing, pathogen research, AI enabled biology, organoids, advanced animal models, and environmental sampling increasingly require integrated scientific, safety, and security review. NIH can help normalize this integration as part of modern biomedical research.

Implementation Considerations

As NIH implements updates to the NIH Guidelines and related biosafety oversight frameworks, incorporating these concepts into scientific impact measures could be phased alongside those policy changes. This would allow institutions to align reporting expectations with evolving federal guidance without creating parallel or conflicting systems. Additionally, these requirements could be incorporated into new and renewing award terms, grant policy statements, and notices of funding opportunities where appropriate. NIH should implement these updates in a way that is practical, scalable, and risk proportionate.

1. Use existing institutional systems where possible. IBC records, training systems, DURC or PEPP review records, occupational health requirements, and inspection findings already exist in many institutions.
2. Avoid creating a one-size-fits-all requirement. Expectations should scale based on the risk profile of the research. A two-tier system, as described above, may help balance broad applicability with institutional flexibility.

3. Protect sensitive security information. Public reporting should not disclose facility vulnerabilities, detailed security controls, exact inventories of materials of concern, or information that could enable misuse.
4. Pilot before broad implementation. NIH could begin with higher relevance categories, such as research involving high-consequence infectious agents, recombinant or synthetic nucleic acids, biological toxins, select agents, PEPP relevant research, or high containment facilities.
5. Engage journals and preprint servers. NIH could work with publishers to develop consistent reporting language that supports transparency without compromising safety or security.
6. Provide templates, checklists, and examples. Investigators and institutions would benefit from short model statements, decision trees, and common data elements.
7. Recognize resource differences across institutions. Smaller institutions, teaching-focused institutions, minority serving institutions, and institutions with limited biosafety infrastructure may need additional guidance and support.

Potential Unintended Consequences and Mitigation

1. Administrative Burden

Risk: New requirements could become another paperwork exercise.

Mitigation: Use existing institutional documentation, create concise reporting templates, and limit detailed reporting to research where biosafety or biosecurity information is relevant to interpretation, reproducibility, or public trust.

2. Inconsistent Institutional Capacity

Risk: Institutions vary widely in biosafety staffing, systems, and documentation maturity.

Mitigation: NIH could develop guidance, common elements, training resources for biosafety personnel, and expect implementation in phases.

3. Disclosure of Sensitive Information

Risk: Publication or reporting expectations could inadvertently reveal private or security-sensitive information that should remain protected.

Mitigation: NIH should clearly distinguish between transparency that supports scientific interpretation and operational details that should not be publicly disclosed.

4. Perverse Incentives

Risk: Investigators or institutions may treat safety reporting as reputation management rather than genuine risk reduction and may suppress reporting of genuine safety concerns.

Mitigation: Indicators should focus on evidence of meaningful risk assessment, oversight, corrective action, and continuous improvement rather than superficial statements of compliance. NIH could also consider direct confidential reporting pathways for safety or oversight concerns, with appropriate protections against retaliation.

5. Overly Rigid Review Criteria

Risk: Safety indicators could be applied mechanically across diverse research fields.

Mitigation: NIH should use a tiered approach that allows flexibility by discipline, material, procedure, scale, and risk level. Not all indicators will be relevant to all fields of biomedical research. NIH should involve biosafety professionals who manage these differences in day-to-day operations to help identify relevant, practical, and meaningful indicators.

Conclusion

Biosafety, biosecurity, and safety oversight should be recognized as measurable components of rigorous and impactful biomedical research. They are not ancillary administrative functions. They shape how research is designed, conducted, interpreted, reproduced, translated, and trusted.

As NIH modernizes its biosafety policy framework to reflect the realities of contemporary life sciences research, incorporating biosafety and biosecurity into measures of scientific impact represents a natural and necessary evolution of that effort. As NIH modernizes its biosafety policy framework to reflect contemporary life sciences research, it has a parallel opportunity to align scientific impact measures with the responsibilities that come with publicly funded science. Gold standard science requires more than discovery. It requires transparent methods, reproducible practices, institutional accountability, responsible innovation, and public trust.

By incorporating biosafety, biosecurity, and safety oversight into its scientific impact framework, NIH can strengthen research quality, promote institutional culture, protect public investments, support emerging technologies, and reinforce a movement in which safe science is understood as excellent science.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: To train a biomedical workforce, there needs to be training in all career types (academia, clinical, industry government, consulting, teaching). There has been a shift in recent years to train more predoctoral fellows on T32s instead of postdoctoral fellows /clinical scientists. This leaves a huge gap in protected time for clinician-scientists, who now more than ever have less protected time for research from clinical duties. More T32s should be provided for postdoctoral level clinical and translational scientists. Benchmarks for success for each program should be based on the specifics of the post-program career types the program produces, as it would vary greatly between clinical coordinators, clinician-scientists, translational researchers, and basic scientists, for examples. At the T/F level of training, better benchmarks are career pathway-oriented, such as positions. At the K level of training, time to promotion in academia/industry and more traditional benchmarks such as publications and subsequent grants may be more appropriate.

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: Public impact is hard to assess short-term. Measures created should have long-term impact in mind.

8. Other Areas: N/A

88. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 7/10/2026

1. Rigor and Reproducibility: NIH would need to completely overhaul grant review to do this. Because right now where you publish and how often you publish run counter to the goal of rigor and reproducibility.

2. Data, Software, and Model Sharing: More databases like Pubmed and GEO are needed.

3. Training and Mentorship: Mentorship should apply to ALL levels of trainees. Smaller schools are going to graduate less PhD students but if their undergrads go on to amazing scientific careers that means they are good mentors. Indicators are outcomes of all trainees, types of papers (one or two student versus 50 people).

4. Collaboration: N/A

5. Entrepreneurship and Translation: NIH money that funds trainees should not also fund patent work. It's a huge conflict of interest and detrimental to students.

6. Foundational Scientific Exploration: Stop funding academics that have had their careers. Most faculty hit their prime well before 70. Yes so much money is going to PIs who refuse to retire and have no moved the needle.

7. Public Impact: N/A

8. Other Areas: There is no equity, review and budget decisions are a sham. And most importantly, the modular budget is woefully inadequate.

89. N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: I am strongly opposed to Section 200.205 - political appointees review of grants. While not employed as a scientist, I understand the scientific method and earned a Ph.D. in 2011. I value my government's investment in and recognition of expert opinion. I have absolutely no desire to see political appointees reviewing grants. This would politicize the scientific process and is absolutely unacceptable. It would result in a degradation of the public trust in NIH research and decision making. We, the public, need to feel confident that our tax dollars are spent / invested wisely and that information provided is based on objective and rigorous methodology.

I am also opposed to 200.454 which makes journal subscriptions unallowable. I value the process of peer review and publication and I understand how these facilitate the dissemination of reliable information within and across fields of study. I want researchers to have access to current, reliable information so that they will stay current in their field of study and reliable, important information will be disseminated within and across fields.

7. Public Impact: N/A

8. Other Areas: I am also opposed to section 200.340 termination provisions. Again, this would inappropriately politicize the scientific process and result in wasted investment (my tax dollars) of projects already underway. You should make every effort to keep politics OUT of scientific decision making and instead make every effort to ensure that an objective, replicable scientific process drives decision making in terms of expenditures / investment of our public resources / tax dollars.

Description: I oppose the politicization of federal financial assistance rules and decision making.

8. Other Areas: N/A

92. Al George

I am responding: On behalf of myself

Name: Al George

Name of Organization: Northwestern University

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 7/15/2026

1. Rigor and Reproducibility: This is an important topic. It is vital to train reviewers of NIH grants to appreciate what this means. Sadly, we don't train reviewers in core aspects of rigor and reproducibility or on best practices for evaluating science. This seems like a major obstacle to implementing this policy. A second major obstacle relates to the recent proposal by OMB to allow political appointees without scientific training to determine which grants are funded or terminated. If the OMB rule goes forward, then peer-review is weakened and efforts to promote rigor and reproducibility at the grant review stage will be neutered.

2. Data, Software, and Model Sharing: no comment

3. Training and Mentorship: no comment

4. Collaboration: Collaboration promotes cross-disciplinary science and is vital to our research enterprise. Every effort should be made to promote and not discourage collaboration. Two recent policy changes or proposed changes will discourage collaboration: 1) limits to the number of grant submissions per PI per year is already discouraging MPI grants (some PIs hit the limit because of MPI grants and are discouraged from collaborating on new projects). 2) the proposed cap on simultaneously held grants will discourage MPI grant applications UNLESS an MPI grant is not counted as ONE grant for each PI (a fractional counting makes the most sense). These unintended consequences of these two policies are not being offset by other initiatives to promote collaboration.

5. Entrepreneurship and Translation: no comment

6. Foundational Scientific Exploration: Promoting risking research was the original intent of the R21 program but this nearly abandoned at this point. There was never enough money or time in an R21 to accomplish a paradiagm-shifting discovery. Breakthrough research is expensive research and the current NIH budget fosters conservative non-risky (safe) science. If we want more breakthroughs, we need to pay for the risky science that lead to them. Limiting grant applications and capping numbers of grants, cutting budgets will have the opposite effect.

7. Public Impact: There should be a stronger effort to inform the public about the benefits of biomedical research including making connections between seemingly obscure basic science findings to medical breakthroughs, and highlighting the long time horizon for translating basic research into advances in health and wellness. The NIH should be the leader in doing this, but it has not been the mission. While

this may sound like public relations, it is very important that NIH educates the public at large about why we do research and its long-term (not short term) benefits. We should also make sure the public knows that China is soon to become the leader in science and taxpayers in this country will have to accept that new drugs, new treatments, and other advances in healthcare will not be coming from the U.S.

8. Other Areas: no comment

93. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 7/15/2026

1. Rigor and Reproducibility: To strengthen rigor and reproducibility, NIH should incentivize independent replication, validation studies, transparent reporting, and the use of standardized protocols. Investigators who develop robust and reproducible research platforms, such as organoid models validated across multiple laboratories or cell lines, should receive recognition comparable to traditional high-impact publications.

2. Data, Software, and Model Sharing: Data, software, model systems, and standardized protocols should be recognized as valuable scientific products. High-quality datasets, computational tools, and experimental platforms that are widely adopted by the research community often have a lasting impact beyond individual publications and should be considered in research evaluation.

3. Training and Mentorship: NIH should also develop better measures of mentorship based on trainee outcomes, independence, and career development rather than simply the number of trainees. Similarly, evaluation of collaboration should move beyond first- or senior-author publications to recognize meaningful contributions to team science, including technology development, methodology, data generation, project leadership, and shared research resources.

4. Collaboration: Researchers should receive recognition for:
conceptualization;
methodology development;
data generation;
analysis;
resource creation;
clinical translation;
project management.

5. Entrepreneurship and Translation: NIH should recognize:
invention disclosures;
patents;
licensing;
startup creation;
clinical trials initiated;
regulatory milestones;

manufacturing platforms;
technology adoption.

6. Foundational Scientific Exploration: The current system sometimes discourages ambitious science because failure negatively affects funding.

NIH should create mechanisms where investigators are rewarded for:

developing new technologies;
exploring unconventional hypotheses;
creating enabling platforms.

Possible indicators:

creation of new research fields;
adoption of new methodologies;
follow-on discoveries by others.

7. Public Impact: Health impact
contribution to clinical guidelines;
improved diagnosis;
therapeutic development;
disease prevention.
Societal impact
patient engagement;
public accessibility;
education;
policy influence.
Economic impact
biotechnology development;
workforce development;
manufacturing capacity.

8. Other Areas: A major unintended consequence is metric overload. If NIH creates 50 new metrics, researchers will spend more time documenting science than doing science. NIH should prioritize a small number of meaningful indicators. Most importantly, these new indicators should be integrated into grant review, funding decisions, and investigator evaluation. Without corresponding changes to reviewer guidance and study section expertise, particularly for New Approach Methodologies (NAMs) and other emerging technologies, these efforts may not meaningfully change the current research culture or fully support innovative, high-impact biomedical science.

Description: I support NIH's effort to broaden the definition of scientific success beyond publication counts and citation metrics. Modern biomedical research increasingly relies on team science, New Approach Methodologies (NAMs), shared resources, and translational platforms that are not adequately recognized under current evaluation systems. However, these new indicators will have meaningful impact only if they are incorporated into grant review, funding decisions, and investigator evaluation.

Otherwise, they risk becoming additional reporting requirements without changing scientific culture. In particular, if NIH seeks to promote NAMs and other innovative technologies, reviewer training and study section composition should include appropriate expertise to ensure these approaches are evaluated fairly rather than judged primarily against traditional methods.

94. Hafizullah Safi

I am responding: On behalf of myself

Name: Hafizullah Safi

Name of Organization: Safi Natural Care Clinic

Type of Organization: Not Applicable

Role: Investigator/Researcher

Date Submitted: 7/16/2026

1. Rigor and Reproducibility: Scientific rigor and reproducibility form the foundation of credible biomedical research. Regardless of scientific discipline or methodology, research findings should be sufficiently transparent and well documented to enable independent researchers to reproduce analyses, verify results, and build upon previous discoveries. Reproducibility not only strengthens confidence in scientific findings but also improves the efficiency of research investments by reducing unnecessary duplication, identifying methodological limitations, and accelerating cumulative scientific progress.
Current academic reward systems often prioritize the novelty of scientific findings over the quality and reproducibility of research methods. Consequently, researchers may receive greater recognition for publishing new discoveries than for validating existing findings, conducting replication studies, improving analytical methods, or producing high-quality datasets that support future research. Although replication studies and negative findings are essential components of the scientific process, they are frequently undervalued in traditional research assessment systems.
NIH has taken important steps through its Replication and Reproducibility Initiative to strengthen scientific integrity. Continued progress, however, will require evaluation systems that actively recognize researchers who consistently demonstrate rigorous scientific practices throughout the research lifecycle. Examples of activities that should receive greater recognition include:
• Publishing detailed study protocols and statistical analysis plans before data analysis.
• Making analytical code, algorithms, and computational workflows openly available whenever appropriate.
• Sharing de-identified research datasets and associated metadata in accordance with ethical and legal requirements.
• Conducting independent validation and replication studies.
• Reporting negative or inconclusive findings that contribute to scientific understanding and reduce publication bias.
• Using standardized reporting guidelines and internationally recognized research standards.
• Implementing transparent quality assurance and quality control procedures throughout data collection and analysis.
• Participating in collaborative efforts to reproduce important scientific findings across different populations and settings.
NIH may also consider incorporating measurable indicators of research rigor into funding and career evaluation processes. Examples include the availability of reproducible analytical workflows, documented data quality procedures, public access to research protocols, successful independent

validation of findings, adherence to FAIR (Findable, Accessible, Interoperable, and Reusable) data principles, and demonstrated compliance with established reporting standards.
Importantly, promoting reproducibility should not be viewed as an administrative requirement but rather as an investment in scientific quality. Rewarding researchers who prioritize methodological excellence, transparency, and validation will strengthen public trust, improve the reliability of biomedical evidence, and increase the long-term value of publicly funded research. A research culture that values reproducibility equally with innovation will produce discoveries that are more robust, more transferable across populations, and more likely to generate lasting scientific and public health impact.

2. Data, Software, and Model Sharing: The value of biomedical research extends well beyond scientific publications. Increasingly, the greatest impact of research is realized through the sharing of high-quality datasets, analytical methods, software, computational models, and research tools that enable other investigators to validate findings, generate new hypotheses, and accelerate scientific discovery. Open and responsible sharing of scientific resources enhances transparency, improves reproducibility, reduces duplication of effort, and maximizes the return on public investment in research.
The COVID-19 pandemic clearly demonstrated the importance of rapid and transparent data sharing. International collaboration through surveillance networks, genomic databases, and open scientific platforms enabled researchers worldwide to monitor pathogen evolution, assess disease transmission, develop diagnostics, evaluate interventions, and accelerate vaccine development. These achievements highlighted that scientific progress depends not only on producing data, but also on making data accessible, interoperable, and reusable by the broader research community.
Despite these benefits, many researchers receive limited academic recognition for developing, curating, maintaining, and sharing valuable scientific datasets or software. Considerable effort is often required to establish surveillance systems, harmonize data standards, ensure data quality, document metadata, develop analytical tools, and maintain long-term databases. These contributions frequently require years of sustained investment but are rarely reflected in conventional measures of scientific productivity.
NIH should recognize data stewardship and scientific resource development as core research contributions. Investigators who make high-quality datasets, software packages, computational pipelines, and predictive models openly available should receive formal recognition comparable to traditional scholarly outputs. Such recognition would encourage broader participation in open science while improving the reproducibility and efficiency of biomedical research.
Future evaluation frameworks could include measurable indicators such as:
• Timely sharing of de-identified research data in accordance with ethical, legal, and regulatory requirements.
• Compliance with FAIR (Findable, Accessible, Interoperable, and Reusable) data principles.
• Development and maintenance of high-quality scientific databases, registries, surveillance systems, and biorepositories.
• Public availability of analytical software, statistical code, machine learning algorithms, and computational workflows.
• Documentation quality, metadata completeness, and standardized data dictionaries.
• Frequency of dataset reuse by independent investigators.
• Integration of shared datasets into national or international scientific platforms.
• Long-term sustainability and accessibility of shared scientific resources.
NIH should also encourage the citation of datasets, software, and digital research products as independent scholarly outputs. Standardized mechanisms for assigning persistent identifiers, such as

Digital Object Identifiers (DOIs), can improve attribution and enable these contributions to be tracked and evaluated alongside traditional publications.

Importantly, data sharing should be implemented responsibly. Policies must continue to safeguard participant privacy, protect confidential information, respect national regulations, and recognize the rights of data-generating institutions and investigators. In particular, researchers working in low- and middle-income countries should receive appropriate authorship, acknowledgment, and opportunities for scientific leadership when their data contribute to international collaborative research.

By recognizing data, software, and model sharing as essential scientific outputs, NIH can foster a research culture that values openness, collaboration, transparency, and long-term scientific utility. Such an approach will accelerate biomedical discovery while strengthening public trust and maximizing the societal benefits of federally funded research.

3. Training and Mentorship: The long-term success of biomedical research depends not only on scientific discoveries but also on the development of a skilled, diverse, and sustainable research workforce. Training and mentorship are fundamental investments that strengthen scientific capacity, promote innovation, improve research quality, and ensure the continuity of scientific excellence across generations. However, these contributions are often underrepresented in current systems used to evaluate scientific impact.

Effective mentorship extends beyond supervising research projects. High-quality mentors cultivate scientific integrity, critical thinking, leadership, collaboration, communication skills, and responsible research practices. They provide guidance that enables trainees to become independent investigators while fostering inclusive and supportive research environments. Similarly, structured training programs that enhance technical competencies, research methodology, data analysis, laboratory quality management, implementation science, and scientific writing contribute substantially to strengthening the biomedical research enterprise.

Current evaluation systems frequently recognize publications and grant income while giving comparatively little credit to sustained mentorship and workforce development. As a result, researchers who dedicate significant time to training early-career scientists, building institutional capacity, or strengthening research infrastructure may receive limited recognition despite their substantial long-term impact.

NIH should incorporate measurable indicators that recognize excellence in training and mentorship. Potential indicators include:

- Successful career progression of trainees into independent research or leadership positions.
- Contributions to multidisciplinary training programs and workforce development initiatives.
- Development of educational resources, curricula, and professional training materials.
- Mentorship of early-career investigators, particularly those from underrepresented or resource-limited settings.
- Establishment of sustainable institutional research capacity.
- Evidence of long-term mentoring relationships and continued professional development of trainees.
- Contributions to strengthening laboratory systems, surveillance capacity, research ethics, and implementation science.
- Recognition received from trainees, institutions, or professional organizations for mentoring excellence.

Importantly, evaluation should emphasize the quality and long-term outcomes of mentorship rather than simply the number of trainees supervised. A single mentor who successfully develops future scientific

leaders may have a greater and more lasting impact than one who supervises many trainees without meaningful professional development.
Investment in mentorship also promotes scientific integrity and reproducibility. Experienced mentors play a critical role in teaching rigorous study design, ethical conduct of research, transparent reporting, responsible data management, and collaborative scientific practices. Strengthening these competencies early in researchers' careers contributes to a more reliable, trustworthy, and resilient biomedical research ecosystem.
Recognizing mentorship and workforce development as essential scientific contributions will encourage researchers to invest in future generations of scientists while strengthening global research capacity and ensuring the long-term sustainability of biomedical innovation.

4. Collaboration: Biomedical research has become increasingly collaborative, interdisciplinary, and international. Addressing today's most pressing health challenges including emerging infectious diseases, antimicrobial resistance, pandemic preparedness, precision medicine, and chronic diseases requires expertise that extends far beyond any single investigator, institution, or scientific discipline. Successful research increasingly depends on effective collaboration among clinicians, epidemiologists, laboratory scientists, data scientists, statisticians, social scientists, engineers, public health practitioners, policymakers, and community stakeholders.
Despite this transformation, research evaluation systems continue to emphasize individual accomplishments, often relying heavily on first or senior authorship, principal investigator status, and individual grant awards. Such approaches may overlook the substantial scientific contributions made by investigators whose expertise is essential to collaborative research but whose roles are less visible in traditional academic metrics. Data managers, surveillance specialists, laboratory scientists, statisticians, software developers, implementation researchers, and project coordinators frequently make indispensable contributions that are difficult to quantify under current evaluation systems.
NIH should further strengthen mechanisms for recognizing meaningful contributions to team science. Evaluation should move beyond publication authorship alone and consider the quality, significance, and impact of each individual's contribution throughout the research process. Modern research benefits when multidisciplinary teams work together to design studies, generate high-quality data, develop analytical methods, interpret findings, and translate evidence into practice.
Potential indicators for recognizing collaborative research may include:
• Participation in multidisciplinary and multi-institutional research projects.
• Contributions to international scientific collaborations and research networks.
• Leadership or coordination of collaborative research initiatives.
• Development of shared research infrastructure, surveillance systems, or laboratory networks.
• Contributions to multicenter studies, implementation research, and consortium-based projects.
• Evidence of equitable partnerships that promote shared leadership and capacity strengthening.
• Collaborative development of standardized protocols, data standards, and quality assurance systems.
• Contributions to cross-disciplinary innovation that integrates complementary areas of expertise.
Evaluation systems should also recognize that impactful collaboration extends beyond academic institutions. Partnerships involving government agencies, public health organizations, healthcare providers, industry, community organizations, patient groups, and international partners often play a critical role in translating scientific discoveries into meaningful health outcomes. These collaborations strengthen the relevance, applicability, and sustainability of biomedical research while increasing its societal impact.

Importantly, collaborative research should be evaluated based on both scientific productivity and the effectiveness of the partnership itself. Indicators such as sustained collaboration, equitable authorship practices, shared decision-making, successful knowledge exchange, and measurable improvements in research capacity may provide valuable insight into the long-term success of collaborative initiatives. By rewarding meaningful collaboration, NIH can encourage researchers to build diverse scientific teams, share expertise across disciplines, reduce unnecessary duplication of effort, and accelerate the translation of scientific discoveries into improved health outcomes.

5. Entrepreneurship and Translation: Scientific discovery achieves its greatest value when research findings are translated into interventions, technologies, policies, diagnostics, therapeutics, and public health practices that improve human health. While fundamental discovery remains essential, evaluation systems should also recognize the processes that move scientific knowledge beyond publication and into real-world application.

Translation is rarely a single event. It involves a continuum of activities including technology development, validation studies, implementation research, regulatory evaluation, commercialization, policy development, clinical adoption, and health system integration. Each stage requires substantial scientific expertise and often involves multidisciplinary collaboration across academia, healthcare, government, and industry. However, many of these activities receive relatively limited recognition within traditional academic evaluation frameworks.

NIH should broaden the definition of translational impact to encompass the full spectrum of activities that convert scientific knowledge into measurable public benefit. Successful translation should not be assessed solely by patents or commercial products but also by the adoption of evidence-based practices, improvements in healthcare delivery, strengthening of public health systems, and incorporation of research findings into national or international guidelines.

Potential indicators of translational impact include:

• Adoption of research findings into clinical practice guidelines or public health policies.
• Development and implementation of new diagnostic methods, surveillance tools, or healthcare technologies.
• Creation of software platforms, digital health applications, decision-support systems, or analytical tools used in healthcare settings.
• Commercialization of biomedical innovations that improve patient care.
• Establishment of public-private partnerships supporting technology development.
• Successful implementation of research findings within healthcare systems or public health programs.
• Demonstrated improvements in healthcare quality, efficiency, or accessibility resulting from research.
• Contribution of scientific evidence to regulatory decisions or national health strategies.

Entrepreneurship should likewise be recognized as an important component of biomedical innovation. Researchers who successfully transform scientific discoveries into scalable solutions frequently contribute to economic development, job creation, technology transfer, and improved healthcare delivery. These activities complement rather than compete with traditional academic research and should be evaluated within the broader context of NIH's mission to improve health.

Importantly, translational success should also include innovations that primarily benefit public health rather than commercial markets. Research that strengthens disease surveillance, enhances laboratory systems, improves outbreak detection, supports emergency preparedness, or informs health policy may generate substantial societal value even when no commercial product results.

Recognizing diverse pathways of translation will encourage researchers to pursue innovations that

address unmet health needs while ensuring that publicly funded biomedical research delivers meaningful and measurable benefits to patients, healthcare systems, and society.

6. Foundational Scientific Exploration: Foundational scientific research is the cornerstone of biomedical discovery. Many of the most significant advances in medicine including vaccines, molecular diagnostics, gene editing technologies, and immunotherapies originated from curiosity driven investigations whose practical applications were not immediately apparent. Likewise, high-risk, high-reward research often challenges existing paradigms, explores unconventional hypotheses, and generates transformative breakthroughs that reshape entire scientific fields.

Despite its importance, foundational research frequently faces challenges within current evaluation systems. Investigators are often encouraged to pursue projects with predictable outcomes and a high likelihood of producing publications and grant renewals within relatively short timeframes. This environment may unintentionally discourage innovative ideas that require longer periods of development, involve greater uncertainty, or have a higher probability of negative or inconclusive findings.

NIH has long recognized the importance of supporting innovative science through programs that encourage high-risk, high-reward research. Continued success will require evaluation frameworks that acknowledge scientific ambition, creativity, and methodological excellence, even when research outcomes are uncertain.

Future evaluation systems should recognize contributions such as:

- Development of novel scientific hypotheses and conceptual frameworks.
- Creation of innovative research methodologies and experimental approaches.
- Exploration of emerging scientific fields with transformative potential.
- Long-term investment in foundational datasets, surveillance systems, and research infrastructure.
- Publication of well-designed negative or inconclusive findings that refine scientific understanding.
- Generation of resources that enable future scientific discoveries beyond the original research objectives.
- Development of interdisciplinary approaches that bridge multiple scientific domains.

Importantly, evaluation should distinguish between unsuccessful research resulting from poor scientific quality and well-designed research that produces unexpected, null, or negative findings. The latter represents an essential component of scientific progress and often prevents unnecessary duplication of effort while informing future investigations.

NIH may also consider rewarding researchers who contribute to long-term scientific infrastructure that benefits the broader research community. Establishing surveillance systems, longitudinal cohort studies, biobanks, reference laboratories, data repositories, and standardized methodologies often requires years of sustained investment before yielding substantial scientific outputs. These foundational resources support countless future investigations and should be recognized as enduring scientific contributions.

By valuing scientific curiosity, methodological innovation, and responsible exploration of challenging research questions, NIH can foster an environment that encourages bold ideas while maintaining the highest standards of scientific rigor and integrity.

7. Public Impact: The ultimate purpose of biomedical research is to improve human health. While scientific publications remain an important means of disseminating knowledge, the true impact of research should also be measured by its contribution to improving health outcomes, informing policy, strengthening healthcare systems, enhancing preparedness, reducing disease burden, and increasing

public trust in science.
Traditional academic metrics primarily measure scientific influence within the research community. Citation counts and publication metrics provide useful indicators of scholarly recognition but do not necessarily reflect whether research has improved clinical practice, informed health policy, strengthened disease surveillance, enhanced healthcare delivery, or benefited patients and communities.
NIH should incorporate broader measures of societal and public health impact into research evaluation. Recognizing these contributions would encourage investigators to pursue research that addresses important health challenges while promoting stronger connections between scientific discovery and real-world implementation.
Examples of measurable public impact may include:
• Adoption of research findings into national or international clinical guidelines and public health policies.
• Improvements in disease prevention, diagnosis, treatment, or patient outcomes resulting from research.
• Strengthening of laboratory systems, surveillance networks, and public health infrastructure.
• Contributions to emergency preparedness and response for emerging infectious diseases and other public health threats.
• Development of evidence that informs vaccination strategies, screening programs, or disease control interventions.
• Improvements in healthcare accessibility, quality, efficiency, or equity.
• Increased public confidence in science through transparent communication and responsible dissemination of research findings.
• Demonstrated societal, economic, or health system benefits attributable to scientific research.
Evaluation should also recognize that public impact often requires sustained engagement with policymakers, healthcare providers, public health authorities, patients, and communities. Activities such as knowledge translation, implementation science, public communication, and evidence-informed policymaking play essential roles in ensuring that scientific discoveries generate meaningful societal benefits.
Importantly, the impact of research should be assessed over appropriate timeframes. Some scientific discoveries produce immediate benefits, while others may influence healthcare practice or public policy years after publication. Flexible evaluation frameworks that recognize both short-term implementation and long-term societal contributions will provide a more comprehensive assessment of scientific value.
Ultimately, scientific success should be measured not only by the number of publications produced, but by the extent to which research improves lives, strengthens health systems, advances equity, informs decision-making, and contributes to healthier and more resilient societies.

8. Other Areas: Toward a Balanced Framework for Measuring Scientific Impact:
As biomedical research continues to evolve, evaluation systems should similarly evolve toward a more comprehensive and balanced approach to recognizing scientific contributions. Rather than relying predominantly on individual publication-based metrics, future assessment frameworks should incorporate multiple complementary dimensions that collectively reflect the diverse ways researchers contribute to scientific advancement.
A balanced evaluation framework should recognize excellence across the following domains:
• Scientific Quality: rigorous study design, reproducibility, methodological transparency, and high-quality publications.

• Open Science: responsible sharing of data, software, analytical methods, and research resources.
• Collaboration: meaningful contributions to multidisciplinary, multi-institutional, and international team science.
• Capacity Building: mentorship, workforce development, laboratory strengthening, and research infrastructure.
• Innovation and Translation: development of new technologies, implementation of research findings, and translation into clinical or public health practice.
• Public Impact: measurable improvements in health outcomes, policy development, preparedness, healthcare delivery, and societal benefit.

These domains should be viewed as complementary rather than competing measures of scientific excellence. Different disciplines, institutions, and career stages contribute to biomedical research in diverse ways, and evaluation systems should provide sufficient flexibility to recognize these differences while maintaining consistent standards of quality and accountability.

Importantly, no single metric can adequately capture scientific impact. Overreliance on publication counts or citation-based indicators may unintentionally discourage collaboration, open science, mentorship, implementation research, and other activities that generate substantial long-term value. A multidimensional evaluation framework would better align incentives with NIH's mission of generating knowledge that enhances health, lengthens life, and reduces illness and disability.

By recognizing a broader range of scientific contributions, NIH can strengthen research integrity, encourage collaboration, promote innovation, improve reproducibility, and maximize the public benefit derived from biomedical research investments.

Executive Summary:

Measuring Scientific Impact Beyond Publications: Recommendations for Rewarding Rigorous, Collaborative, and Public Health-Oriented Research:

Scientific discovery has traditionally been evaluated using indicators such as publication counts, citation metrics, journal impact factors, and grant funding. While these measures remain important, they no longer fully reflect the diverse contributions that drive modern biomedical research. Today's scientific enterprise is increasingly collaborative, multidisciplinary, data-intensive, and implementation-oriented. Many of the most valuable scientific contributions such as developing surveillance systems, sharing high-quality data, strengthening laboratory capacity, mentoring researchers, informing public health policy, and improving health outcomes are not adequately recognized by conventional evaluation metrics.

Based on experience in infectious disease surveillance, pandemic preparedness, implementation research, and international public health collaboration, this response recommends expanding the definition of scientific impact to better reflect contributions that improve research quality and public health. Scientific excellence should be measured not only by the production of new knowledge, but also by the reproducibility, accessibility, implementation, and real-world impact of that knowledge.

This response proposes that NIH adopt a more balanced framework for evaluating scientific contributions by recognizing excellence across multiple complementary domains, including:

- Scientific rigor and reproducibility.
- Open sharing of data, software, protocols, and analytical methods.
- Capacity building through training and mentorship.
- Contributions to interdisciplinary and international team science.
- Translation of research into policy, clinical practice, and public health action.
- Support for foundational and high-risk scientific exploration; and
- Demonstrable improvements in population health, preparedness, and societal benefit.

The recommendations presented in this document emphasize practical and measurable indicators that can be applied across different research disciplines, career stages, and institutional settings. They are intended to complement, rather than replace, traditional academic metrics while encouraging behaviors that strengthen scientific integrity, accelerate discovery, promote collaboration, and maximize the return on public investment in biomedical research.

Ultimately, scientific success should be defined not only by what researchers publish, but by how their work advances knowledge, strengthens health systems, informs decision-making, improves public health, and benefits society.

Key Recommendations to NIH

To better align research evaluation with the realities of modern biomedical science, NIH may consider the following recommendations:

1. Move Beyond Publication-Centric Metrics

Complement traditional indicators such as publication counts, journal impact factors, and citation metrics with broader measures that capture the full spectrum of scientific contributions and real-world impact.

2. Strengthen Recognition of Scientific Rigor and Reproducibility

Reward researchers who demonstrate methodological excellence through transparent reporting, protocol registration, replication studies, validation of findings, and adherence to established reporting standards.

3. Recognize Open Science as a Core Scientific Contribution

Incentivize responsible sharing of research data, software, analytical code, protocols, and other scientific resources that improve transparency, reproducibility, and research efficiency.

4. Reward High-Quality Data Stewardship and Resource Sharing

Recognize the development, maintenance, and sharing of high-quality datasets, surveillance systems, biorepositories, computational tools, and other research infrastructure that enable future scientific discovery.

5. Promote and Reward Team Science

Develop evaluation approaches that recognize meaningful contributions to multidisciplinary, multi-institutional, and international collaborative research, regardless of traditional authorship position.

6. Value Training, Mentorship, and Capacity Building

Recognize researchers who contribute to developing the next generation of scientists through mentorship, workforce development, laboratory strengthening, and sustainable research capacity.

7. Expand Recognition of Translation and Implementation

Reward research that successfully informs public health policy, clinical practice, healthcare delivery, implementation science, technology development, and evidence-based decision-making.

8. Measure Public Health and Societal Impact

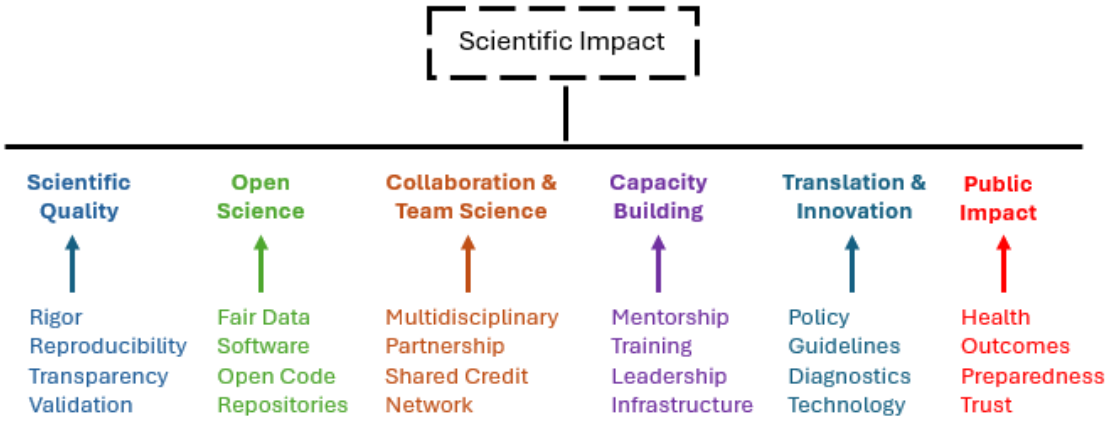
Incorporate indicators that evaluate how research contributes to improving health outcomes, strengthening health systems, enhancing preparedness, reducing disease burden, and increasing public trust in science.

9. Support Foundational and High-Risk Scientific Exploration

Continue to encourage innovative, curiosity-driven, and high-risk research by recognizing scientific quality, creativity, and long-term contributions, even when immediate outcomes are uncertain.

10. Adopt a Multidimensional Framework for Scientific Impact

Implement a balanced evaluation framework that integrates scientific quality, open science, collaboration, capacity building, translation, and public impact to provide a more comprehensive assessment of scientific excellence across career stages, disciplines, and institutional settings.



The future of biomedical research depends not only on generating new scientific knowledge, but also on ensuring that this knowledge is rigorous, reproducible, openly shared, collaboratively developed, effectively translated into practice, and ultimately improves human health. By adopting a more comprehensive and balanced approach to measuring scientific impact, NIH can strengthen research integrity, foster innovation, promote collaboration, and maximize the public value of biomedical research investments.

The six domains presented below represent complementary dimensions of modern biomedical research. Together, they encompass the full research lifecycle—from rigorous knowledge generation and scientific quality to open science, collaboration, translation, implementation, and measurable public health impact.

Figure 1. A Conceptual Framework for Measuring Scientific Impact in Modern Biomedical Research.

Traditional publication-based metrics should be complemented by six interconnected domains that collectively capture the diverse contributions required to advance biomedical discovery and improve public health.

Scientific impact should be evaluated as a multidimensional construct rather than through any single metric.

Table 1. Suggested Indicators for Measuring Scientific Impact Across the Six Domains

Domain	Examples of Scientific Contributions	Suggested Measurable Indicators
1. Scientific Quality	Rigorous study design, reproducibility, methodological transparency, validation studies	Evidence of reproducible research practices; independent validation of findings; adherence to reporting guidelines (CONSORT, STROBE, PRISMA, etc.); protocol registration; quality assurance measures; publication of negative findings
2. Open Science	Data sharing, software development, analytical pipelines, research protocols	FAIR data compliance; publicly available datasets; software/code repositories; dataset DOI citations; number of external

		dataset reuses; availability of statistical code and protocols
3. Collaboration & Team Science	Multidisciplinary research, international partnerships, shared infrastructure	Number of multi-institutional projects; multidisciplinary publications; international collaborations; contribution statements (CRediT taxonomy); leadership of collaborative networks; long-term partnerships
4. Capacity Building	Mentorship, workforce development, laboratory strengthening, research infrastructure	Number of trainees successfully mentored; trainee career progression; training programs developed; laboratory accreditation achieved; surveillance systems strengthened; institutional research capacity established
5. Translation & Innovation	Technology development, implementation science, clinical or public health application	Research incorporated into clinical guidelines or public health policy; patents; diagnostic tools developed; software adopted; implementation of new interventions; technology transfer activities
6. Public Impact	Health improvement, policy influence, preparedness, societal benefit	Health outcomes improved; disease burden reduced; policy adoption; surveillance performance improved; healthcare quality enhanced; public trust initiatives; preparedness indicators; cost savings to health systems

Table 2. Proposed Balanced Scientific Impact Assessment Framework

Domain	Primary Evaluation Focus	Illustrative Relative Weight*
Scientific Quality	Rigor, reproducibility, methodological excellence	25%
Open Science	Data, software, protocols, transparency	15%
Collaboration & Team Science	Interdisciplinary and international partnerships	15%
Capacity Building	Mentorship, workforce development, infrastructure	15%
Translation & Innovation	Policy, clinical implementation, commercialization	15%
Public Impact	Health outcomes, preparedness, societal benefit	15%

The framework and indicators presented above provide a practical foundation for the recommendations discussed in the following sections. Each domain is explored in greater detail with suggested approaches for strengthening research evaluation and recognizing scientific contributions.

Introduction

The biomedical research landscape has changed dramatically over the past several decades. Scientific discovery has evolved from predominantly individual laboratory-based research into a highly collaborative, multidisciplinary, and globally connected enterprise. Advances in genomics, artificial intelligence, digital health, large-scale surveillance systems, and international research partnerships have transformed the way scientific knowledge is generated, validated, and translated into public health action. These changes have created new opportunities for accelerating biomedical discovery while also highlighting the need for research systems that prioritize scientific rigor, transparency, reproducibility, and collaboration.

Despite these advances, the methods used to evaluate scientific success have changed relatively little. Publications, citation counts, journal impact factors, and grant funding continue to serve as the primary indicators of scientific achievement. Although these metrics provide useful information regarding research productivity and scholarly influence, they often fail to capture many of the activities that are essential for advancing modern biomedical science. Contributions such as data sharing, development of research infrastructure, implementation of surveillance systems, mentorship, multidisciplinary

collaboration, capacity building, policy translation, and improvements in population health frequently receive limited recognition despite their substantial scientific and societal value.

The COVID-19 pandemic clearly demonstrated that impactful science extends far beyond scientific publications. Rapid international data sharing, open access to genomic sequences, collaborative research networks, coordinated laboratory systems, and transparent communication enabled the global scientific community to characterize a novel pathogen, develop diagnostic methods, evaluate interventions, and accelerate vaccine development within an unprecedented timeframe. These achievements were possible because researchers, public health institutions, governments, and international organizations worked together under principles of openness, collaboration, and shared scientific responsibility.

As biomedical research continues to evolve, evaluation systems should similarly evolve to recognize the broad range of contributions that advance scientific knowledge and improve public health. Measuring scientific impact should not only assess the generation of new discoveries but also the quality, reproducibility, accessibility, implementation, and real-world influence of those discoveries.

The following recommendations propose practical approaches that NIH may consider when developing future frameworks for measuring and rewarding scientific impact. These recommendations aim to complement traditional academic metrics by incorporating indicators that encourage rigorous, collaborative, transparent, and mission-driven biomedical research.

Section 1. Rigor and Reproducibility

Scientific rigor and reproducibility form the foundation of credible biomedical research. Regardless of scientific discipline or methodology, research findings should be sufficiently transparent and well documented to enable independent researchers to reproduce analyses, verify results, and build upon previous discoveries. Reproducibility not only strengthens confidence in scientific findings but also improves the efficiency of research investments by reducing unnecessary duplication, identifying methodological limitations, and accelerating cumulative scientific progress.

Current academic reward systems often prioritize the novelty of scientific findings over the quality and reproducibility of research methods. Consequently, researchers may receive greater recognition for publishing new discoveries than for validating existing findings, conducting replication studies, improving analytical methods, or producing high-quality datasets that support future research. Although replication studies and negative findings are essential components of the scientific process, they are frequently undervalued in traditional research assessment systems.

NIH has taken important steps through its Replication and Reproducibility Initiative to strengthen scientific integrity. Continued progress, however, will require evaluation

systems that actively recognize researchers who consistently demonstrate rigorous scientific practices throughout the research lifecycle.

Examples of activities that should receive greater recognition include:

- Publishing detailed study protocols and statistical analysis plans before data analysis.
- Making analytical code, algorithms, and computational workflows openly available whenever appropriate.
- Sharing de-identified research datasets and associated metadata in accordance with ethical and legal requirements.
- Conducting independent validation and replication studies.
- Reporting negative or inconclusive findings that contribute to scientific understanding and reduce publication bias.
- Using standardized reporting guidelines and internationally recognized research standards.
- Implementing transparent quality assurance and quality control procedures throughout data collection and analysis.
- Participating in collaborative efforts to reproduce important scientific findings across different populations and settings.

NIH may also consider incorporating measurable indicators of research rigor into funding and career evaluation processes. Examples include the availability of reproducible analytical workflows, documented data quality procedures, public access to research protocols, successful independent validation of findings, adherence to FAIR (Findable, Accessible, Interoperable, and Reusable) data principles, and demonstrated compliance with established reporting standards.

Importantly, promoting reproducibility should not be viewed as an administrative requirement but rather as an investment in scientific quality. Rewarding researchers who prioritize methodological excellence, transparency, and validation will strengthen public trust, improve the reliability of biomedical evidence, and increase the long-term value of publicly funded research. A research culture that values reproducibility equally with innovation will produce discoveries that are more robust, more transferable across populations, and more likely to generate lasting scientific and public health impact.

Section 2. Data, Software, and Model Sharing

The value of biomedical research extends well beyond scientific publications. Increasingly, the greatest impact of research is realized through the sharing of high-quality datasets, analytical methods, software, computational models, and research tools that enable other

investigators to validate findings, generate new hypotheses, and accelerate scientific discovery. Open and responsible sharing of scientific resources enhances transparency, improves reproducibility, reduces duplication of effort, and maximizes the return on public investment in research.

The COVID-19 pandemic clearly demonstrated the importance of rapid and transparent data sharing. International collaboration through surveillance networks, genomic databases, and open scientific platforms enabled researchers worldwide to monitor pathogen evolution, assess disease transmission, develop diagnostics, evaluate interventions, and accelerate vaccine development. These achievements highlighted that scientific progress depends not only on producing data, but also on making data accessible, interoperable, and reusable by the broader research community.

Despite these benefits, many researchers receive limited academic recognition for developing, curating, maintaining, and sharing valuable scientific datasets or software. Considerable effort is often required to establish surveillance systems, harmonize data standards, ensure data quality, document metadata, develop analytical tools, and maintain long-term databases. These contributions frequently require years of sustained investment but are rarely reflected in conventional measures of scientific productivity.

NIH should recognize data stewardship and scientific resource development as core research contributions. Investigators who make high-quality datasets, software packages, computational pipelines, and predictive models openly available should receive formal recognition comparable to traditional scholarly outputs. Such recognition would encourage broader participation in open science while improving the reproducibility and efficiency of biomedical research.

Future evaluation frameworks could include measurable indicators such as:

- Timely sharing of de-identified research data in accordance with ethical, legal, and regulatory requirements.
- Compliance with FAIR (Findable, Accessible, Interoperable, and Reusable) data principles.
- Development and maintenance of high-quality scientific databases, registries, surveillance systems, and biorepositories.
- Public availability of analytical software, statistical code, machine learning algorithms, and computational workflows.
- Documentation quality, metadata completeness, and standardized data dictionaries.
- Frequency of dataset reuse by independent investigators.
- Integration of shared datasets into national or international scientific platforms.
- Long-term sustainability and accessibility of shared scientific resources.

NIH should also encourage the citation of datasets, software, and digital research products as independent scholarly outputs. Standardized mechanisms for assigning persistent identifiers, such as Digital Object Identifiers (DOIs), can improve attribution and enable these contributions to be tracked and evaluated alongside traditional publications.

Importantly, data sharing should be implemented responsibly. Policies must continue to safeguard participant privacy, protect confidential information, respect national regulations, and recognize the rights of data-generating institutions and investigators. In particular, researchers working in low- and middle-income countries should receive appropriate authorship, acknowledgment, and opportunities for scientific leadership when their data contribute to international collaborative research.

By recognizing data, software, and model sharing as essential scientific outputs, NIH can foster a research culture that values openness, collaboration, transparency, and long-term scientific utility. Such an approach will accelerate biomedical discovery while strengthening public trust and maximizing the societal benefits of federally funded research.

Section 3. Training and Mentorship

The long-term success of biomedical research depends not only on scientific discoveries but also on the development of a skilled, diverse, and sustainable research workforce. Training and mentorship are fundamental investments that strengthen scientific capacity, promote innovation, improve research quality, and ensure the continuity of scientific excellence across generations. However, these contributions are often underrepresented in current systems used to evaluate scientific impact.

Effective mentorship extends beyond supervising research projects. High-quality mentors cultivate scientific integrity, critical thinking, leadership, collaboration, communication skills, and responsible research practices. They provide guidance that enables trainees to become independent investigators while fostering inclusive and supportive research environments. Similarly, structured training programs that enhance technical competencies, research methodology, data analysis, laboratory quality management, implementation science, and scientific writing contribute substantially to strengthening the biomedical research enterprise.

Current evaluation systems frequently recognize publications and grant income while giving comparatively little credit to sustained mentorship and workforce development. As a result, researchers who dedicate significant time to training early-career scientists, building institutional capacity, or strengthening research infrastructure may receive limited recognition despite their substantial long-term impact.

NIH should incorporate measurable indicators that recognize excellence in training and mentorship. Potential indicators include:

- Successful career progression of trainees into independent research or leadership positions.
- Contributions to multidisciplinary training programs and workforce development initiatives.
- Development of educational resources, curricula, and professional training materials.
- Mentorship of early-career investigators, particularly those from underrepresented or resource-limited settings.
- Establishment of sustainable institutional research capacity.
- Evidence of long-term mentoring relationships and continued professional development of trainees.
- Contributions to strengthening laboratory systems, surveillance capacity, research ethics, and implementation science.
- Recognition received from trainees, institutions, or professional organizations for mentoring excellence.

Importantly, evaluation should emphasize the quality and long-term outcomes of mentorship rather than simply the number of trainees supervised. A single mentor who successfully develops future scientific leaders may have a greater and more lasting impact than one who supervises many trainees without meaningful professional development.

Investment in mentorship also promotes scientific integrity and reproducibility. Experienced mentors play a critical role in teaching rigorous study design, ethical conduct of research, transparent reporting, responsible data management, and collaborative scientific practices. Strengthening these competencies early in researchers' careers contributes to a more reliable, trustworthy, and resilient biomedical research ecosystem.

Recognizing mentorship and workforce development as essential scientific contributions will encourage researchers to invest in future generations of scientists while strengthening global research capacity and ensuring the long-term sustainability of biomedical innovation.

Section 4. Collaboration

Biomedical research has become increasingly collaborative, interdisciplinary, and international. Addressing today's most pressing health challenges including emerging infectious diseases, antimicrobial resistance, pandemic preparedness, precision medicine, and chronic diseases requires expertise that extends far beyond any single investigator, institution, or scientific discipline. Successful research increasingly depends on effective collaboration among clinicians, epidemiologists, laboratory scientists, data scientists, statisticians, social scientists, engineers, public health practitioners, policymakers, and community stakeholders.

Despite this transformation, research evaluation systems continue to emphasize individual accomplishments, often relying heavily on first or senior authorship, principal investigator status, and individual grant awards. Such approaches may overlook the substantial scientific contributions made by investigators whose expertise is essential to collaborative research but whose roles are less visible in traditional academic metrics. Data managers, surveillance specialists, laboratory scientists, statisticians, software developers, implementation researchers, and project coordinators frequently make indispensable contributions that are difficult to quantify under current evaluation systems.

NIH should further strengthen mechanisms for recognizing meaningful contributions to team science. Evaluation should move beyond publication authorship alone and consider the quality, significance, and impact of each individual's contribution throughout the research process. Modern research benefits when multidisciplinary teams work together to design studies, generate high-quality data, develop analytical methods, interpret findings, and translate evidence into practice.

Potential indicators for recognizing collaborative research may include:

- Participation in multidisciplinary and multi-institutional research projects.
- Contributions to international scientific collaborations and research networks.
- Leadership or coordination of collaborative research initiatives.
- Development of shared research infrastructure, surveillance systems, or laboratory networks.
- Contributions to multicenter studies, implementation research, and consortium-based projects.
- Evidence of equitable partnerships that promote shared leadership and capacity strengthening.
- Collaborative development of standardized protocols, data standards, and quality assurance systems.
- Contributions to cross-disciplinary innovation that integrates complementary areas of expertise.

Evaluation systems should also recognize that impactful collaboration extends beyond academic institutions. Partnerships involving government agencies, public health organizations, healthcare providers, industry, community organizations, patient groups, and international partners often play a critical role in translating scientific discoveries into meaningful health outcomes. These collaborations strengthen the relevance, applicability, and sustainability of biomedical research while increasing its societal impact.

Importantly, collaborative research should be evaluated based on both scientific productivity and the effectiveness of the partnership itself. Indicators such as sustained

collaboration, equitable authorship practices, shared decision-making, successful knowledge exchange, and measurable improvements in research capacity may provide valuable insight into the long-term success of collaborative initiatives.

By rewarding meaningful collaboration, NIH can encourage researchers to build diverse scientific teams, share expertise across disciplines, reduce unnecessary duplication of effort, and accelerate the translation of scientific discoveries into improved health outcomes.

Section 5. Entrepreneurship and Translation

Scientific discovery achieves its greatest value when research findings are translated into interventions, technologies, policies, diagnostics, therapeutics, and public health practices that improve human health. While fundamental discovery remains essential, evaluation systems should also recognize the processes that move scientific knowledge beyond publication and into real-world application.

Translation is rarely a single event. It involves a continuum of activities including technology development, validation studies, implementation research, regulatory evaluation, commercialization, policy development, clinical adoption, and health system integration. Each stage requires substantial scientific expertise and often involves multidisciplinary collaboration across academia, healthcare, government, and industry. However, many of these activities receive relatively limited recognition within traditional academic evaluation frameworks.

NIH should broaden the definition of translational impact to encompass the full spectrum of activities that convert scientific knowledge into measurable public benefit. Successful translation should not be assessed solely by patents or commercial products but also by the adoption of evidence-based practices, improvements in healthcare delivery, strengthening of public health systems, and incorporation of research findings into national or international guidelines.

Potential indicators of translational impact include:

- Adoption of research findings into clinical practice guidelines or public health policies.
- Development and implementation of new diagnostic methods, surveillance tools, or healthcare technologies.
- Creation of software platforms, digital health applications, decision-support systems, or analytical tools used in healthcare settings.
- Commercialization of biomedical innovations that improve patient care.
- Establishment of public-private partnerships supporting technology development.

- Successful implementation of research findings within healthcare systems or public health programs.
- Demonstrated improvements in healthcare quality, efficiency, or accessibility resulting from research.
- Contribution of scientific evidence to regulatory decisions or national health strategies.

Entrepreneurship should likewise be recognized as an important component of biomedical innovation. Researchers who successfully transform scientific discoveries into scalable solutions frequently contribute to economic development, job creation, technology transfer, and improved healthcare delivery. These activities complement rather than compete with traditional academic research and should be evaluated within the broader context of NIH's mission to improve health.

Importantly, translational success should also include innovations that primarily benefit public health rather than commercial markets. Research that strengthens disease surveillance, enhances laboratory systems, improves outbreak detection, supports emergency preparedness, or informs health policy may generate substantial societal value even when no commercial product results.

Recognizing diverse pathways of translation will encourage researchers to pursue innovations that address unmet health needs while ensuring that publicly funded biomedical research delivers meaningful and measurable benefits to patients, healthcare systems, and society.

Section 6. Foundational Scientific Exploration

Foundational scientific research is the cornerstone of biomedical discovery. Many of the most significant advances in medicine including vaccines, molecular diagnostics, gene editing technologies, and immunotherapies originated from curiosity driven investigations whose practical applications were not immediately apparent. Likewise, high-risk, high-reward research often challenges existing paradigms, explores unconventional hypotheses, and generates transformative breakthroughs that reshape entire scientific fields.

Despite its importance, foundational research frequently faces challenges within current evaluation systems. Investigators are often encouraged to pursue projects with predictable outcomes and a high likelihood of producing publications and grant renewals within relatively short timeframes. This environment may unintentionally discourage innovative ideas that require longer periods of development, involve greater uncertainty, or have a higher probability of negative or inconclusive findings.

NIH has long recognized the importance of supporting innovative science through programs that encourage high-risk, high-reward research. Continued success will require evaluation

frameworks that acknowledge scientific ambition, creativity, and methodological excellence, even when research outcomes are uncertain.

Future evaluation systems should recognize contributions such as:

- Development of novel scientific hypotheses and conceptual frameworks.
- Creation of innovative research methodologies and experimental approaches.
- Exploration of emerging scientific fields with transformative potential.
- Long-term investment in foundational datasets, surveillance systems, and research infrastructure.
- Publication of well-designed negative or inconclusive findings that refine scientific understanding.
- Generation of resources that enable future scientific discoveries beyond the original research objectives.
- Development of interdisciplinary approaches that bridge multiple scientific domains.

Importantly, evaluation should distinguish between unsuccessful research resulting from poor scientific quality and well-designed research that produces unexpected, null, or negative findings. The latter represents an essential component of scientific progress and often prevents unnecessary duplication of effort while informing future investigations.

NIH may also consider rewarding researchers who contribute to long-term scientific infrastructure that benefits the broader research community. Establishing surveillance systems, longitudinal cohort studies, biobanks, reference laboratories, data repositories, and standardized methodologies often requires years of sustained investment before yielding substantial scientific outputs. These foundational resources support countless future investigations and should be recognized as enduring scientific contributions.

By valuing scientific curiosity, methodological innovation, and responsible exploration of challenging research questions, NIH can foster an environment that encourages bold ideas while maintaining the highest standards of scientific rigor and integrity.

Section 7. Public Impact

The ultimate purpose of biomedical research is to improve human health. While scientific publications remain an important means of disseminating knowledge, the true impact of research should also be measured by its contribution to improving health outcomes, informing policy, strengthening healthcare systems, enhancing preparedness, reducing disease burden, and increasing public trust in science.

Traditional academic metrics primarily measure scientific influence within the research community. Citation counts and publication metrics provide useful indicators of scholarly recognition but do not necessarily reflect whether research has improved clinical practice, informed health policy, strengthened disease surveillance, enhanced healthcare delivery, or benefited patients and communities.

NIH should incorporate broader measures of societal and public health impact into research evaluation. Recognizing these contributions would encourage investigators to pursue research that addresses important health challenges while promoting stronger connections between scientific discovery and real-world implementation.

Examples of measurable public impact may include:

- Adoption of research findings into national or international clinical guidelines and public health policies.
- Improvements in disease prevention, diagnosis, treatment, or patient outcomes resulting from research.
- Strengthening of laboratory systems, surveillance networks, and public health infrastructure.
- Contributions to emergency preparedness and response for emerging infectious diseases and other public health threats.
- Development of evidence that informs vaccination strategies, screening programs, or disease control interventions.
- Improvements in healthcare accessibility, quality, efficiency, or equity.
- Increased public confidence in science through transparent communication and responsible dissemination of research findings.
- Demonstrated societal, economic, or health system benefits attributable to scientific research.

Evaluation should also recognize that public impact often requires sustained engagement with policymakers, healthcare providers, public health authorities, patients, and communities. Activities such as knowledge translation, implementation science, public communication, and evidence-informed policymaking play essential roles in ensuring that scientific discoveries generate meaningful societal benefits.

Importantly, the impact of research should be assessed over appropriate timeframes. Some scientific discoveries produce immediate benefits, while others may influence healthcare practice or public policy years after publication. Flexible evaluation frameworks that recognize both short-term implementation and long-term societal contributions will provide a more comprehensive assessment of scientific value.

Ultimately, scientific success should be measured not only by the number of publications produced, but by the extent to which research improves lives, strengthens health systems, advances equity, informs decision-making, and contributes to healthier and more resilient societies.

Section 8. Other Areas: Toward a Balanced Framework for Measuring Scientific Impact

As biomedical research continues to evolve, evaluation systems should similarly evolve toward a more comprehensive and balanced approach to recognizing scientific contributions. Rather than relying predominantly on individual publication-based metrics, future assessment frameworks should incorporate multiple complementary dimensions that collectively reflect the diverse ways researchers contribute to scientific advancement.

A balanced evaluation framework should recognize excellence across the following domains:

- **Scientific Quality:** rigorous study design, reproducibility, methodological transparency, and high-quality publications.
- **Open Science:** responsible sharing of data, software, analytical methods, and research resources.
- **Collaboration:** meaningful contributions to multidisciplinary, multi-institutional, and international team science.
- **Capacity Building:** mentorship, workforce development, laboratory strengthening, and research infrastructure.
- **Innovation and Translation:** development of new technologies, implementation of research findings, and translation into clinical or public health practice.
- **Public Impact:** measurable improvements in health outcomes, policy development, preparedness, healthcare delivery, and societal benefit.

These domains should be viewed as complementary rather than competing measures of scientific excellence. Different disciplines, institutions, and career stages contribute to biomedical research in diverse ways, and evaluation systems should provide sufficient flexibility to recognize these differences while maintaining consistent standards of quality and accountability.

Importantly, no single metric can adequately capture scientific impact. Overreliance on publication counts or citation-based indicators may unintentionally discourage collaboration, open science, mentorship, implementation research, and other activities that generate substantial long-term value. A multidimensional evaluation framework would better align incentives with NIH's mission of generating knowledge that enhances health, lengthens life, and reduces illness and disability.

By recognizing a broader range of scientific contributions, NIH can strengthen research integrity, encourage collaboration, promote innovation, improve reproducibility, and maximize the public benefit derived from biomedical research investments.

Considerations

The recommendations presented in this document are intended to provide general principles for strengthening research evaluation across diverse biomedical disciplines. The relative importance of individual indicators will vary according to research field, career stage, institutional mission, and funding mechanism. Accordingly, a flexible and context-specific implementation approach will be essential.

Conclusion

Biomedical research has entered an era characterized by unprecedented collaboration, technological innovation, data generation, and global scientific connectivity. While traditional measures of research productivity remain valuable, they should be complemented by evaluation approaches that more accurately reflect the diverse activities required to generate trustworthy scientific knowledge and translate discoveries into meaningful improvements in health.

The recommendations presented in this response are intended to support NIH's ongoing efforts to strengthen rigor, reproducibility, transparency, collaboration, and public trust in biomedical research. Expanding evaluation frameworks to recognize data sharing, team science, mentorship, implementation, innovation, and public health impact will encourage behaviors that improve both the quality and the societal value of scientific research.

Ultimately, the success of biomedical research should be measured not solely by the number of publications produced, but by the quality, reproducibility, accessibility, implementation, and lasting impact of scientific knowledge. A more balanced and inclusive approach to research assessment will better recognize the full spectrum of contributions that advance discovery, improve health, and strengthen the global biomedical research enterprise.

95. JP Flores

I am responding: On behalf of myself

Name: JP Flores

Name of Organization: Case Western Reserve University

Type of Organization: Academic Institution

Role: Research Trainee/Fellow

Date Submitted: 7/16/2026

1. Rigor and Reproducibility: Scientific rigor should be recognized as a primary research output rather than a compliance requirement. While biomedical research has traditionally rewarded novelty, equally important activities, including replication studies, validation experiments, publication of negative or null findings, benchmarking analyses, and methodological refinement, remain undervalued despite their essential role in building a trustworthy scientific literature.

NIH should develop measurable indicators that recognize contributions to reproducibility, including publication of independent replication studies, release of reproducible computational workflows, transparent reporting of methods and quality-control metrics, reanalysis of publicly available datasets, and development of benchmark datasets or community standards. Well-designed studies that produce negative or null results should be recognized as valuable scientific contributions because they prevent unnecessary duplication, refine biological hypotheses, and improve future experimental design.

To further incentivize rigorous science, NIH should consider dedicated funding mechanisms for replication studies, administrative supplements to validate influential findings, and grant review criteria that explicitly reward reproducibility efforts. Expectations should remain flexible across disciplines and career stages while recognizing that rigorous science is an ongoing process of refining knowledge rather than simply producing novel discoveries.

2. Data, Software, and Model Sharing: Data, software, computational workflows, and predictive models have become foundational products of modern biomedical research. Yet these resources often receive substantially less recognition than traditional publications despite enabling thousands of downstream discoveries.

NIH should explicitly recognize open-source software, databases, computational workflows, interoperable standards, and publicly accessible datasets as primary scholarly outputs. Indicators of impact should include software adoption, community contributions, dataset reuse, workflow implementation, API usage, long-term maintenance, and compliance with FAIR (Findable, Accessible, Interoperable, Reusable) data principles rather than publication citations alone.

Importantly, NIH should establish dedicated funding mechanisms to support the development, maintenance, and long-term sustainability of open-source scientific software and infrastructure. Many of

the most widely used computational tools in biomedical research are developed and maintained by small research groups with limited long-term support despite serving thousands of investigators worldwide. Sustaining these resources should be recognized as a valuable scientific contribution, not merely technical service.

3. Training and Mentorship: The future strength of the biomedical research enterprise depends not only on producing excellent science but also on preparing scientists for the increasingly diverse roles they play in society. Modern scientists serve as mentors, educators, communicators, entrepreneurs, software developers, policy advisors, and community partners in addition to conducting research.

NIH should broaden how mentorship and training are evaluated by recognizing contributions that prepare trainees for this evolving landscape. Potential indicators include trainee career outcomes across academia, industry, government, education, policy, entrepreneurship, nonprofit organizations, and clinical practice; evidence-based mentoring practices; trainee independence; structured mentorship programs; and mentoring climate.

Training programs should also incentivize skills that are increasingly essential to modern science but are often treated as optional. These include science communication, science policy, community engagement, entrepreneurship, open science practices, data stewardship, peer review, and interdisciplinary collaboration. Investigators who train students in transparent scientific practices, including preprinting, reproducible computational workflows, responsible data sharing, accessible communication, and constructive peer review, should receive formal recognition for these contributions.

Scientific excellence should include preparing the next generation of scientists not only to conduct outstanding research but also to effectively communicate, translate, and steward that research for the benefit of society.

4. Collaboration: Biomedical research increasingly relies on interdisciplinary teams that span institutions, sectors, and scientific disciplines. However, many evaluation systems continue to emphasize individual accomplishments rather than collaborative contributions.

NIH should recognize meaningful contributions to team science regardless of publication authorship position by considering leadership of collaborative projects, development of shared infrastructure, multi-investigator grants, co-mentorship, community resource development, and documented contributions through narrative team science statements or contributor role taxonomies.

In addition, NIH should expand funding mechanisms that intentionally build scientific capacity through collaborations with Minority Serving Institutions (MSIs), Historically Black Colleges and Universities (HBCUs), Tribal Colleges and Universities (TCUs), community colleges, primarily undergraduate institutions, and emerging research institutions. These partnerships should be structured as reciprocal scientific collaborations that build long-term research capacity rather than short-term subcontracting arrangements.

Such investments would not only strengthen scientific discovery but also broaden participation in biomedical research while expanding research capacity throughout the United States.

5. Entrepreneurship and Translation: Translation should be viewed as a bidirectional process rather than a one-way pathway from bench to bedside. Basic scientists should have greater opportunities to move discoveries toward clinical implementation, while clinicians, patients, engineers, public health practitioners, policymakers, and industry partners should have meaningful opportunities to inform fundamental biological discovery.

NIH should recognize diverse forms of translation, including clinical implementation, public health impact, policy translation, development of diagnostics and research tools, open-source technologies, nonprofit partnerships, educational innovations, and commercialization where appropriate.

Expanding funding mechanisms that intentionally connect basic science laboratories with clinicians, public health practitioners, patient organizations, entrepreneurs, and industry partners would strengthen the entire translational ecosystem. These partnerships should be viewed as complementary approaches for maximizing the public benefit of biomedical research rather than competing models of scientific impact.

6. Foundational Scientific Exploration: Many of the most transformative advances in biomedical research emerge from high-risk, high-reward investigations that require sustained investment and may not produce immediate publications or translational outcomes. Current incentive structures often favor predictable projects with short-term deliverables over ambitious questions capable of fundamentally changing scientific understanding.

NIH should continue expanding support for foundational scientific exploration by recognizing long-term infrastructure development, technology innovation, biological resource generation, atlas-building efforts, methodological advances, and exploratory research that creates new scientific directions.

Review criteria should emphasize scientific significance, originality, and long-term potential rather than short-term publication metrics alone. Investigators should not be penalized for pursuing ambitious projects whose greatest impacts may emerge years after the initial funding period.

7. Public Impact: The ultimate purpose of biomedical research is to improve human health and benefit society. Accordingly, public impact should become a core dimension of scientific excellence.

Public impact should extend beyond counting outreach activities or media appearances. Instead, NIH should recognize sustained, reciprocal relationships between scientists and the communities they serve.

Potential indicators include long-term partnerships with patient advocacy organizations, community advisory boards, collaborations with K-12 schools and community colleges, publicly accessible educational resources, contributions to evidence-informed policymaking, citizen science initiatives, implementation of research findings into clinical practice or public health, and measurable efforts to strengthen public trust in science.

NIH should also recognize contributions that improve the accessibility and transparency of science itself, including open educational resources, accessible software, publicly available datasets, preprints, transparent communication of findings, and efforts to make biomedical knowledge broadly

understandable and reusable.

The goal should not simply be increasing public awareness of science but strengthening enduring relationships between scientific institutions and the communities they exist to serve.

8. Other Areas: One area deserving additional consideration is modernization of scientific publishing itself. The current publication system remains one of the strongest drivers of scientific incentives, yet many activities essential to scientific quality remain largely invisible during evaluation.

NIH has an opportunity to encourage a transition toward more open, transparent, and efficient models of scientific communication by explicitly recognizing preprints, open peer review, and emerging Publish, Review, Curate (PRC) models. These approaches separate dissemination, evaluation, and curation into distinct scholarly activities, allowing discoveries to become immediately accessible while expert review and long-term curation continue transparently.

NIH should consider allowing investigators to document preprints, citable peer reviews, open review activities, and community curation efforts as evidence of scholarly impact. Likewise, reviewer contributions, editorial leadership, and development of community standards should be recognized as meaningful scientific outputs rather than invisible service activities.

Finally, NIH should consider adopting a broader Scientific Impact Portfolio that complements traditional publication metrics. Such a portfolio would allow investigators to document contributions across scientific discovery, reproducibility, software and data infrastructure, mentorship, collaboration, translation, public engagement, scientific citizenship, and open science. This approach would better reflect the collaborative, interdisciplinary, and mission-driven nature of modern biomedical research while creating incentives that strengthen the scientific enterprise as a whole rather than rewarding only individual productivity.

Description: Word document version of my responses

Response to NIH Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Rigor and Reproducibility

Scientific rigor should be recognized as a primary research output rather than a compliance requirement. While biomedical research has traditionally rewarded novelty, equally important activities, including replication studies, validation experiments, publication of negative or null findings, benchmarking analyses, and methodological refinement, remain undervalued despite their essential role in building a trustworthy scientific literature.

NIH should develop measurable indicators that recognize contributions to reproducibility, including publication of independent replication studies, release of reproducible computational workflows, transparent reporting of methods and quality-control metrics, reanalysis of publicly available datasets, and development of benchmark datasets or community standards. Well-designed studies that produce negative or null results should be recognized as valuable scientific contributions because they prevent unnecessary duplication, refine biological hypotheses, and improve future experimental design.

To further incentivize rigorous science, NIH should consider dedicated funding mechanisms for replication studies, administrative supplements to validate influential findings, and grant review criteria that explicitly reward reproducibility efforts. Expectations should remain flexible across disciplines and career stages while recognizing that rigorous science is an ongoing process of refining knowledge rather than simply producing novel discoveries.

Data, Software, and Model Sharing

Data, software, computational workflows, and predictive models have become foundational products of modern biomedical research. Yet these resources often receive substantially less recognition than traditional publications despite enabling thousands of downstream discoveries.

NIH should explicitly recognize open-source software, databases, computational workflows, interoperable standards, and publicly accessible datasets as primary scholarly outputs. Indicators of impact should include software adoption, community contributions, dataset reuse, workflow implementation, API usage, long-term maintenance, and compliance with FAIR (Findable, Accessible, Interoperable, Reusable) data principles rather than publication citations alone.

Importantly, NIH should establish dedicated funding mechanisms to support the development, maintenance, and long-term sustainability of open-source scientific software and infrastructure. Many of the most widely used computational tools in biomedical research are developed and maintained by small research groups with

limited long-term support despite serving thousands of investigators worldwide. Sustaining these resources should be recognized as a valuable scientific contribution, not merely technical service.

Training and Mentorship

The future strength of the biomedical research enterprise depends not only on producing excellent science but also on preparing scientists for the increasingly diverse roles they play in society. Modern scientists serve as mentors, educators, communicators, entrepreneurs, software developers, policy advisors, and community partners in addition to conducting research.

NIH should broaden how mentorship and training are evaluated by recognizing contributions that prepare trainees for this evolving landscape. Potential indicators include trainee career outcomes across academia, industry, government, education, policy, entrepreneurship, nonprofit organizations, and clinical practice; evidence-based mentoring practices; trainee independence; structured mentorship programs; and mentoring climate.

Training programs should also incentivize skills that are increasingly essential to modern science but are often treated as optional. These include science communication, science policy, community engagement, entrepreneurship, open science practices, data stewardship, peer review, and interdisciplinary collaboration. Investigators who train students in transparent scientific practices, including preprinting, reproducible computational workflows, responsible data sharing, accessible communication, and constructive peer review, should receive formal recognition for these contributions.

Scientific excellence should include preparing the next generation of scientists not only to conduct outstanding research but also to effectively communicate, translate, and steward that research for the benefit of society.

Collaboration

Biomedical research increasingly relies on interdisciplinary teams that span institutions, sectors, and scientific disciplines. However, many evaluation systems continue to emphasize individual accomplishments rather than collaborative contributions.

NIH should recognize meaningful contributions to team science regardless of publication authorship position by considering leadership of collaborative projects, development of shared infrastructure, multi-investigator grants, co-mentorship, community resource development, and documented contributions through narrative team science statements or contributor role taxonomies.

In addition, NIH should expand funding mechanisms that intentionally build scientific capacity through collaborations with Minority Serving Institutions (MSIs), Historically

Black Colleges and Universities (HBCUs), Tribal Colleges and Universities (TCUs), community colleges, primarily undergraduate institutions, and emerging research institutions. These partnerships should be structured as reciprocal scientific collaborations that build long-term research capacity rather than short-term subcontracting arrangements.

Such investments would not only strengthen scientific discovery but also broaden participation in biomedical research while expanding research capacity throughout the United States.

Entrepreneurship and Translation

Translation should be viewed as a bidirectional process rather than a one-way pathway from bench to bedside. Basic scientists should have greater opportunities to move discoveries toward clinical implementation, while clinicians, patients, engineers, public health practitioners, policymakers, and industry partners should have meaningful opportunities to inform fundamental biological discovery.

NIH should recognize diverse forms of translation, including clinical implementation, public health impact, policy translation, development of diagnostics and research tools, open-source technologies, nonprofit partnerships, educational innovations, and commercialization where appropriate.

Expanding funding mechanisms that intentionally connect basic science laboratories with clinicians, public health practitioners, patient organizations, entrepreneurs, and industry partners would strengthen the entire translational ecosystem. These partnerships should be viewed as complementary approaches for maximizing the public benefit of biomedical research rather than competing models of scientific impact.

Foundational Scientific Exploration

Many of the most transformative advances in biomedical research emerge from high-risk, high-reward investigations that require sustained investment and may not produce immediate publications or translational outcomes. Current incentive structures often favor predictable projects with short-term deliverables over ambitious questions capable of fundamentally changing scientific understanding.

NIH should continue expanding support for foundational scientific exploration by recognizing long-term infrastructure development, technology innovation, biological resource generation, atlas-building efforts, methodological advances, and exploratory research that creates new scientific directions.

Review criteria should emphasize scientific significance, originality, and long-term potential rather than short-term publication metrics alone. Investigators should not be penalized for pursuing ambitious projects whose greatest impacts may emerge years after the initial funding period.

Public Impact

The ultimate purpose of biomedical research is to improve human health and benefit society. Accordingly, public impact should become a core dimension of scientific excellence.

Public impact should extend beyond counting outreach activities or media appearances. Instead, NIH should recognize sustained, reciprocal relationships between scientists and the communities they serve.

Potential indicators include long-term partnerships with patient advocacy organizations, community advisory boards, collaborations with K-12 schools and community colleges, publicly accessible educational resources, contributions to evidence-informed policymaking, citizen science initiatives, implementation of research findings into clinical practice or public health, and measurable efforts to strengthen public trust in science.

NIH should also recognize contributions that improve the accessibility and transparency of science itself, including open educational resources, accessible software, publicly available datasets, preprints, transparent communication of findings, and efforts to make biomedical knowledge broadly understandable and reusable.

The goal should not simply be increasing public awareness of science but strengthening enduring relationships between scientific institutions and the communities they exist to serve.

Other Areas

One area deserving additional consideration is modernization of scientific publishing itself. The current publication system remains one of the strongest drivers of scientific incentives, yet many activities essential to scientific quality remain largely invisible during evaluation.

NIH has an opportunity to encourage a transition toward more open, transparent, and efficient models of scientific communication by explicitly recognizing preprints, open peer review, and emerging Publish, Review, Curate (PRC) models. These approaches separate dissemination, evaluation, and curation into distinct scholarly activities, allowing discoveries to become immediately accessible while expert review and long-term curation continue transparently.

NIH should consider allowing investigators to document preprints, citable peer reviews, open review activities, and community curation efforts as evidence of scholarly impact. Likewise, reviewer contributions, editorial leadership, and development of community standards should be recognized as meaningful scientific outputs rather than invisible service activities.

Finally, NIH should consider adopting a broader Scientific Impact Portfolio that complements traditional publication metrics. Such a portfolio would allow investigators to document contributions across scientific discovery, reproducibility, software and data infrastructure, mentorship, collaboration, translation, public engagement, scientific citizenship, and open science. This approach would better reflect the collaborative, interdisciplinary, and mission-driven nature of modern biomedical research while creating incentives that strengthen the scientific enterprise as a whole rather than rewarding only individual productivity.

Sincerely,

JP Flores, PhD

1. Rigor and Reproducibility: The requires a culture change that unfortunately is an uphill battle. From my experience, "rigor" is not well defined as a concept and as a result instead gets wielded as a weapon to tank proposals rather than as a guide for reproducible research. For a reviewer on an NIH panel, rigor can mean sticking to analysis conventions in the field or it can mean thoughtfully considering alternative hypotheses. I think there needs to be a review of what "rigor" actually means for scientists and a way to separate superficial methods of analysis or data presentation from substantive critiques of lack of consideration of alternative hypotheses or flaws in experimental design. Then we can move onto reproducibility.

For the rigor problem, this should involve a core definition of "rigor" and what this means to science. They, very importantly, this requires active monitoring from NIH staff when critiques of rigor are inappropriately applied.

Next for reproducibility, this first requires a standardization of methods reporting in publications. Next, financial incentives for other groups to reproduce or refute findings from a previous study. This would be as simple as an RFA that specifically requests reproducibility studies or a dedicated NIH internal laboratory.

2. Data, Software, and Model Sharing: This is easy as well, just make complete accessibility of all datasets a requirement of all NIH grants. Start canceling grants that do not comply. To be honest, I think this has not been happening not due to fraud but because it takes work.

3. Training and Mentorship: I would contend that T-training programs are not a good use of money. They are commonly given to well-funded institutions and are sort of an afterthought for most investigators, rather a conduit to fund a student instead of a mechanism for training. Most training occurs in the 1:1 relationship between mentor/mentee. So, start rewarding good individual mentors. Look for track records of successful students, relative to the funding a mentor has received. Surveying trainees are also a critical piece in here. Beyond the scope of the NIH, but we need to, as a scientific community, start rewarding effective mentorship and shaming poor mentorship.

4. Collaboration: I think this is already relatively well done, especially if the scientists lead the endeavors. I think the only minor concern is the "silent" collaborator, one who is an important name but doesn't

actually contribute to the research. If this is seen in yearly progress reports, I think removing them from the grant is a good option.

5. Entrepreneurship and Translation: I think this is honestly outside the NIH purview. I think the NIH needs more programs collaborating with industry to move translation.

6. Foundational Scientific Exploration: This is probably the area with the most room for growth and is fundamentally a problem of the broken peer-review system, which inherently prioritizes middle-of-the-road, moderate impact science. This is due to the 3 reviewer paradigm, where if one reviewer doesn't understand or believe in a high-risk idea, the project is doomed, even if the other two are enthusiastic. I have seen this first-hand dozens of time, both in my grants and others, where a flimsy "rigor" critique bleeds into the factor 1 score and ruins the grant. This is where the SROs need to have more autonomy to push back on reviews that mis-categorize their review critiques. Additionally, there is also a problem with well-funded institutes getting a passive benefit of the doubt and an inherently lower bar for rigor due to the reputation of the institution or investigator. This is a tricky problem, as it is more likely that a well established PI will have access to more resources and will get some productive science out of it. So in a sense, this bias is justified, but also leads to the same institutions with the same mindsets getting the majority of the funding, which can lead to a lack of new ideas and perspectives.

My suggestions on how to fix:
1. Make an initial letter of intent round to only focus on the innovative idea rather than "rigor".
2. Make this initial stage double blind to remove bias, only focus on the ideas
3. Allow applicants to review the reviewers on their review to get more feedback and train or drop poor performing reviewers. This needs to be done very carefully and considered in context with reviewer scores of applicants.
4. If possible, allow for "outlier" scores to be dropped
5. More high-risk/high reward funding proposals. We also need to drop the idea that all funding proposals requires (either implicitly or explicitly) preliminary data. It is an open secret that R21 actually require some preliminary data in order to be funded.

7. Public Impact: This is a hard one too. This is inherently against the headwinds of our poor political climate, which public support for biomedical research. I think framing the NIH as responsible for tax dollars and being open about how the money is spent is important. I think public access to all financial data and I would argue even peer review records would be helpful. If scientists want public funding, all their research efforts are then open to public scrutiny. I personally think that public shaming of bad actors in the biomedical research world is an underused strategy that could improve public trust.

8. Other Areas: I hate the funding application limit of 6 per year. This needs to be updated to factor in number of proposals currently supported. If a PI (like me) is set to completely run out of money, there needs to be a consideration of that and an increase in the limit.

Description: Consequences of poor definitation of rigor, institutional biases are driving poor peer review results leading to some stagnation and lack of public trust

8. Other Areas: As an Early Stage Investigator, I appreciate NIH's efforts to improve application quality and review efficiency. However, a fixed limit on the number of proposals per year (6 applications annually) may have unintended consequences for ESIs. Early investigators often require multiple funding attempts while establishing independent research programs, generating preliminary data, and developing grantsmanship skills. Unlike established investigators, ESIs generally have fewer alternative funding sources and smaller research infrastructures. Restricting the number of applications may therefore reduce innovation and slow the development of the next generation of NIH-funded investigators. I encourage NIH to consider exempting ESIs from the application cap or adopting a higher limit specifically for ESIs. Alternatively, NIH could exempt ESI-specific funding mechanisms (e.g., DP2, R21 Trailblazer, MIRA ESI, and R16 SuRE-First) from the proposal cap, as these programs are specifically intended to support early-career investigators.

7. Public Impact: N/A

8. Other Areas: All NIH institutes and centers need to converge into a computable NIH ecosystem so that terminology, knowledge, services, and information is machine readable and executable across all organizational boundaries.

The NLM's regional medical libraries need to move to FHIR APIs at scale so that the NLM's regional network can provide education, assistance, and utilize terminology services which would allow healthcare organizations to adopt rxnorm, LOINC, SNOMED CT, and FHIR at scale, and other interoperability standards (including the NIH related standards such as GA4GH, OMOP, HPO, Orphanet) at scale. This will scale EBM on FHIR, Vulcan, between the academic, research, and clinical communities.

1. Rigor and Reproducibility: AI use disclosure: Apple Intelligence "Writing Tools" used to proofread the document's word and character count and tighten the prose.

Across the domains, a single theme recurs: as artificial intelligence (AI) tools enter both the conduct of research and the training of researchers, the indicators NIH uses to measure success should reward verifiable, well-documented, reproducible contributions and the human competencies that produce them, rather than raw output. The recommendations below emphasize measurable indicators, implementation feasibility, and the unintended consequences worth anticipating.

Reproducibility is foundational to rigor, and AI tools cut both ways. Used well, they can make analyses more reproducible through their scripts, documented pipelines, and structured artifacts that can be re-run. Used uncritically, they introduce new and distinctive failure modes that undermine reproducibility with fabricated citations, hallucinated findings presented fluently, silent dependence on training data that may not match the study population, and outputs that vary with imperceptible changes in prompting. New incentives and infrastructure for replication should therefore explicitly account for AI-assisted work.

Recommended measurable indicators:
1. Documented verification of AI-assisted outputs
Where AI tools contribute to analysis, code, or synthesis, reward documented evidence that the output was independently verified i.e. citations checked against primary sources, analyses independently reproduced, generated code validated against known inputs. Absence of this is itself informative. Something as benign as Apple Intelligence's "Writing Tools" used to reshape a manuscript to bring it within a word limit needs to be verified and disclosed as being done as such. The discipline of verification is a reproducibility skill one must hone in an AI-assisted workflow.
2. Reproducibility of the artifact, not just the result
Research utilizing the artifacts must disclose the artifact unless documentation of proprietary use. NIH must favor research products that are sent with the means to reproduce them including the data, code, environment, and a clear account of any AI assistance. A reproducible analysis script tied to its data and a figure traceable to its source values are assessable, re-runnable units of rigor.
3. Replication and validation studies as rewarded outputs
Replication and validation are currently under-incentivized relative to novel findings. Recognizing them

as fundable, creditable contributions (including validation of AI-based tools and models across populations and settings) addresses the distribution-shift failure mode that makes many AI findings non-reproducible across sites.
4. Transparent AI-use disclosure tied to the record
Disclosure of which tool was used, by whom, when, for what purpose, and how the output was verified should travel with the research product. This is a low-cost indicator that supports auditing and reproduction and aligns with existing publisher and funder norms.

Tool evolution lag
There is a structural mismatch between the pace of AI development and the timelines of biomedical publishing and policy. The interval between submission and publication of a paper, with the longer interval over which a funding policy stays in force, is measured in months to years, while the capabilities, failure modes, and even the identities of widely used AI tools change on a far shorter cycle i.e days to weeks. A specific tool named in a paper, a specific model behavior described in a methods section, or a specific prohibition written into a policy can be out of date before the work reaches its audience. This has two consequences for how NIH should frame reproducibility indicators:
1. Appraise the verification process, not the named tool
Because the tools change faster than the literature that describes them, durable indicators should reward the generalizable competency i.e. did the researcher critically appraise and verify the AI output, document the basis for trusting it, and check whether it transfers to their setting, rather than endorsing or prohibiting particular named products that will be superseded. The appraisal skills are stable across tool generations but the tools are not.
2. Specify behavior and intent, not brand
Disclosure and policy language should describe the function and the verification expected (“a generative model was used to draft X and all output was verified against primary sources”) rather than freezing a brand name or version into a permanent record, so that the requirement remains meaningful as the underlying technology turns over.
3. Build in periodic re-evaluation
Any standard that touches AI should carry an explicit re-evaluation cadence (a 6-to-12-month cycle is a reasonable starting point, but as tools evolve, that may need to occur on a much shorter timeline) so that indicators and guidance are refreshed as tools evolve, rather than ossifying around a single moment in the technology’s development.

Implementation Feasibility
Verification records, disclosure statements, and reproducibility packages (data plus code plus environment) reuse practices that rigorous labs already follow; the change is making them an explicit, rewarded part of how success is measured. Re-evaluation cadences are administratively light (a scheduled review rather than new infrastructure). The heaviest lift is cultural: shifting credit from volume of output toward verifiable, reproducible, well-documented contribution.

Unintended consequences to anticipate
1. Verification documentation can become a box-checking ritual; spot-checking a sample of verification records, rather than trusting attestation alone, preserves its meaning.
2. Over-specifying reproducibility packaging may disadvantage fields where data cannot be shared (for

example, work involving protected health information); requirements should be calibrated to what each discipline can feasibly and ethically share.
3. A prohibition-based stance toward specific AI tools will age poorly and may push use underground; a verification- and disclosure-based stance is more durable and more honest about how research is now done.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: NIH notes that advancing its mission requires a stable, growing biomedical workforce and that additional indicators are needed to assess the impact of training and mentorship. We suggest that, in the current moment, a defensible indicator set must account for how AI tools are reshaping what trainees learn to do and what they may fail to learn. The risk is not hypothetical: when AI assistance is available for literature synthesis, drafting, coding, and analysis, trainees can produce competent-looking output without developing the underlying competence. We have found it useful to distinguish de-skilling (erosion of an established skill in an experienced researcher) from never-skilling (failure to develop a foundational skill in the first place, because a tool supplied the answer before the trainee built the capacity). Training metrics that count only outputs are blind to this distinction.

Recommended measurable indicators
1. Competency attainment, not output counts
Track demonstrated research competencies attained per trainee against a defined framework (for example, study design, data management, statistical reasoning, responsible conduct, and critical appraisal of AI-assisted outputs), assessed through mentored observation rather than publication or citation tallies. Competency frameworks already exist or are emerging across disciplines and can be adapted; the measurable unit is the verified competency, not the paper.
2. AI-literacy as an explicit, assessed competency
Add critical appraisal of AI tools such as recognition of fabricated citations, hallucinated findings, training-data drift, and distribution shift, to required training, and assess it directly. A trainee who can identify why an AI-generated reference is fabricated, or when a model's performance will not transfer to a new population, is demonstrating a reproducibility-relevant skill that should be recognized.
3. Verification discipline as a trackable behavior
Where AI assistance is used in trainee work, the verification step (independent reproduction of an analysis, source-checking of every AI-suggested citation, validation of AI-generated code against known inputs) is itself the teachable, assessable competency. Programs can record whether verification was performed and documented, giving NIH a process indicator that is feasible to collect and directly tied to research integrity.
4. Mentorship effort made visible
Protected mentorship time is supported by existing policy but is under-measured. A simple, feasible indicator is documented mentored-effort hours per trainee (the actual effort in hours a mentor devotes to a trainee's development) captured through the same effort-reporting infrastructure institutions already maintain. This converts an invisible contribution into a quantity NIH can assess, and it rewards mentors whose value does not show up in their own publication record.

Implementation and feasibility
Effort-based and competency-based indicators are feasible because they reuse infrastructure institutions

already operate: effort certification systems, milestone and evaluation records, and individual development plans. The marginal cost is structuring these records so that mentored effort and competency attainment can be summarized, not inventing a new reporting system. Structured, auditable records of mentored effort and competency milestones can be maintained in standard project-tracking tools and exported for reporting; the discipline is consistency of entry, not new technology.

Unintended consequences to anticipate
1. Any competency checklist can be gamed if attainment is self-attested without verification; mentored observation or work-product review should anchor the assessment.
2. Counting mentored hours could incentivize quantity of contact over quality; pairing the hours indicator with trainee-outcome and competency measures mitigates this.
3. Mandating AI-literacy training without supplying current teaching material risks the training aging faster than it can be delivered (see Tool Evolution Lag in Rigor and Reproducibility)

4. Collaboration: NIH seeks new approaches for assessing and recognizing contributions to team-based science as research grows more interdisciplinary. The dominant current metrics of authorship position and citation counts capture team contribution poorly and are especially ill-suited to the kinds of contribution that make team science reproducible i.e. data stewardship, methods and software development, operational coordination, and the verification work that lets one team build on another's results. AI tools sharpen this problem, because a contributor can now generate a large volume of text or code quickly, and output volume is an even weaker proxy for contribution than it was before.

Recommended measurable indicators
1. Structured contribution taxonomies
Adopt and reward use of a structured contributor-role taxonomy (such as CRediT) so that data curation, software, methodology, validation, and project administration are recognized alongside writing. The measurable indicator is the presence and granularity of contribution statements, which NIH can request and assess. This directly surfaces the reproducibility-supporting roles that authorship order hides.
2. Recognition for shared, reusable research infrastructure
Credit the creation of shared resources the whole team and field reuse: documented datasets, validated analysis pipelines, reusable templates and schemas for data collection, and operational tooling. A practical indicator is documented adoption of a shared resource by other projects or teams, which rewards the contributor who built the thing everyone depends on rather than only the contributor who published first.
3. Verifiable, attributable artifacts over prose volume
As AI lowers the cost of producing prose, contribution is better assessed through discrete verifiable artifacts such as a validated dataset, a reproducible analysis script, a documented data-collection schema, a figure traceable to its source data, each attributable to a named contributor and independently checkable. These artifacts are more meaningful units of team contribution than word count and are inherently reproducibility-friendly because they can be re-run and re-checked.
4. Disclosure of AI assistance as a team norm
Recognize teams that maintain clear, consistent disclosure of where and how AI tools contributed to the work. Transparent disclosure is a marker of a well-governed collaboration and supports downstream reproducibility; its presence and consistency are assessable.

Implementation feasibility
CRediT and similar taxonomies are already in use at many journals and impose minimal burden. Crediting reusable infrastructure requires a lightweight way to register and cite resources (persistent identifiers for datasets, code, and protocols already exist). Attributing verifiable artifacts to contributors is feasible wherever version control or structured project records are kept, which is increasingly standard.

Unintended consequences to anticipate
1. Contribution taxonomies can be inflated (everyone credited for everything); periodic audit of a sample of contribution statements keeps them meaningful.
2. Rewarding reusable infrastructure could bias effort toward tool-building over discovery if over-weighted; it should complement, not replace, scientific-contribution measures.
3. Artifact-based credit favors fields and teams with mature data and code practices; NIH should calibrate expectations across disciplines and institution types so that less-resourced groups are not penalized.

1. Rigor and Reproducibility: Use of NIH $ to support replication of studies is not a valid use of taxpayer funds. The existing system already ensures rigorous and reproducible science is that which is advanced. If something isn't replicable it isn't pursued.

2. Data, Software, and Model Sharing: Excellent. NIH has already invested in data sharing policies. Funds should be included in grants to ensure compliance with FAIR standards.

3. Training and Mentorship: Short term metrics here are largely meaningless. The impact of a mentor is measured over many years if not actually decades and not subject to the vagaries or whims of any short term assessment
.

4. Collaboration: Abandon your plans to penalize investigators who have many shared grants. This is what your misguided notion of capping grants will do. Incentivize collaborative grants.

5. Entrepreneurship and Translation: This is a goal of all science. It is naive to think that one can predict what basic science will ultimately be translational. For example…. studying phage defense mechanisms…(not supported by NIH). Many examples of work funded that was not immediately apparently translational that ultimately was (reverse genetics of vsv being an example)

6. Foundational Scientific Exploration: Absolutely. This is why peer review with a lack of political interference is so critical. It's also why not wasting $ funding replication work is also important. What works gets picked up, and followed.

7. Public Impact: Remove political oversight. And invest in science communication regardless of whether that is politically uncomfortable. Science is the pursuit of truth.

Description: Response to NOT_OD_26_087

Responding to NOT-OD-26-087

Dear NIH Office of Science Policy,

With respect to neurobiology laboratories, specific, measurable indicators and incentives that reflect the collaborative, rigorous, and mission-driven laboratories in modern biomedical science should likely reflect the small N and iterative experimentation and exploration that results from this type of research. Metrics like pre-registration are not typically performed for this type of research, so creating a multi-point metric that measures the level of technical rigor should look differently for neurobiology labs compared to labs that use large datasets of human data.

However, technical rigor is not the same as scientific rigor. And a publication can be extremely technically rigorous, with every statistic listed and every virus catalogued, but the paper could be biased on where or how the experiment was focused and be missing the bigger picture of the biology. So how do we measure scientific judgement?

Here are a handful of things to think about:

1. Alternative hypotheses Testing Index

Was more than one plausible competing hypothesis experimentally addressed? Here are examples: were multiple brain regions shown after tract tracing and did the author give a reason grounded in the evidence and/or literature for following up on the one chosen? Were neighboring or connected structures tested? Were collateral projections tested? Were multiple cell types tested or surveyed? Off-target behavioral pharmacology ruled out? And especially for pain research, when the sensory system is tested, were motivational-affective versus motor effects isolated?

2. Biological Fidelity Index

The NIH has traditionally emphasized hypothesis-driven work, but major advances have come from exploratory or discovery-driven research. Informative datasets like spatial transcriptomic projection mapping, longitudinal calcium imaging across disease progression, along with mechanism testing would make a robust biological fidelity index. Other elements could be is anatomical axis (e.g. rostrocaudal axis) sampled rather than a single coronal section? An example of why this is important is the hyperfocus in the posterior ventrolateral periaqueductal gray for pain when that brain region is enormous and has a large rostrocaudal axis. Is sufficient temporal resolution considered to detect state transitions? Are multiple cell types or circuit components considered when the biology is known to be heterogenous? The NIH already requires inclusion of sex as a biological variable, so this extension to incorporate more biological fidelity follows in that spirit.

3. Mechanistic Depth and Multiple Levels of Evidence

This can be a metric that quantifies the level of evidence accumulated over a career. Did a scientist incorporate multiple neuroanatomical regions, multiple techniques measuring physiology, measuring necessity and sufficiency, temporal dynamics, upstream effectors and downstream targets, multiple types of behaviors specificity? And what is the breadth of this within a paper or within a timespan?

4. Literature Integration Score

What I find frustrating is that most neuroscientists I meet are obsessed with keeping up with the Joneses with respect to reading and then pursuing projects that are trendy, and all the work coming out seems to be different flavors of the same thing. Suddenly, everyone is using t-SNE plots on everything, even micro-behaviors, when a plot with pretty colors and a seeming complexity doesn't really tell you anything new about what the animal is doing. What I see more rarely are scientists that are comfortable digging up older lines of research that were abandoned and using modern tools to explore the finding. In addition, leaps of logic and baseless definitions are sometimes allowed in publications and caution should be used when interpreting the results when the literature does not support the basis for the study. To me, literature from 40 or 50 years ago was often on the cusp of finding important biology, but we were limited by the tools available. There are so many good studies from literature of the 1970s through 1990s that were simply set aside because of a lack of tools. Novel ideas are great and I applaud them, but if you dig down, those novel ideas are often based on findings from researchers of previous generations. I would like to see more competing lines of study followed through using modern techniques.

5. Effort toward falsifying the hypothesis

Outstanding science often comes from time spent trying to disprove the central hypothesis, yet this effort is invisible with today's metrics. What experiments were performed specifically because they could have disproven the central hypothesis? Attempts at refutation are central to strong scientific effort.

6. Conceptual Longevity

At two, 5, 10, 15 and 20 years later, are scientists still building on the framework produced? This cannot evaluate early work but should be considered for retrospective assessments.

7. Uncertainty Reduction

Instead of productivity in terms of paper count, what could be scored is whether competing hypotheses were tested, whether assumptions were explicitly stated, whether negative results were reported that strengthened or reshaped hypotheses, whether conclusions matched evidence, whether limitations were discussed quantitatively, and whether other labs were able to identify remaining uncertainty extending the findings.

Given these lines of thinking, here is a putative Scientific Scorecard that combines technical and scientific rigor:

Metric	Example Target
Publications with complete methods	>95%
Statistics cataloged with effect sizes, analysis code and datasets made available for replication	>80%
Independent replication within laboratory (e.g. independent cohorts, different experimenters, etc)	>75% of major findings
Blinded or automated behavioral scoring	>90% where applicable

Histological verification and exclusion criteria reported	100%
RRIDs and reagents reported	100%
Alternative hypotheses experimentally tested	≥2 major competing explanations addressed per principal conclusion, where appropriate
Scientific completeness (mechanistic depth)	Major studies integrate multiple complementary lines of evidence (e.g., anatomy, physiology, behavior, causal manipulation, temporal dynamics)
Biological fidelity of experimental models	Experimental design reflects clinically or biologically relevant spatial, temporal, and physiological scales (e.g., chronic disease duration, anatomical organization, longitudinal measurements)
Assumption testing	Regular publication of studies that explicitly evaluate widely accepted methodological or conceptual assumptions in the field
Shared resources adopted externally	Increasing over time
Trainee mentoring evaluations	Above NIH benchmark
External collaborations	Multiple active projects

On the topic of training and mentorship, why does the NIH not have exit questionnaires for the NIH supported trainees with respect to all mentors encountered at the respective institution? I feel especially if the trainee left early, you should ask. I understand that these should be considered in the light of a stressful training environment, but I genuinely wonder why the NIH does not simply ask the trainees for feedback? One negative feedback should not weigh heavily on a faculty member, but a pattern may arise over time. The categories could be varied, such as how much do you feel this mentor advanced your scientific rigor, your ability to identify proper experimental controls, your grasp on the scientific literature? These kinds of letters of support are always a tricky thing in science, but if it goes one direction (the trainee must get letters of recommendation), then why not in the other (the mentor must get letters of mentorship evaluation). The trainees are trying to become part of the scientific workforce. Why not ask them about their experiences? You could also create a scorecard for institutions based on trainee exist evaluations that are delivered not to their institutional email addresses but their personal email addresses.

On the topic of entrepreneurship and translation – personally I am a behavioral neuroscientist and I want to warn against too much percent weight of a score toward commercialization and entrepreneurship. My goal as a scientist is to share data and build the scientific knowledge base. If you want me to commercialize what I produce, this goes against the sharing spirit. I understand for tools this is different but I do think that documenting and sharing a tool can equally achieve integration of scientific knowledge into health advances. What I see is a push for professors to start commercial businesses and develop tools that can be patented. This to me goes against the spirit of sharing knowledge.

On the topic of public impact, one of the major elements I want to point out is a recent push from the public against biomedical research using animal models. It is of course my duty as a scientist to reduce and replace the use of animal models whenever necessary, and to always

consider the health and welfare of the animal when designing experiments. However, there seems to be a lack of understanding that in order to address human suffering and loss of quality of life, we must address the biopsychological aspects of behavior. To do this, we use animal models because this cannot be done in a chip, and mechanistic biological findings cannot be achieved through neural imaging. We have made massive progress toward understanding how disease works through use of animal models. I want to reiterate that many scientists have a deep reverence for the models they use and do not take the matter lightly. But in order to make progress in how the brain gets stuck in chronic pain and why depression and cognitive deficits correlate with chronic pain we need to use animal models. And I think the NIH itself can help the public understand that the funding dollars going toward research using animal models has made a real impact on healthcare knowledge. This research is difficult to perform. The neurobiologists spend years learning how to design and perform experiments to study disease. We regularly discuss ethics and alternatives around our experiments. But we genuinely want to help solve healthcare problems and that's why we do what we do. I think the NIH could help publicize this sentiment to help build public trust and understanding of the societal benefit that is being funded.

Thank you for your time.

1. Rigor and Reproducibility: Reward a lab's replication track record, pre-registration, reporting-standard and reagent-authentication compliance; fund replication directly. Guard: credit well-powered attempts regardless of outcome; don't penalize genuine exploration.

2. Data, Software, and Model Sharing: Reward verified FAIR compliance and downstream reuse (dataset/software citations, dependent works), not mere deposit. Guard: weight reuse over raw volume; fund curation for small labs; controlled-access credit for sensitive data.

3. Training and Mentorship: Reward longitudinal trainee outcomes, independence, and mentees' own rigor. Guard: value diverse (non-academic) paths; normalize for placement rates; centralize tracking so small/MSIs aren't penalized.

4. Collaboration: Reward specific roles via the CRediT taxonomy and enabling "invisible" work. Guard: make credit role-based, not authorship-count-based; don't penalize sole-investigator fields.

5. Entrepreneurship and Translation: Reward downstream translation (patents, licenses, INDs, guideline adoption) on realistic time lags, plus credit for enabling others' translation. Guard: keep as one axis; don't starve basic science or judge ECRs on products.

6. Foundational Scientific Exploration: Reward productive failure (rigorous null results), long-horizon impact, and assess high-risk work at portfolio level. Guard: de-weight productivity counts here — metrics can kill the risk-taking they measure.

7. Public Impact: Reward contribution to health outcomes, reach/equity, and transparency, via peer-assessed impact narratives (REF-style). Guard: require evidence; sample rather than universally mandate; support smaller institutions.

8. Other Areas: Replace single scores with a role-appropriate dashboard — a small basket of mission-aligned indicators matched to role and career stage, not the h-index or JIF. Design against Goodhart's law — pair hard-to-game quantitative indicators with peer-assessed narrative; audit; retire captured metrics. Reward reliability directly — fund and credit replication, null results, data/software reuse, and mentorship; this is where the reproducibility dividend is recovered. Differentiate by career stage, discipline, and institution type — one uniform standard predictably disadvantages ECRs, basic scientists, and smaller/minority-serving institutions. Pilot, evaluate, and sunset — treat each new metric as a hypothesis; measure whether it changes behavior and improves reliability; retire it if it backfires.

1. Rigor and Reproducibility: Current incentives in biomedical research continue to reward scientific productivity more consistently than scientific reliability. Publications, citations, and novelty remain the dominant measures of success, while the activities that increase confidence in scientific knowledge—replication, methodological validation, transparent reporting, and rigorous negative findings—receive comparatively little recognition. NIH has a unique opportunity to change this by rewarding activities that strengthen confidence in biomedical evidence, not only those that generate new discoveries.
Rigor should be evaluated through a balanced portfolio of indicators rather than a single metric. These include transparent study design and reporting, appropriate protocol registration, independent replication or validation, availability of protocols and analytical code, adherence to discipline-specific reporting standards, and evidence that research outputs can be independently verified or meaningfully reused. NIH should also recognize contributions that improve the reliability of an entire field, including standardized methods, validated outcome measures, reporting guidelines, and multicenter harmonization initiatives.
Implementation should emphasize scientific principles rather than compliance checklists. Expectations should be appropriate to the research question, study design, discipline, career stage, and available resources. Likewise, causal inference should be judged by whether the chosen methodology appropriately addresses the scientific question rather than by a rigid hierarchy of study designs.
Ultimately, NIH should reward activities that increase confidence in scientific knowledge. Doing so would shift the research culture from maximizing scientific output to maximizing scientific reliability—the foundation on which meaningful discoveries and improvements in human health ultimately depend.

2. Data, Software, and Model Sharing: The value of data, software, and model sharing should be measured by their scientific reuse rather than by repository deposition alone. Making resources publicly available is an important first step, but it does not necessarily increase scientific impact if they cannot be readily understood, reproduced, or integrated into future research. NIH should reward the creation of reusable scientific assets rather than compliance with data-sharing requirements.
Evaluation should emphasize scientific utility through indicators such as adherence to FAIR principles, high-quality metadata and documentation, interoperable standards, reproducible analytical workflows, and evidence of independent reuse or validation. Development and long-term stewardship of widely adopted datasets, software, protocols, and other shared resources should be recognized as meaningful scientific contributions because they enable discoveries far beyond the original research project.
Implementation should remain flexible across disciplines and research settings. Expectations should

reflect differences in data sensitivity, participant privacy, intellectual property, and the types of resources generated by different fields. Controlled-access mechanisms should be supported when appropriate to balance scientific openness with ethical and regulatory responsibilities.
By rewarding scientific reuse rather than data sharing alone, NIH can maximize the value of public investment, strengthen collaboration, reduce unnecessary duplication of effort, and accelerate reliable biomedical discovery.

3. Training and Mentorship: Training and mentorship should be recognized as core scientific contributions because they determine the future strength of the biomedical research enterprise. Current evaluation systems often emphasize the number of trainees or training grants, yet these measures say little about the quality or long-term impact of mentorship. NIH should reward the development of people rather than simply the supervision of trainees.
Evaluation should focus on meaningful outcomes, including trainee career progression, scientific independence, multidisciplinary engagement, responsible research practices, leadership development, and preparation for diverse careers across academia, healthcare, industry, government, and other sectors of the biomedical workforce. Contributions that strengthen the broader research community—such as mentoring early-career investigators, fostering interdisciplinary collaboration, developing shared educational resources, and promoting international scientific exchange—should also be recognized as valuable scientific contributions.
Implementation should recognize that effective mentorship occurs under very different institutional and disciplinary contexts. Expectations should therefore reflect career stage, institutional mission, available resources, and the diversity of scientific career pathways rather than applying uniform benchmarks across the biomedical enterprise.
By rewarding meaningful mentorship and workforce development, NIH can strengthen the sustainability, diversity of perspectives, and long-term excellence of biomedical research while ensuring that future generations of scientists are prepared to address increasingly complex health challenges.

4. Collaboration: Modern biomedical research increasingly depends on interdisciplinary teams, yet research evaluation continues to rely heavily on traditional indicators such as principal investigator status and first or senior authorship. These measures often fail to recognize the diverse expertise required to produce rigorous, innovative, and translational science. NIH has an opportunity to shift from rewarding position within a project to recognizing meaningful scientific contribution.
Evaluation should emphasize how collaboration increases scientific value rather than simply counting collaborators or publications. Potential indicators include leadership of multidisciplinary initiatives, development of shared infrastructure or methodologies, successful coordination of multicenter studies, data stewardship, and sustained participation in collaborative networks that produce reproducible and impactful science. Standardized contribution statements, such as the CRediT taxonomy, should complement traditional metrics to better recognize individual scientific roles.
Implementation should encourage collaborations that bring together complementary expertise, technologies, patient populations, and perspectives that would otherwise be unavailable. International collaborations deserve particular consideration because they often provide unique scientific capabilities, longitudinal cohorts, specialized technologies, or access to diverse populations that cannot be replicated within a single institution or country. While appropriate oversight is essential, administrative and financial requirements should remain proportional so they do not unnecessarily discourage scientifically valuable partnerships.

By rewarding meaningful scientific contributions rather than authorship position or collaboration volume alone, NIH can foster a research culture that better reflects the realities of modern team science while accelerating innovation, reproducibility, and improvements in human health.

5. Entrepreneurship and Translation: Entrepreneurship and translation should be evaluated by their contribution to improving human health rather than by commercial success alone. While patents, licenses, startup companies, and industry partnerships are important pathways for translating biomedical discoveries, many of the greatest public health advances improve lives through changes in clinical practice, prevention, healthcare delivery, implementation, education, or widely adopted research tools. NIH should recognize this diversity of translational pathways.

Evaluation should emphasize measurable progress toward real-world impact, including adoption into clinical guidelines or healthcare systems, implementation of evidence-based interventions, development of validated diagnostics, software, or decision-support tools, regulatory milestones, commercialization when appropriate, and documented improvements in patient care or population health. Expectations should reflect the discipline and the pathway through which research delivers public benefit rather than applying a single model of translation.

Implementation should reward meaningful progress along the translational continuum rather than only end-stage commercialization. NIH should also avoid creating incentives that favor commercial potential over scientific or public health value, particularly in fields where the greatest impact is achieved through prevention, implementation, healthcare delivery, or reducing health disparities.

By recognizing multiple pathways through which discoveries improve health, NIH can foster an innovation ecosystem that rewards meaningful societal impact while ensuring that publicly funded research delivers lasting benefits to patients and communities.

6. Foundational Scientific Exploration: Foundational scientific exploration is essential because transformative discoveries rarely emerge from highly predictable research. Yet current evaluation systems often favor projects with extensive preliminary data, lower scientific uncertainty, and more predictable outcomes. While this may reduce funding risk, it can also discourage the bold ideas that have historically driven major advances in biomedical science.

NIH should recognize scientifically rigorous exploration as a valuable contribution in itself. Evaluation should reward originality of research questions, development of innovative methods or technologies, generation of foundational knowledge, and creation of new scientific directions, regardless of whether the original hypothesis is ultimately confirmed. Scientific uncertainty should not be viewed as methodological weakness.

Implementation should distinguish scientific risk from methodological rigor. High-risk research should be held to the same standards of study design, transparency, and reproducibility as any other research while recognizing that ambitious questions inherently carry a greater likelihood of unexpected or negative findings. Well-designed studies that challenge prevailing assumptions or eliminate unsupported hypotheses should be recognized as advancing science rather than representing scientific failure.

The goal of NIH investment should not be to minimize the risk of failure, but to maximize the opportunity for meaningful discovery through scientifically rigorous exploration.

7. Public Impact: The ultimate public impact of biomedical research should be measured by how it improves human health and well-being rather than by scientific visibility or commercial success alone. Publications, citations, patents, and media attention are useful indicators, but they are not the ultimate outcomes of publicly funded research. NIH should prioritize how research changes clinical practice,

healthcare delivery, public health, and the lives of patients and communities.
Evaluation should recognize multiple pathways to societal impact, including incorporation into clinical guidelines or health policy, implementation of evidence-based interventions, improvements in patient outcomes, development of accessible diagnostics, technologies, software, educational resources, and scientific tools that enable future discoveries. Public trust should also be recognized as an important outcome, built through rigorous, transparent, ethical, and responsible science.
Implementation should recognize that meaningful public impact is often cumulative, collaborative, and realized over many years. Expectations should therefore reflect differences in disciplines and translational pathways while maintaining a common focus on improving health and generating lasting societal benefit.
Ultimately, publicly funded research should be evaluated not only by the discoveries it generates, but by the extent to which those discoveries become accessible, trusted, adopted, and beneficial to society. By aligning research assessment with these outcomes, NIH can ensure that public investment delivers the greatest possible benefit to science, healthcare, and the American public.

8. Other Areas: Beyond the domains discussed above, NIH should explicitly recognize scientific stewardship as a core component of scientific impact. Many activities that strengthen the biomedical research enterprise—including developing community standards, maintaining shared resources, building collaborative networks, improving research integrity, contributing to peer review, harmonizing methodologies, and creating infrastructure for future discovery—remain largely invisible in traditional research assessment despite generating substantial long-term value.
More broadly, NIH should adopt a multidimensional evaluation framework that recognizes there is no single pathway to scientific excellence. Researchers contribute through discovery, methodological innovation, mentorship, collaboration, stewardship, translation, implementation, and scientific leadership. Rather than relying on single metrics or composite scores, NIH should evaluate a balanced portfolio of complementary contributions that collectively strengthen the biomedical research ecosystem and maximize the long-term value of public investment in biomedical research.

I commend NIH for undertaking this important initiative. The greatest opportunity is not simply to develop new metrics, but to redesign the incentives that shape biomedical research. Ultimately, research assessment should reward the behaviors that maximize the long-term value of publicly funded science rather than primarily measuring individual academic productivity. The incentives NIH establishes today will shape the culture of biomedical research for decades to come. By recognizing scientific contributions that improve the quality, reliability, translation, and societal impact of research, NIH can strengthen the biomedical research ecosystem while maximizing the public benefit of its investments.

106. N/A

I am responding: On behalf of myself

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 7/22/2026

1. Rigor and Reproducibility: A panel can list out traditional interventions that have not been re-evaluated in the past 10-20years (e.g., routine blood tests in adults starting annually at age 18, daily or twice daily labs in inpatients, pap smears in women who have had the hpv vaccine) and then an RFA or dedicated funds where researchers can evaluate the impact of these traditional interventions.

2. Data, Software, and Model Sharing: This is one space where I am not sure whats the best approach. There is already so much data out there and I cannot imagine anyone out there wanting to run my data again to validate my results. But that may be specific to my work. I do believe any observational studies funded by the NIH should automatically include a separate funding announcement that can be applied for to validate the results once the authors make their datasets available. There are many bioinformatics/statisticians who could contribute to validating findings.

3. Training and Mentorship: The traditional indicators (publications, grants, clinical trials, appointments) are likely sufficient because there are so many unrealized gains from training that cannot be captured. For example, a clinician who is trained in research methodology is reading the literature and applying findings in their practice- something that directly impacts a patients life. There isnt any way this can be captured.

4. Collaboration: Team based science is already being enforced through study sections where peer reviewers request new study personnel to be added for their expertise. What is important is not pushing team based science as much because it creates an incentive to include members who may not be truly needed to accomplish the goals of the project but are included just to satisfy the study section reviewers.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: It is the study section peer review process that thwarts bold and innovative ideas. It may also be that those who sell "bold and innovative" ideas are just good at marketing and the ideas are not truly bold or innovative. Having served on many study sections- I am yet not sure if any of the grants I have supported have yielded a single discovery that has helped people live better or longer lives. Yet I hear so much excitement from my colleagues about how a particular idea is so "innovative"- perhaps innovation is over-rated and unnecessary for many grants. Sometimes you just need the grunt work to answer a basic question using standard methods- rigor and reproducibility work will never be innovative for example. Factor 1 already removed innovation (it really should only be about

significance)- yet we are getting comments like- there is no innovation. Maybe have "pitch" sessions for the IC directors where they invite 10-20% of applicants of grants that were competitive not discussed or not discussed (but whose ideas, if they work, could be game-changers and where projects are fatally flawed)- the IC directors can pick a few of these for funding and compare how they perform with the 1-3rd percentile grants. I wouldn't be surprised if they perform similarly using current metrics.

7. Public Impact: Its important that IC directors look at outcomes of grants (before funding) in a way that peer reviewers may not be looking. There are some very excellent grant writers out there who can sell ideas and there are reviewers who do similar things and so they get perfect scores. But when you look at their outcomes it becomes obvious there is no clear translation plan. For example, if someone is creating a public health messaging campaign to figure out whether it might land well to alter a certain behavior (for example increase medication adherence or increase acceptance of screening)- if the whole grant will create and test messages and then they publish their results - a tax payer may wonder how this actually changed the behavior in question. There must be a requirement to include a trial where the campaign is launched in the real world and the behaviors are tested to understand efficacy- otherwise these campaigns are created and never read a single person who could benefit. Similarly there are many basic science studies with no plan for translation even if they work- while it may be that some pharma company will pick it up for development it would help to have a standard pipeline to ensure the best and most promising discoveries in basic science are moved forward into drug development and phase 1 clinical trials.

8. Other Areas: AI could be leveraged to resurrect ideas from the past 5-10 years that researchers may have abandoned because study section peer reviewers just wouldn't score them high enough for funding. Applicants could be asked to reapply and then selection could be done by lottery. In general a small portion of grants that are not fatally flawed in some way (any unfunded grant can fall in this space) should be funded regardless of the peer review process via lottery (and perhaps after a pitch or video meeting between the PO and the applicant to ensure they can defend their ideas) and then outcomes of these lottery funded grants should be compared with the grants that are funded through the traditional process. The rock stars who keep getting grants have figured out a winning formula (they write well and have three peer-reviewers who think just like them). They don't necessarily move the science forward and they aren't necessarily creating ground-breaking discoveries. Ideas that are outside the realm of what peer-reviewers would think of funding are likely falling in the lower score areas but they may yield something. Another space to look is at the performance of the study sections- if there are metrics that come out from this process that would identify "impact"- we may find that certain study sections perform worse at identifying good grants. Those study sections likely need to be disbanded or restructured (or have more than one study section chair and train them really well in intervening when reviewers go down a path of reasoning that isnt helpful).

Date Submitted: 7/22/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: This is important, but needs to have resources available to support it (e.g., money for staff, costs for platform maintenance).

3. Training and Mentorship: I believe that this is very undervalued in our evaluation of impact. I also believe that this needs to carefully consider one's career stage. Often early stage investigators are dinged for not having had prior trainees when they have a trainee submit a K or F grant, but someone has to be their first trainee!

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

8. Other Areas: I think it is important to recognize that not all scientists will be doing all of these things at all stages of their careers. Thus, any new method of evaluating them needs to consider career stage, field of study, and current scientific work.

1. Rigor and Reproducibility: PROPOSAL: SOLVING THE REAGENT REPRODUCIBILITY CRISIS VIA SEQUENCE-DEFINED FLUORABODY® PROBES

1. THE TRUST PROBLEM IN CONTEMPORARY SCIENCE
The NIH must address the fact that reagent variability is the #1 cause of assay failure, driving 36% of all cases. Traditional fluorescent labeling fails due to inconsistent fluorophore stoichiometry, brightness, and spectral drift caused by chemical conjugation. Legacy fluorescent antibodies vary heavily in quality, forcing labs to spend $1K+ per reagent to re-validate what they cannot trust. This systemic problem contributes to:
a) ~$170B in annual global research waste.
b) ~50% of all preclinical research failing to reproduce.
c) Over 50% of commercial antibodies failing validation as sold.
d) Independent 2026 findings flagging 462 problematic validation images in major commercial catalogs, proving that marketing imagery cannot replace molecular validation.

2. THE PLATFORM SOLUTION: THE FLUORABODY® ENGINE
To restore reproducibility, the NIH should incentivize a transition to sequence-defined, animal-free reagents built at scale. The Sandia Biotech FluorAbody® Engine solves this by turning known antibody sequences directly into intrinsically fluorescent, sequence-defined scFv reagents.

By grafting target sequences onto an engineered scaffold fused to a fluorescent protein (with 8 colors available), the platform builds fluorescence directly into the antibody sequence itself. This guarantees predictable, controlled fluorophore loading and strict stoichiometry. True monoclonality removes polyclonal heterogeneity and off-target binding, delivering a reliable quantitative readout that stays trustworthy forever with zero lot-to-lot drift.

3. MEASURABLE POLICY INDICATORS
The NIH should implement a "Reagent Fidelity Metric" within peer review. Grant applications should receive preferential scoring under the "Approach" criterion if they commit to utilizing sequence-defined, recombinantly expressed biological detection engines over volatile, chemically conjugated legacy reagents.

2. Data, Software, and Model Sharing: PROPOSAL: ENHANCING TRANSPARENCY THROUGH SEQUENCE-LEVEL ASSAY DISCLOSURE

1. THE SHARING GAP IN BIOMEDICAL RESEARCH
True data sharing and assay reuse under current Data Management and Sharing (DMS) guidelines are blocked because legacy reagents are molecular "black boxes." When investigators share raw quantitative data, subsequent labs cannot compare or identically repeat the experiments because the exact physical properties, sequence identities, and labeling variations of the commercial probes are unrecorded. This inconsistent labeling undermines quantitative interpretation and breaks reproducibility across labs.

2. A DIRECT BRIDGE FROM DIGITAL SEQUENCE TO REAGENT
The future of data sharing relies on digital sequence databases, AI, and in-silico binder programs. The FluorAbody® Engine acts as a direct sequence-to-reagent workflow. The engine takes digital sequence inputs, extracts the paratope, and integrates it onto an engineered scaffold for recombinant expression. This converts digital sequences instantly into detection-ready, quantitative reporters. Because the blueprint is digital and sequence-defined, the physical identity of the probe is fully transparent and auditable.

3. STRATEGIES FOR MANDATORY REPORTING
The NIH should update mandatory DMS checklists to include a "Reagent Blueprint Table." PIs using fluorescent detection should be required to log the exact amino acid sequences or precise molecular definitions of their probes. Utilizing open-access sequence blueprints ensures any laboratory worldwide can express the identical physical tool, enabling lossless data reuse and flawless replication.

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: PROPOSAL: ACCELERATING PRECLINICAL TRANSLATION VIA WORKFLOW COMPRESSION AND SCALABLE ENGINES

1. CLINICAL AND TRANSLATIONAL BOTTLENECKS
Translating academic breakthroughs into robust diagnostic or clinical products is severely bottlenecked by time waste and cost, contributing to a $28B annual U.S. R&D loss. Traditional immunofluorescence requires a multi-step workflow (fix, wash, block, primary antibody, wash, secondary antibody, wash) taking over 4 hours. This high-volume workflow amplifies human error and reagent variability, causing mismatched research and clinical outcomes.

2. OPERATIONAL IMPACT OF WORKFLOW COMPRESSION
Federal funding should prioritize entrepreneurial innovations that compress assay workflows without compromising quality. The FluorAbody® framework compresses detection into a rapid, single-step direct-staining protocol (fix, wash, stain, wash) completed in under 2 hours. This streamlined approach delivers:50% less assay time.43% fewer protocol steps.2x faster results.

In practice, this operational efficiency yields a sharp, highly localized, low-background signal that improves tissue penetration and accelerates biomarker validation (e.g., membrane HER2, EphA2, EGFR)

in regulated environments.

3. COMMERCIAL SCALABILITY AND ACQUISITION TARGETING
The NIH should utilize SBIR funding to support platform engines that scale seamlessly across entire product pipelines. The FluorAbody® Engine features a highly defensible model, including an active patent license from UNM Rainforest Innovations with no field-of-use restrictions, and a commercial portfolio of 71 unique validated targets across oncology, inflammation, and neurodegeneration. Transitioning small business incentives toward sequence-defined, recombinant platforms ensures that early-stage discoveries cleanly integrate into corporate automation catalogs, accelerating commercial diagnostic translation.

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

8. Other Areas: N/A

109. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Healthcare Institution

Date Submitted: 7/23/2026

1. Rigor and Reproducibility: There is a laudable effort from NIH and publishers for science that is accurate, rigorous and reproducible. However, there an in-built bias as many scientists are known and well connected, sometimes they are able to publish okay studies in big journals. This practice should be somehow reduced/discouraged. NIH should consider funding proposals which are based on medium impact factor journals but with detailed analysis/robust data.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: Although collaboration is a big part of any scientific endeavor, its increasingly connected to "network" and "networking" for getting grant scored better and funded. May be NIH should ask every PI who is submitting a RO1 kind proposal to submit a list of talks they organized or faculties they invited to their home institute. None of these people should be in a grant review meeting for that host PI. Someone's NETWORK MUST NOT DRIVE FUNDING SUCEESS. I think NIH should limit number of R01 or large DoD grants a PI can have at a given time (feedback sought in another Request for Information) and PI MUST BE ASKED TO DECLARE A LIST OF SCIENTISTS/FACULTIES THEY INVITED/HOSTED at their home institute IN LAST 5 YEARS to reduce grant review bias/undeclared potential conflict.

110. Dennis Drayna

I am responding: On behalf of myself

Name: Dennis Drayna

Name of Organization: NIH (Emeritus)

Type of Organization: Government Agency

Role: Investigator/Researcher

Date Submitted: 7/23/2026

1. Rigor and Reproducibility: You'll have to convince NIH study sections that giving money to a replication study is just as exciting and interesting as giving money to a new area of investigation.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: MD's wishing to do laboratory research face a fundamental and unchangeable hurdle, which is that any time away from the lab (for clinical work in particular) turns them into less than full time bench scientists. This puts them at a disadvantage for funding compared to those who devote full time to bench research. Lowering standards for the evaluation of funding applications for those who spend some of their time doing something other than bench research is not the answer to this problem. Personally, I believe one solution would be to remain insistent on the very highest, most competitive standards in bench research but offer a bonus system for applicants who bring patients or other clinical resources to the application.

4. Collaboration: When I started in research 50 years ago, I wanted to have (and often did have) as few authors on my papers as possible. Few authors on the paper other than me indicated that I did the heavy lifting and it raised my visibility and prestige within the scientific community. Now, journals tacitly want large (sometimes very large) authorship lists, as they believe papers with more authors equal more work and thus more importance and more impact. For example, I published some of my most important papers with 2 or 3 total authors on those papers. Today there are essentially zero papers in Cell, to choose an example, with 2 or 3 authors. This and other factors have now severely limited the career growth and development opportunities for young investigators, who now often labor under the intellectual and financial control of prominent scientists. This may be an efficient way of accomplishing one person's scientific vision and goals, but I believe we are squandering the most energetic and creative years of scientists' careers. Big Team science has advantages, but it should be recognized that this approach comes at a cost to the development of our future scientific workforce. The K99/R00 mechanism is one step toward solving this problem, but the real test is in the R01 world. Finding good people and getting them well started is what we need to do to maintain our world leadership in science.

5. Entrepreneurship and Translation: Put more money into SBIR funding, and solve the problem that arises when investors refuse to allow those funds to buy into the company and thus dilute their investment and control. To put it bluntly, the NIH's money invested in an enterprise is the same color as the investors' money, plain and simple.

6. Foundational Scientific Exploration: This is what made US science the best in the world. Remove political meddling and keep peer review as the primary gate keeper of funding. Make it a legal requirement that any NDA to the FDA must list the 25 most important basic research papers that led up to the development of that drug. And, insist that the funding source for those papers (it will overwhelmingly be the NIH) are an integral part of that list and are clearly visible to the public.

7. Public Impact: N/A

Date Submitted: 7/23/2026

1. Rigor and Reproducibility: Perhaps this should have been a consideration long ago. In today's published science realm, I have never seen the published outcomes less rigorous and more suspect with regard to "real or unreal". The question then is, in lieu of unrealistic approaches to control publications, what is the best way to assure reliable results. Results, if reliable, DO NOT have be the outcome of an unflawed hypothesis. They can the outcome of a flawed notion, as long as the results are replicable. The hypothesis is the focus of testing and imagination, not the result of testing. Perhaps the best approach to all of this is a highly geographically integrated team with a non-project oversight group, similar to clinical trials. The downside to this, is a significant increase in cost per project. But in the end, if 20-60% (maybe more, depending on research specialty) of all research is not replicable, is it really less cost-effective? The elimination of poor research, fraud, and waste will never be 100%. But new approaches appear to be necessary to stem the tide of lousy research.

2. Data, Software, and Model Sharing: As my comments above suggest, the sharing data sets (ORIGINAL), tightening the data capture procedures, videoing some work in progress (although invasive), auditing source documents, having a CCRA-type person with authority as part of a department or team, etc., may necessary. All of these things are invasive and may be counterproductive, e.g., stifling innovation. But some measures need to be adopted in order to maintain scientific integrity (which has suffered profoundly over the last 6 years, at least).

3. Training and Mentorship: In my experience, mentorship and outcome are solely dependent on the particular mentor and how their operations are run---- very individual dependent. This is a very difficult matter to manage. It is also institutionally impacted. Many mentors seek to be very hands on while institutionally, they are warned, "Hands off". Any change in how this is handled needs to be a "do IT or lose the funding" approach. If you show institutional favor, all is lost. But this too, is a problem. You cannot force this onto institutions where the requirements impose exorbitant costs, where such an approach favors the wealthy institutions. This will be simply more of same IVY crap that is evident among some study sections.

4. Collaboration: I am all for it. But in order to accomplish this, you need to impose rules that institutionally reward the participants. During my tenure at a major academic institution, we positioned the entirety of the research effort to become a team/collaborative effort. This did NOT go well with department chairs. Systems of reward, both monetary and productivity based, were not adapted to service a team effort. Push-back was tremendous. But the solution was to revamp the rewards and

promotion system. In the end it was do it or else (or else your department won't get anything). The days of a single or two investigators working behind closed doors, publishing lone results, and waiting for the promotion, ended. Perhaps this is really telling with regard to current institutional structures and rewards systems that need a revamping.

5. Entrepreneurship and Translation: Franky, this is the only thing that matters. If this is not the focus, what are you really doing???? Bench-to-bedside MUST BE a major part of the equation. It took center stage at my institution, and it paid off (not without the pain of restructuring).

6. Foundational Scientific Exploration: See "Rigor and Responsibility"

7. Public Impact: If the NIH mission is to be a consideration for the expenditure of any tax dollars, then public impact must be outcome optic. But really, this is a public health and safety optic. And it flows from ALL FEDERAL STRUCTURES. When one fails, e.g., CDC or FDA or NIH, all are seen as a failure. Better integration of the Federal (and State) agencies better soon happen, or the public, fed up with catastrophes over the past 6-12 years, will demands cuts or major reorganization. Perhaps it is time for MAJOR reorganization.

8. Other Areas: 1. With all that is considered in these sections, I would also suggest a complete overhaul of the study section system. My experience is that it is institutionally biased. Heavy northeast and west coast. And please don't tell me this is where the great science is REALLY DONE. Find a better way to assess applications or to divey up funding.

2. Indirect costs: In the end if you wish to find a way to improve rewards, consider a significant reduction for indirect costs. This can give you the money you need without an increase in budget. After all, why should any institution get more than another. If their overhead is 20-40% higher, tough!! Fixed fee overhead is the only way to go (try 25%). Use the difference to structure a rewards program for collaborations, for clinical translation, for outcomes, for true impactful science breakthroughs. You really have to ask yourself, why the hell is Harvard, with the largest endowment of any university, getting 68.5% overhead when other universities and small business biotech get ~45% and 10%, respectively? Com'on, you can do better than that, and the optics....not a good picture.

112. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

1. Rigor and Reproducibility: While the effort to maximize

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

8. Other Areas: The notion of improving impact and rigor is laudable. It has hardly been the first time that folks (researchers included) have thought about this and the issue it raises.

However, the reason it has remained an ongoing concern is that the solution is not easy/straightforward, and there is no answer that is without negative repercussions.

How are we to measure how impactful something is? Take a paper for example. Is it how many people read it? How many people cite it? How many marketable products it generates? Whether it leads to another grant? Whether it leads to private funding? Importantly, what is the timeline? There is plenty of research that doesn't make a high mark on any of these metrics in the immediate short term but then years or decades later ends up informing other discoveries and products. In many of those cases, the primary investigator is onto different types of projects or is retired altogether. So how can you reward 'impact' in that situation?

This effort broadly strikes me as a way to weaponize results against researchers and their future efforts. In other words, especially in the new "unified funding strategy" it gives administrators at NIH just one more reason they can use to pick winners and losers, potentially under influence by politicians, rather than letting the scientific review process play out.

Name of Organization:

Type of Organization: Not Applicable

Role: Investigator/Researcher

Date Submitted: 7/24/2026

1. Rigor and Reproducibility: Rigor and reproducibility are essential to scientific progress but are difficult to measure and reward. Independent replication often requires specialized expertise, unique resources, and substantial time and funding. In many cases, expecting individual laboratories to routinely reproduce influential findings may not be feasible without dedicated resources or programs focused on replication.

One potential approach would be to create mechanisms for researchers to confidentially report unsuccessful replication attempts, including methods used, limitations encountered, and possible explanations for discrepancies. These reports should not automatically be interpreted as evidence that original findings are incorrect, as differences in expertise, materials, methods, or experimental conditions may contribute. However, aggregating such information could identify areas where formal replication efforts are most valuable.

It is also important to recognize that reproducibility often emerges through the cumulative process of science. Multiple laboratories investigating similar questions using different approaches contribute to confidence in findings over time. Reproducibility should therefore be viewed not only as direct replication of individual studies, but also as the broader process by which scientific knowledge is validated.

NIH should also recognize that creating reusable resources—including validated datasets, harmonized data, and well-maintained repositories—is an important scientific contribution. These activities can enable future discoveries but currently receive less recognition than publications. Grant evaluation should consider the long-term value of shared resources, data validation, and reuse in addition to traditional metrics such as papers and citations. Incentives and funding mechanisms that support data curation, integration, and validation would encourage researchers to invest in these activities while maintaining career competitiveness.

2. Data, Software, and Model Sharing: Making scientific data, software, and models accessible is essential for accelerating biomedical discovery. As an early-career scientist, access to existing datasets and computational resources creates opportunities to address important questions that may otherwise be limited by the cost and infrastructure required for new data generation. Shared resources enable validation, collaboration, and greater return on publicly funded research investments.

However, there are legitimate concerns from investigators who generate these resources. Large datasets require years of funding, specialized expertise, and substantial effort to collect, curate, and validate. Researchers may worry about losing scientific priority, having ideas pursued before they can complete analyses, receiving insufficient credit, or creating disincentives for future data generation.

A potential solution is to distinguish between data accessibility and release of the entire research process. Making raw or minimally processed data available with appropriate metadata and documentation can enable reuse while preserving opportunities for original investigators to develop additional analyses. Importantly, datasets must include sufficient context—such as experimental design, quality-control procedures, and limitations—to be scientifically interpretable. Data that are accessible but poorly documented may have limited value.

NIH should also recognize that generating knowledge from existing datasets requires significant expertise and effort. Developing models, integrating datasets, and performing secondary analyses are important scientific contributions that should be rewarded. At the same time, new data generation remains essential for rigor and reproducibility because independent data collection is often needed to validate findings, address limitations, and test new hypotheses.

NIH could promote this balance by:

Recognizing datasets, software, models, and secondary analyses as meaningful scientific outputs.
Providing credit for data generation, stewardship, validation, and reuse.
Supporting infrastructure for data documentation, attribution, and long-term maintenance.
Encouraging responsible sharing practices that protect contributor recognition while maximizing scientific value.

A successful sharing ecosystem should reward both researchers who generate high-quality resources and researchers who use those resources to make new discoveries.

3. Training and Mentorship: Mentorship is essential for sustaining the biomedical workforce, but it often competes with incentives that prioritize publications and grants. Effective mentorship requires substantial time and effort, yet these contributions are difficult to measure and frequently undervalued.

The stability of the training pipeline is also a major concern. Postdoctoral positions are limited, and compensation may not be sufficient to support researchers and their families given current costs of living. These pressures can discourage talented individuals from pursuing long-term research careers. In addition, many postdocs face uncertainty about academic career prospects and may not have sufficient opportunities to develop the grant writing, leadership, and independent research skills needed for long-term success. Creating additional pathways that allow postdoctoral researchers to pursue more independent research projects with appropriate mentorship and support could help prepare the next generation of scientific leaders.

Current incentives may also limit access to training opportunities by favoring trainees with existing publication records rather than recognizing potential, growth, and diverse paths into research. Similarly, many early research experiences, including volunteer opportunities, are more accessible to individuals

with financial flexibility. Expanding supported opportunities for research training could help reduce barriers for talented individuals who cannot afford unpaid or low-paid experiences. Personally, I believe all scientists should be rewarded for outreach (as connection to the public is critical to the long-term stability of the science).

Mentorship metrics should avoid becoming another publication-based measure that rewards only already successful trainees. Instead, they should consider trainee development, skill growth, career outcomes, and the creation of supportive research environments.

NIH should consider:

Recognizing mentorship as a meaningful scientific contribution.
Rewarding researchers who invest in training, including mentorship that does not immediately result in publications.
Supporting sustainable postdoctoral and trainee positions.
Expanding accessible, supported research training opportunities.
Measuring mentorship impact through trainee growth and long-term contributions to science.

Training future scientists is itself a critical research investment, and the biomedical enterprise should better recognize and support those who make that investment.

4. Collaboration: As biomedical research becomes increasingly interdisciplinary, collaboration and team-based science are essential for addressing complex problems. However, policies and incentives should be aligned with this goal. Restricting the number of times a principal investigator can serve as a multi-PI (MPI) on grants may unintentionally create barriers to collaboration, limit productive research partnerships, and reduce opportunities for trainees to participate in interdisciplinary science.

MPI structures can be particularly valuable for early-career researchers by providing access to complementary expertise, infrastructure, and mentorship that may not exist within a single laboratory. Restricting these collaborations may unintentionally reinforce advantages for large, established laboratories while limiting opportunities for trainees and emerging investigators to develop within collaborative research environments.

NIH should consider approaches that recognize individual contributions within team science, including leadership, coordination, mentorship, methodological expertise, and development of shared resources. Evaluation and funding policies should encourage effective collaboration while ensuring accountability, rather than creating barriers that discourage the interdisciplinary partnerships needed for modern biomedical research.

5. Entrepreneurship and Translation: Translating discoveries into products and clinical advances requires researchers to take risks, explore new directions, and engage with partners outside traditional academic settings. However, pursuing entrepreneurial activities often requires significant time away from generating publications and grants, which can create career risks for investigators.

Researchers may reasonably ask how an applicant who dedicates time to developing a venture,

technology, or translational effort—but consequently produces fewer publications during that period—will be evaluated in future funding decisions. Without mechanisms that recognize entrepreneurial efforts as legitimate scientific contributions, investigators may be discouraged from pursuing opportunities that could have significant public impact.

NIH should consider ways to reduce these barriers by recognizing innovation, technology development, commercialization efforts, and industry partnerships as meaningful research outcomes. Evaluation criteria should consider the broader impact of a researcher's contributions rather than relying primarily on publication metrics.

Supporting entrepreneurial pathways may also require mechanisms that provide financial and career stability during periods of transition, allowing researchers to pursue translation without jeopardizing long-term scientific careers. A successful innovation ecosystem should reward thoughtful risk-taking and recognize that impactful discoveries may require time away from traditional academic productivity measures.

6. Foundational Scientific Exploration: Basic research and high-risk, high-reward initiatives are essential because scientific progress often depends on pursuing questions whose importance is not immediately apparent. As a society, we often underestimate how much remains unknown and how difficult it is to predict which discoveries will ultimately transform medicine or technology.

Many major advances have emerged because researchers were able to pursue ideas that initially appeared speculative, impractical, or disconnected from immediate applications. In many cases, the significance of a discovery only becomes clear after years of additional research, when foundational knowledge enables new technologies, therapies, or unexpected applications.

NIH should continue to support scientific exploration that allows investigators to pursue ambitious questions without requiring immediate evidence of translational potential. Evaluation systems should recognize that failure is an inherent part of discovery and that long-term scientific progress depends on maintaining a portfolio that includes both incremental advances and bold, uncertain ideas.

Supporting foundational research requires incentives that value scientific insight, development of new knowledge, and creation of future opportunities—not only short-term outcomes. The ability to pursue unanswered questions is essential because innovation often occurs only after researchers have invested the time needed to understand a field deeply enough to reveal its broader potential.

To encourage bold scientific exploration, funding structures should consider the career and financial risks associated with pursuing uncertain ideas. Although investigators may technically complete projects earlier than the allotted grant period, doing so may create financial and career disadvantages because future funding often depends on sustained productivity and continued support. More flexible funding mechanisms, shorter grant cycles for exploratory work, milestone-based funding, or opportunities to transition based on scientific contribution rather than only successful outcomes could allow researchers to pursue high-risk ideas while reducing career risk.

Importantly, high-risk research should not be evaluated solely by whether the original hypothesis was

confirmed. Studies that generate valuable knowledge, reveal limitations, develop new methods, produce important datasets, or redirect a field can represent meaningful scientific contributions even when the expected outcome is not achieved.

7. Public Impact: Biomedical research can have broad impacts beyond publications, including improvements in health outcomes, clinical practice, economic development, accessibility, and public trust. However, researchers often lack the resources, training, and opportunities needed to develop these broader impacts.

NIH could support public impact by creating funding opportunities, workshops, and conferences that help researchers build partnerships beyond traditional academic settings, including with clinicians, patients, communities, industry, educators, and policymakers. These opportunities could help investigators translate discoveries, communicate findings effectively, and identify applications that may not be apparent within a single research environment.

Public impact should also be recognized as a meaningful research contribution. Evaluation metrics could consider outcomes such as adoption of research findings, development of useful resources, contributions to clinical practice or policy, community engagement, improved accessibility, and successful translation of discoveries into practice.

However, public impact is often difficult to predict at the time research is funded. Many foundational discoveries produce societal benefits only after years of additional development and understanding. NIH should avoid creating incentives that prioritize only projects with immediate or easily measurable applications, as this may undervalue basic research and high-risk discoveries.

Supporting public impact requires both recognizing outcomes and creating the infrastructure, partnerships, and opportunities that allow discoveries to reach society. A successful approach should value near-term engagement as well as long-term contributions to health and societal advancement.

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: The biomedical scientific community is in a dramatic funding crisis and many people are leaving academia or leaving the country. In the current funding climate, there are two very basic and quite straight-forward changes that could –and should–be made to better distribute NIH funding so that more of the people who can produce the results–at all levels–that we all desire will be funded.

First, eliminate funding based on an individual's connection to a particular disease; rather, fund researchers on the Howard Hughes model, which funds the scientific rigor, abilities and accomplishments of the individual or team. There are WAY too many clinicians who receive funding because they are experts in a particular disease area, not because they are good scientists, but because there's an urgent–sometimes desperate–need to find therapies/cures. Instead of pushing a field forward, much of the output from these groups is derivative and incremental and cannot meet NIH's goals. A genuine, deep desire to help one's patients, or how accomplished someone may be in their clinical specialty never made anyone a scientist, let alone a good one.
There are plenty of M.D.s who are great scientists (Harold Varmus, etc.), but the only reliable way to distribute VERY limited funds is to get those funds to the best scientists, period - not to people who work on a particular disease area. One of the best ways to do this is to use the Howards Hughes model and have a panel of outside experts (study sections have far too many conflicts) to evaluate a grant applicant's abilities as a scientist.

Second, award funding to people who do scientific research FULL TIME. There are, again, WAY too many clinicians who do "research" as an afterthought. You would not hire a lawyer who practiced law half a day or one day a week, but such a schedule is routine in virtually all major medical centers, again because there is disease-based grant money available. Success in scientific research requires a major

investment of time and effort, and it is a privilege that the taxpayer expects to have carried out on a full-time basis.

If you do just these two things, you will jump-start the research enterprise in this country and accelerate progress towards understanding and cures (not to mention the enormous positive affect it has on the economy). If you want to be even more effective, increase NIH funding.

7. Public Impact: N/A

8. Other Areas: N/A

115. N/A

I am responding: On behalf of an organization

Name:

Name of Organization:

Role - Other: Evaluation team

Date Submitted: 7/27/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: Various indicators/tools for Training and Mentoring impact evaluation such as:
- High-level success story – to share to public on the trainee journey and their research outcome
- Post-award progress reporting for academic output tied to funding (presentations, posters, papers), follow on grants for calculating ROI.
- Utilization of Flight Tracker for Scholars for post-award progress reporting. Flight Tracker is a REDCap module developed by Vanderbilt University, used to track the academic career development of CTSI education program scholars by scraping data from several databases and repositories, including NIH REPORTER and PubMed. FT will help research staff in reporting the outcome and impact more automatically, which helps staff's bandwidth.
- Metric to measure the percent of protected time (need to set a minimum threshold) across institutions.
- Standardized survey to measure satisfaction of training across institutions

4. Collaboration: Assessing:
Evaluating team science needs to define success across diverse disciplines and project phases, ensure fair credit distribution among team members, and navigate complex organizational structures. For implementation approach, team science needs supporting staff who can make ongoing observations of team dynamics and implement best practice interventions.
Key outcomes include achieving scientific goals, improving collaborative skills, and fostering a positive team environment. Metrics for these outcomes include productivity, publications, grant funding, team satisfaction, percent of potential academic and industry collaborations outside home institutions utilized and engagement.
Evaluating team science needs to focus on both team processes and outcomes including assessing communication, collaboration, and conflict resolution within the team, as well as the impact of the team's work on research outputs, scientific advancement, and practical applications.
For collaboration with community, CIROP (Community Impacts of Research-Oriented Partnerships) survey can be used to measure the impact of research partnership from the perspective of community

members. This survey will help to demonstrate impact of research partnership with community members in the areas of: 1) personal knowledge development, 2) personal research skill development, 3) organizational/group access to and use of information, and 4) community and organizational development.

Recognizing:
Tie the achievement of met goals to promotion opportunities.
Best practice articles/case studies/success stories.

5. Entrepreneurship and Translation: Assess:
Various tools for Entrepreneurship and Translation impact evaluation such as:
- Number and type of scientific and/or operational innovations developed and/or disseminated
- Number and type of patents or trademarks filed and/or received (e.g. IP data, implementation science etc.)
- Number and type of FDA approvals received by CTSA Hubs
Utilization of TSBM framework for impact evaluation will be suitable for translating/ demonstrating the impact on real world in four areas: four areas: Clinical and Medical Benefits, Community and Public Health Benefits, Economic Benefits, Policy and Legislative Benefits.

Incentivize:
Tie the achievement of met goals to promotion opportunities.
Best practice articles/case studies/success stories.

Integrate:
Develop NIH common metrics and approaches

6. Foundational Scientific Exploration: N/A

7. Public Impact: Assessing:
Utilization of Translational Science Benefit Model (TSBM) for impact evaluation. TSBM is a framework to help demonstrate impact of translational science in the real world. The model identifies benefits of clinical and translational research in four areas:
• Clinical and Medical Benefits (person-involved care, procedures & guidelines, tools & products)
• Community and Public Health Benefits (community engagement & wellness, health activities & products, health care characteristics, health promotion)
• Economic Benefits (commercial products, financial savings & benefits, healthcare workforce)
• Policy and Legislative Benefits (advisory activities, community-centered policy, policies & legislation)
TSBM has available tools to help guide data collection, building case study, and building impact profile (Washington University Tool Kit). TSBM helps to guide researchers to share their research impact in real world setting to public. Since research impact can take many years, TSBM framework allows both demonstrated (benefits that had been achieved) and potential (benefits that had not yet been achieved but could be achieved by the project) indicators of benefits.

Recognizing:
Tie the achievement of met goals to promotion opportunities.
Best practice articles/case studies/success stories.

1. Rigor and Reproducibility: Replicability of human pathophysiological or diseases in basic research models needs to be recognized and rewarded by the NIH.

2. Data, Software, and Model Sharing: Data reuse is a great idea. However, there have to be safeguards to protect the rights of the original data depositor both when the reused data is reused in NIH applications or submitted manuscripts.

3. Training and Mentorship: N/A

4. Collaboration: This effort has significantly grown and is currently well reconized by the NIH. Perhaps, less emphasis needs to be devoted to the names of the established researchers and institutions than current practices by reviewers. The efforts of the PI and collaborators need to be evaluated based on their capabilities to conduct the proposed studies rather than on their standing and reputation.

5. Entrepreneurship and Translation: Both factors are important. However, in recent years, reviewers have been paying too much attention to catchy techniques/methodologies when evaluating the innovation of the application. While the efforts of the reviewers are highly appreciated, generational changes led to downplaying the importance of animal studies using basic and translationally important techniques.

6. Foundational Scientific Exploration: This is a great idea that reinforces the comment just above this idea.

7. Public Impact: Yes, this endeavor deserves continued recognition.

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: Science is a tedious process of knowledge accretion. Students depend on access to the latest research/thinking/findings to adapt to, and prepare for, future careers.

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: I'm especially interested in slowing or reversing the rise in substance use disorders. Toward that end, I've begun a project in which students (high school, college, graduate) work in teams to translate one empirical paper at a time for social media. Thus scientific findings are amplified by young people, for young people. In this way, scientific understanding about this critical topic is able to reach the people who need it most so that they are able to make informed decisions.

8. Other Areas: N/A

118. Hoda Badr

I am responding: On behalf of myself

Name: Hoda Badr

Name of Organization: Sidney Kimmel Comprehensive Cancer Center at Thomas Jefferson University

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 7/29/2026

1. Rigor and Reproducibility: Rigor should be evaluated using measures that reflect the full biomedical research enterprise, including basic, clinical, behavioral, implementation, and population sciences. Reproducibility should encompass transparent reporting of study methods, intervention protocols, analytic approaches, implementation procedures, and community engagement methods so that findings can be evaluated and applied in diverse settings.

Potential indicators: Public availability of study protocols, statistical analysis plans, intervention manuals, analytic code, common data elements, and successful independent replication across healthcare settings and populations.

Implementation: NIH could incorporate these measures into progress reports and final reports using standardized reporting expectations across funding mechanisms.

Potential unintended consequences: Expectations should be proportional to study design and resources so that requirements do not create unnecessary barriers for early-stage investigators or smaller institutions.

2. Data, Software, and Model Sharing: Scientific value extends beyond datasets and software. Many federally funded studies produce reusable resources such as intervention manuals, implementation toolkits, REDCap instruments, qualitative codebooks, common data elements, and longitudinal cohorts that enable future discovery.

Potential indicators: Number of external investigators using shared resources, incorporation into multicenter studies, citations of shared datasets or tools, and new grants or publications enabled by these resources.

Implementation: NIH could encourage standardized repositories and recognize resource development as a scholarly product within biosketches and progress reports.

Potential unintended consequences: Expectations for sharing should account for participant privacy, community agreements, and the additional resources required to curate high-quality datasets.

3. Training and Mentorship: Training should be evaluated by the success of the next generation of scientists rather than the number of trainees supported. Strong mentorship develops independent investigators, promotes interdisciplinary collaboration, and prepares scientists to address increasingly complex biomedical challenges.

Potential indicators: Transition to independent funding, scientific leadership, interdisciplinary publications, successful careers in biomedical research, and contributions to collaborative science.

Implementation: Standardized mentoring outcomes could be reported through existing NIH progress reports while recognizing differences across career stages and disciplines.

Potential unintended consequences: Evaluation should recognize that meaningful mentorship often extends beyond grant-funded trainees and that career trajectories differ across scientific fields.

4. Collaboration: Many of today's most important biomedical questions require multidisciplinary teams. Advances in prevention, treatment, survivorship, and chronic disease management increasingly depend on collaboration among laboratory scientists, clinicians, behavioral scientists, population scientists, implementation scientists, data scientists, and community partners.

Potential indicators: Sustained multidisciplinary collaborations, shared leadership, contribution-based authorship statements, development of shared research infrastructure, and collaborative grant funding.

Implementation: NIH could encourage standardized reporting of scientific contributions that complements traditional publication metrics.

Potential unintended consequences: These measures should complement rather than replace traditional indicators of scientific productivity, recognizing that collaboration opportunities vary across disciplines and career stages.

5. Entrepreneurship and Translation: Translation should be defined broadly to include both commercialization and implementation into routine healthcare and community settings. Many NIH-supported discoveries improve health through evidence-based care models, behavioral interventions, survivorship programs, caregiver interventions, patient navigation, and improvements in healthcare delivery rather than commercial products.

Potential indicators: Adoption by healthcare organizations, incorporation into professional guidelines, sustained implementation after funding, and documented improvements in patient care.

Implementation: Investigators could report implementation outcomes through existing NIH reporting mechanisms using standardized definitions.

Potential unintended consequences: Translation metrics should recognize that opportunities for commercialization differ substantially across scientific disciplines.

6. Foundational Scientific Exploration: Transformative discoveries arise across the full spectrum of biomedical science. In addition to laboratory discoveries, foundational advances may include innovative behavioral interventions, healthcare delivery models, implementation strategies, digital health approaches, and new conceptual frameworks for improving health.

Potential indicators: Development of novel scientific methods, demonstration of feasibility for innovative concepts, subsequent external funding, and evidence that new approaches influence future research directions.

Implementation: NIH should continue to support high-risk, high-reward research while recognizing innovation across multiple scientific disciplines.

Potential unintended consequences: Evaluation should recognize that transformative discoveries often require substantial time before their ultimate impact becomes evident.

7. Public Impact: Scientific impact should be measured not only by what is discovered, but also by what changes because of the discovery. Publications and citations remain important measures of scientific productivity, but they should be complemented by indicators that reflect improvements in health, healthcare delivery, and public health.

Research should be recognized for improving physical health, mental health, quality of life, functional status, symptom management, healthcare delivery, and long-term outcomes. Mental health and behavioral outcomes are fundamental components of health and should be valued alongside traditional biomedical outcomes.

Cancer survivorship illustrates this opportunity. Advances in prevention, detection, and treatment have created millions of cancer survivors living with the long-term physical, psychological, social, and financial effects of cancer and its treatment. Research that improves survivorship care, symptom management, care coordination, and quality of life translates scientific discovery into meaningful improvements in people's lives.

Potential indicators: Improvements in patient-reported outcomes, implementation into clinical practice, incorporation into professional guidelines, reductions in avoidable healthcare utilization, and measurable improvements in population health.

Implementation: These measures could be incorporated into NIH progress reports and final reports using standardized definitions appropriate to different research disciplines.

Potential unintended consequences: Because opportunities to influence policy or clinical practice vary across disciplines and career stages, these measures should complement rather than replace traditional scientific metrics.

8. Other Areas: ---

Other Areas

Biomedical research increasingly demonstrates that health is shaped not only by biology but also by behavior, families, healthcare systems, and the communities in which people live. NIH's framework for measuring scientific impact should explicitly recognize these dimensions.

Behavioral science, population science, implementation science, and health services research provide the essential bridge between discovery and improved health. These disciplines help determine whether scientific advances are adopted, sustained, and ultimately improve the lives of patients and families.

Family caregivers play a central role in prevention, treatment, survivorship, serious illness, and long-term management of chronic disease. They influence treatment adherence, symptom management, healthcare utilization, and patient well-being, while often experiencing substantial physical, emotional, and financial burdens themselves. Research that improves caregiver health and effectiveness has the potential to improve outcomes for both patients and families and should be recognized as an important contributor to NIH's mission.

Finally, NIH should recognize the value of community-engaged research that is conducted in partnership with the populations it is intended to serve and that disseminates findings back to those communities. Scientific impact is strengthened when discoveries are translated into sustainable improvements in health for individuals, families, healthcare systems, and communities.

1. Rigor and Reproducibility: Would like further clarification if qualitative research would follow under the requirements for rigor and reproducibility. Commonly, qualitative research is appropriately used in biomedical and public health research. However, the nature of qualitative research does not easily follow into the same classification as quantitative. Reproducibility may not always be the end goal with qualitative, simply being that qualitative research is extremely context dependent. Qualitative research still relies heavily on rigor, such as the use of triangulation, thick description, and transparent detail on how the researchers own experience can influence the interpretation of the data. With all the being said, would want to stress, that high-quality qualitative research, may not be reproducible, and these standards, in no way, limit high-quality, high-rigorous qualitative research.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: In addition to focus on quantifying mentorship, would also high-stress the importance of gathering qualitative data - focus on the quality of mentoring.

4. Collaboration: Collaboration is important. How will NIH assess international collaboration, especially where there is increasing standards and policies (including from the NIH) to limit international collaboration?

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

1. Rigor and Reproducibility: PUBLIC SUBMISSION TO THE NATIONAL INSTITUTES OF HEALTH (NIH)

Title: Restoring Gold Standard Science: Addressing Implementation Failures, Protocol Integrity, and Unvetted Assumptions in Federally Funded Clinical Trials
Target Mechanism: NIH Request for Information (RFI): Measuring Scientific Impact, Research Rigor, and Reproducibility (Notice NOT-OD-26-087)
Respondent: Hamid Khosrowshahi, President, FloSure Technologies LLC | Independent Forensic Medical Researcher & Patient Safety Advocate
Date of Submission: July 31, 2026

1. Executive Summary & Statement of Intent
The National Institutes of Health's initiative to refine how scientific impact, rigor, and reproducibility are measured is essential for safeguarding public trust and ensuring taxpayer funds deliver meaningful clinical outcomes. Traditional trial evaluation metrics often fail to distinguish between intervention futility and implementation failure. When a multi-million-dollar, federally funded trial suffers from execution flaws, unverified physical assumptions, and protocol non-compliance, publishing its conclusions as proof that a technology "does not work" misleads the medical community, distorts clinical practice guidelines, and harms patient care.
This submission presents a forensic case study of the NIH-funded PreVent 2 trial to illustrate how protocol degradation and unmeasured mechanical variables compromise research integrity. It outlines concrete governance reforms to ensure future NIH-funded interdisciplinary and device/interface research meets the highest standards of scientific rigor.
(Case Study Reference: PreVent 2 trial supported by the National Institutes of Health / National Heart, Lung, and Blood Institute under Grant Numbers R61HL138650 and R33HL138650).

2. Case Study in Research Degradation: PreVent 2 vs. Historical Verification Standards
A primary example of federal grant allocation yielding misleading outcomes is the NIH-funded PreVent 2 trial. Designed to evaluate Subglottic Secretion Drainage (SSD) and endotracheal tube (ETT) cuff materials, the trial suffered from fatal execution gaps and ignored established biophysical literature, invalidating its conclusions.

A. Redundant Human Exposure to Known Physical Hazards (The Berra 2004 Precedent)

The trial's protocol relied heavily on Continuous Aspiration Subglottic Suctioning (CASS) without incorporating mandatory verification or pressure-relief controls. It has been well-established in critical care literature for over two decades, specifically demonstrated in the animal model study by Berra et al. (2004), that unmonitored continuous suction creates a "vacuum-lock" against the tracheal mucosa, causing severe tissue trauma, port occlusion, and drainage failure.
Critically, the study's own investigators explicitly acknowledged in earlier 2010 and 2016 publications, including phase-one grant work (PreVent 1 under R61HL138650), that continuous subglottic suctioning CASS carries well-documented risks of severe mucosal injury and that intermittent methods offer safety advantages.
Despite this established evidence, the PreVent 2 trial utilized unmonitored CASS in human subjects under a $10M federal grant, predictably replicating the exact outcome of the 2004 animal model by generating an 83–84% tracheal mucosal injury rate. Using substantial public funds to subject human patients to a known mechanical hazard, only to confirm 20-year-old animal trial data and then misattribute the resulting mucosal trauma and port blockages to "technology futility", represents a profound failure in trial design, grant oversight, and research ethics.

B. The 30-Year Research Regression (1995 vs. 2025)
A forensic comparison between foundational verification studies (e.g., Vallés, Rello, et al., 1995) and PreVent 2 reveals a complete degradation of trial rigor (See Attached Figure: The 30-Year Research Regression):
1. The Verification Gap: Foundational 1995 protocols mandated 4-hour saline flushes to confirm subglottic port permeability. PreVent 2 abandoned active verification, leaving port functional status completely unknown throughout the trial ("zombie ports").
2. The Fluid Volume Blindspot: 1995 protocols recorded daily aspirated fluid volume to track physical fluid dynamics (addressing the 800–1500 mL/day of upper airway secretions documented in human physiology – Guyton & Hall 2020). PreVent 2 failed to measure or document evacuated fluid volume; claiming an evacuation device failed without measuring evacuated volume is a fundamental scientific contradiction.
3. Expanded Monitoring Windows: 1995 protocols required 4-hour cuff pressure checks to maintain seal integrity. PreVent 2 expanded monitoring gaps to 12-hour intervals, creating deliberate structural windows where microaspiration inevitably occurred regardless of cuff material.

C. Editorial Amplification and Guideline Distortions:
The systemic impact of funding methodologically flawed research is amplified when companion editorial commentaries immediately use implementation failures to advocate for clinical abandonment. Key leadership involved in national guideline panels (such as the SHEA/IDSA updates) authored accompanying editorials in The Lancet calling to "pull the plug" on subglottic secretion drainage, using PreVent 2's flawed implementation outcomes as justification.
This creates a closed feedback loop where trials designed with catastrophic execution gaps, such as unverified lines and unmonitored CASS protocol hazards, are immediately cited by editorialists to dismantle mechanical source control guidelines. Prematurely stripping away mechanical prevention measures directly compromises national patient safety initiatives targeting Ventilator-Associated Pneumonia (VAP), secondary Sepsis, Antimicrobial Resistance (AMR), and Post-Intensive Care Syndrome (PICS).

This forensic assessment reflects the established consensus of ventilator-associated pneumonia (VAP) research pioneers: SSD is highly effective when implemented well with active verification, but fails when basic operational controls are stripped away. Measuring poor implementation and misrepresenting it as "intervention futility" misleads the medical community and damages national clinical practice guidelines.

3. Actionable Policy Recommendations for NIH Grant Metrics & Research Oversight
To prevent taxpayer resources from funding trials that generate misleading clinical paradigms, the NIH should adopt four structural criteria for evaluating, funding, and auditing clinical research:

I. Mandatory Physical & Engineering Verification in Trial Design
Clinical trials evaluating physical, mechanical, or anatomical interventions (such as fluid evacuation, airway management, or mechanical ventilation) must undergo independent engineering and biophysical review before grant approval. Trial protocols must account for basic physical dynamics (e.g., fluid accumulation rates, surface tension, and gravity vectors) rather than relying solely on observational or behavioral checklists.

II. Structural Separation of "Implementation Failure" from "Intervention Futility"
The NIH must mandate that multi-center clinical trials institute verifiable, continuous protocol-adherence tracking. If a trial fails to enforce its own intervention protocol (e.g., unverified drainage ports, unmonitored 12-hour pressure gaps, or unmeasured volume outputs), the study outcome must be formally classified and indexed as an implementation failure, prohibiting authors from claiming intervention futility.

III. Formal Audit Mechanisms for Guideline-Impacting Federal Research
When forensic analysis reveals that an NIH-funded trial contained major protocol execution flaws that threaten national standard-of-care guidelines, the NIH Office of Research Integrity (ORI) or Office of Science Policy (OSP) should maintain a rapid-review mechanism. This panel would audit raw compliance data and issue formal scientific clarifications to prevent premature guideline downgrades.

IV. Institutional & Grantee Accountability Controls
To enforce reproducibility, NIH grant agreements should incorporate strict compliance milestones. Principal investigators and institutions that receive multi-million-dollar grants but abandon fundamental verification controls, misreport implementation failures as clinical futility, or refuse to address verified methodological discrepancies should face formal funding audits and restrictions on future federal grant eligibility.

4. Conclusion
Measuring true scientific impact requires looking beyond publication metrics to inspect the underlying mechanical and methodological integrity of funded research. By holding clinical trials accountable to basic physical reality and rigorous implementation standards, the NIH can eliminate the waste of public funds, prevent the premature abandonment of lifesaving mechanical interventions, and ensure that federal research drives true, reproducible progress in patient safety.

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: Enabling researchers to investigate the impact of research on policy decisions is critical and should not be misunderstood as lobbying. Research funded by the NIH/tax payers should be meaningfully shared with decision-makers including policy actors. This ensures that research funded by tax payers is one of many inputs for them to consider. Terminating or deciding to not fund research because it seeks to measure the impact of research on policy decisions would prevent real public impact from being achieved and be a bad return on investment for the public tax payers. An actionable recommendation is to encourage researchers to share their results with different audiences including the public and policy actors, and to not penalize researchers who aim to study the impact of research on policy decisions.

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: The ending of millions of dollars of funding for the research enterprise of the USA does not demonstrate a support of training or any interest in "promoting the growth and stability of the biomedical research workforce." There has been a clear impact of the NIH's current modus operandi on the research workforce. It is overwhelmingly negative with thousands of jobs lost, stark decreases in the number of trainees pursuing research careers, and a mass exodus of scientific talent from to US to countries that are much more transparent in their support of science.

4. Collaboration: N/A

5. Entrepreneurship and Translation: The NIH is not a business or a place to grow profits. The NIH exists to further the health and knowledge of the American people, not to line the pockets of millionaire and billionaire investors. This purpose is stated clearly in its mission statement which reads as follows: "NIH's mission is to seek fundamental knowledge about the nature and behavior of living systems and the application of that knowledge to enhance health, lengthen life, and reduce illness and disability." Nowhere in that statement is there a mention of entrepreneurship or products. Innovation to further knowledge and to expand the scientific toolset should be rewarded and incentivized, whether or not it results in a new patent or product.

6. Foundational Scientific Exploration: N/A

7. Public Impact: See my comment above on "Entrepreneurship and Translation". Economic growth is not the end goal of scientific research. Additionally, what the Trump administration and Dr. Bhattacharya view as "societal benefit" should not be used as a gold standard. Famously, they both are willing to perpetuate bigotry, disinformation, and hate backed up by research that has been proven to be fabricated, misrepresented, or without basis in scientific fact.

123. Aimee Payne, MD, PhD

I am responding: On behalf of myself

Name: Aimee Payne, MD, PhD

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/3/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: T/F/K awards are essential to support our biomedical research workforce. One issue that is most affecting the success of these efforts currently is the uncertainty of future funding and university cutbacks in many areas of the research mission (eg, fewer graduate students trained, less dollars going to research faculty recruitment in favor of investing in the clinical enterprise, etc). I am hesitant to recommend putting more administrative burden on universities receiving T/F/K awards to prove how well they are doing (beyond what is already required) during a period when institutions are cutting back on hiring due to uncertainty of federal support for research.

4. Collaboration: To a certain extent, recognition of team-based science is already captured through the h-index, which reflects highly cited papers agnostic to where the researcher is in the author list (this can disproportionately reward individuals who participate in reviews and clinical guidelines and not recognize papers where the PI was corresponding or first author - to my knowledge no index measures that important measure of impact). I agree that team-based science is important (which often occurs through P/U mechanisms), but an equally important issue going forward is that we need to ensure that our foundation of investigator-initiated and single PI-based studies remain funded as they are an essential component of developing new knowledge. The US research enterprise became powerful because we trained students and junior faculty through individual and institutional T/F/K awards and then supported the most competitive applicants to pursue new knowledge in the research fields they know best through R/P/U mechanisms, with additional awards such as ARPA-H and DOD funding to support targeted initiatives of national interest. When individuals are strong, team science becomes powerful. If there is not a diverse and deep foundation of expertise across individual faculty, then team science can't achieve its potential.

5. Entrepreneurship and Translation: ARPA-H and SBIR/STTR address this to a certain extent. One challenge is when the call for applications becomes overly proscriptive, as this can run the risk of duplicating what the private sector is already prioritizing and missing out on innovative ideas that need help to advance before they become commercially viable.

6. Foundational Scientific Exploration: 100% agree. There needs to be funding support for faculty who create new knowledge and devote their time and careers to this pursuit.

7. Public Impact: N/A

8. Other Areas: N/A

124. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/3/2026

1. Rigor and Reproducibility: First of all, goals (short-term or long-term) of majority of research is identify targets or develop interventions. If the researcher able to identify targets, develop target-specific interventions and advance from preclinical to commercialization. That is a clear indication of rigor and reproducibility and trying to full fill the promised goals. If the research does not go anywhere except several grants and publications, it is not helping taxpayers or society and simply helping the researchers from friendly peer review both in terms of a greater number of grants and publications. This also short chains another researcher who earnestly trying to contribute to the society. This may be one of the reasons we do have cures for all most all major diseases despite decades and decades public funding for research.

2. Data, Software, and Model Sharing: Data, software and model sharing is useful but not sure how much this would advance. Best way to encourage and reward the research is to reward to those who transitioned basic preclinical bench research to clinical trial and commercialization. This will encourage others follow the same path.

3. Training and Mentorship: Useful for developing next generation scientists. However, majority of scientists main goal is to get more grants and publish more to advance their career and promotion beyond that this type of research goes nowhere.

4. Collaboration: Interdisciplinary collaboration is very helpful to advance in short time.

5. Entrepreneurship and Translation: This really needs to be encouraged, supported and rewarded. This represents rigor, reproducibility and achievement of goals. Discourage researcher obtained grants after grants for 20-30 years with a promise of interventions but never advanced anything except publications and grants with help of friendly review and career advancement in research administration.

6. Foundational Scientific Exploration: This is not helpful in my opinion.

7. Public Impact: Public impact such as health outcomes, economic growth and societal benefit should be the measure and not publications, grants, impact scores or career advancement of the researcher. In fact, researchers above Departmental chair has hardly time to devote for research and funds better utilized on those whose devote whole time on research and not career advancement in research administration.

8. Other Areas: Encourage those try to patent and commercialize their research societal use and reward those who advanced their research through clinical trials. They may develop and advance many more bench to bedside transition through their research if encouraged properly and others will follow.

125. Peter Karp

I am responding: On behalf of myself

Name: Peter Karp

Name of Organization: SRI International

Type of Organization: Non-Profit Research Organization

Role: Investigator/Researcher

Date Submitted: 8/3/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: In the bioinformatics field, our primary outputs include online databases and software tools. Both can be characterized and measured to a degree.

For example, to assess the contributions of a researcher who has developed a database, we would ask questions such as what is the
size of the database? What is its scope in terms of the types of data it captures? Does the database occupy a novel niche, and did
the researcher invent that niche, or did they simply maintain a database that was conceptualized by someone earlier? What type
of search mechanisms, data quality improvements, visualizations, and analysis tools does the database provide?

To assess the contributions of a researcher who developed a software tool, we should also consider the size of that
software tool, since software can vary in size by several orders of magnitude. Someone who has authorized a
software tool consisting of a million lines of code has made a contribution that is 100x more significant (along that dimension) than someone
who developed a tool containing ten thousand lines of code. As with the case of a database, the software contribution
should also be assessed based on its originality and the scope of problems that it solves.

3. Training and Mentorship: N/A

4. Collaboration: Perhaps have each of the principal contributors in a team assess the magnitude of the contributions
made by the other contributors, and average the results.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: I have been disappointed in recent years to see that NIGMS has measured investigator productivity based simply

on the number of publications they published. Although publication counting could be an element of a larger
approach to measuring productivity, by itself this approach is much too simplistic because publications vary
tremendously in significance.

7. Public Impact: N/A

8. Other Areas: N/A

126. Jun Yang

I am responding: On behalf of myself

Name: Jun Yang

Name of Organization: St Jude Children's Research Hospital

Type of Organization: Non-Profit Research Organization

Role: Investigator/Researcher

Date Submitted: 8/3/2026

1. Rigor and Reproducibility: Rigor and reproducibility are critical to science. However, relying on validation by independent third-party labs is often inefficient and resource-intensive. A far more effective strategy is integrating cross-validation into the active research phase through multi-lab collaborations. For example, NIH initiatives such as MPI grants can require participating groups to independently test and validate each other's key findings prior to publication. This proactive co-validation model offers two major advantages:
(1) Resource Efficiency: It leverages existing grant infrastructure, reagents, and expertise across collaborating sites rather than requiring a third party to rebuild a project from scratch. (2) Proactive Rigor: It identifies potential discrepancies, batch effects, or protocol sensitivities before data reaches the public domain, directly curbing the reproducibility crisis. By embedding internal replication into the research design itself, funding agencies can maximize the impact of research dollars while significantly raising the standard of scientific reliability.

2. Data, Software, and Model Sharing: To accelerate scientific discovery and enhance data integrity, NIH could introduce a payline bonus for open science. Under this model, PIs and laboratories that consistently practice active, transparent sharing including raw datasets, custom software, analytical code, and research models would qualify for a favorable adjustment to their grant paylines (e.g., a percent-line boost or a dedicated score discount during review).

3. Training and Mentorship: Evaluating mentorship and training productivity presents a challenge. Institutions vary wildly in size: some have a low turnover of graduate students, while others struggle to attract top postdoc talent due to location or resources. To create a fair, standardized metric for grant evaluation, NIH could track the publication productivity and fellowship grant awards of the specific trainees funded by the grant. Specifically, NIH can assess how many peer-reviewed papers are published and/or grants are obtained by the postdocs and graduate students explicitly listed in the grant's budget justification.

4. Collaboration: Scientific collaboration should be defined by intellectual and operational contributions, not resource gatekeeping. When tools, mouse models, software, or reagents are developed using NIH grant funding, they are public assets that should be shared openly with the research community. Simply providing access to an existing grant-funded resource does not inherently constitute co-authorship or formal collaboration.

5. Entrepreneurship and Translation: NA

6. Foundational Scientific Exploration: N/A

7. Public Impact: Such impact may take a long term to manifest. NIH could use AI to predict the impact.

Name: Mikail Rubinov

Name of Organization: Vanderbilt University

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/4/2026

1. Rigor and Reproducibility: • Many scientific results are exciting, replicable, and accepted in the literature, but are also redundant with existing knowledge, in a way that is often hard to discern. The accumulation of these results in the literature creates a false impression of progress even as it actually indicates stagnation (and leads to wasted time, money, and effort).
• This problem is especially important in basic biomedical research where rapid advances in methods, data, and analyses can coexist with vast, scattered, and implicit bodies of existing knowledge. See this article for an illustration of the scope and importance of this problem in systems and network neuroscience: https://elifesciences.org/articles/79559
• The NIH needs to incentivize the development of new rigorous statistical tests of proposed novelty against established existing knowledge. The ideal deliverables of such incentives would be new hypothesis tests for basic research fields that match the highest standards of evidence of other fields (most notably randomized controlled trials).

130. Professor

I am responding: On behalf of myself

Name: Professor

Name of Organization: Major university

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/4/2026

1. Rigor and Reproducibility: Unfortunately, this is being approached by the NIH/NHLBI from a small game perspective, e.g. high enough Ns, good stats etc. This does not address the problem of publication of highly ambitious papers that no one even tries to reproduce because of their specialized technical nature. Much of this is being driven by for-profit journals such as Nature and Cell press. It is much less of a problem in lower impact but highly respected journals. The NIH can most improve their analysis by mandating service on NIH study sections. The lack of expertise is very noticeable and influences peer review in a very negative way.

2. Data, Software, and Model Sharing: This seems like less of a problem in my mind. The present arrangements mostly work. Again, the major issues are with the journals.

3. Training and Mentorship: There is irony here. The NIH seems to be favoring the funding of younger investigators to an extent that their natural mentors will need to retire early and thus they create the vacuum they are most concerned about.

4. Collaboration: N/A

5. Entrepreneurship and Translation: This is over-emphasized by the NIH and NHLBI. The SBIR/STTR is quite effective, but the main role of the institute should be to advance basic science knowledge. The free market should and does ensure timely translation.

6. Foundational Scientific Exploration: The concept of "high risk high reward" usually means high speculation little data in the real world. I think that most exciting ideas are funded in a reasonable time frame. Throwing money at promises that mostly cannot be kept is not the answer here. Instead, the institute should not lose sight of the importance of funding basic science research.

7. Public Impact: When the head of HHS and NIH are actively pursuing strategies known to negatively impact the health of American citizens, it is pointless to address this question.

8. Other Areas: N/A

1. Rigor and Reproducibility: As far as I am concerned, this focus on reproducibility is a bit of a boondoggle (also know as a "pipe dream")!!! Two observations during my 50 years as a "basic" scientist: (1) Results are often not strictly reproducible. This in fact 'drives' science and is in fact very important; i.e., if something is not reproducible, that drives investigators to investigate why! (2) Observation #1 no doubt is highly dependent on the number of observations! This means that funding agencies need to recognize the importance of non-reproducible results, as well as negative results, and provide the funding sources to replicate the results and determine why they are providing what on the surface seem to be conflicting results!!!

2. Data, Software, and Model Sharing: This effort, again, is in my opinion a bit of a boondoggle. This already is a component of every grant I submit to review, and I have served, since 1986, on 75 federal grant-review panels for NIH (61, chair of 7), USDA (10, chair of 2), NSF (1, ad hoc reviewer), and the Fulbright Scholar Program (3). I have also reviewed grants for federal programs in Australia, Brazil, Canada, France, Germany, Holland, Hong Kong, Israel, Italy, the U.K., Norway, Poland, Spain, and Switzerland.

3. Training and Mentorship: As with any assessment of research quality and impact, this can and should be reflected by publications, grants, and positions attained by mentees, as well as the participation of mentees in their profession; e.g., grants received, collaborations, invited talks, etc. This already is done and evaluated for training grants, so, again, a bit of a boondoggle!!!

4. Collaboration: Other than joint publications and lists of collaborators, and perhaps letters of support from current and past collaborators, I can see no other "approaches" for "assessing and recognizing contributions to team-based science." Again, this "seeking" is a boondoggle and makes me think the "seekers" have had little experience in actually doing science!!!

5. Entrepreneurship and Translation: The only thing I can see in terms of "More [that] can be done to incentivize, assess, and integrate the impact of innovation and entrepreneurial efforts as critical to the NIH mission" is to provide more support for grant programs designed to promote "translation of discoveries into products for people!!!"

6. Foundational Scientific Exploration: In my view, the only thing that will "Further [embed] these approaches within the academic enterprise" is to provide additional funding and programs to do so. Again, another boondoggle.

7. Public Impact: This is the only topic that is not a boondoggle. Additional support, including grant programs and funding, for "assessing and recognizing the broader public impact of biomedical research, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit" is certainly warranted. In fact, based on this NIH effort on which I am commenting, even the NIH leadership has little understanding of how science is done, how it progresses, and the needs for advancing science, which, to me, from a federal standpoint is very well in-hand for many decades now, but simply needs more monetary and public (meaning from those connected to the public, like politicians for example) support!!! As I often tell my students and mentees, "This is not magic - the bottom line is the need for support, especially monetary - see places like the EU for example!!!

8. Other Areas: Glad to discuss this with NIH officials at any time!!!

3. Training and Mentorship: N/A

4. Collaboration: Rubrics commonly utilized for promotion metrics on the research track in academic medicine remain focused on metrics tailored to individual investigators and do little to acknowledge or reward significant contributions to team science, particularly if the contributor was not named first or senior author on any resultant publication. This essentially penalizes collaboration by not viewing it as an important and valuable contribution towards science and towards the growth of the investigator's research program and institution. A byproduct of this is that investigators know that having their name anywhere other than first or last is not seen as significant intellectual contribution, which can be misleading and paint an inaccurate picture of an individual's important contributions, and as such, may be hesitant to engage with groups where they are not the lead. This is harmful for individual career trajectories, talent retention, and addressing the more challenging questions that our research is trying to address.

1. Rigor and Reproducibility: Although the number of times an article is cited by another publication is important, understanding the impact of our research beyond this traditional measure is equally important to provide a total view of impact as well as rich context for that citation. However, to accomplish this, the NIH needs to provide resources for personnel to implement, monitor, and address these alternative metrics. There needs to be an additional budget item, beyond the budget max for the research, for this effort. Research dollars are already maxed out on many projects; we are often asked to do more with less. We will not be able to effectively have a broader impact and track that broader impact without additional funds, even small amounts like $50k per year.

Suggested indicators:
- # times researchers post their scientific findings on a public facing site or social media platform, and then the number of times that post is shared, mentioned, commented on, and forwarded.
- # times article is posted by someone else, and then the number of times that post is shared, mentioned, commented on, and forwarded.
- # times study, article, or researcher is cited in a news media piece or interviewed for the news media

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: '- # papers a researcher publishes with a student
- where student collaborators are employed after graduation (government, corporate, NGO, etc.)
- student evaluations of researcher mentorship: quantitative Likert scale ratings of satisfaction, amount learned, preparation for the workforce

4. Collaboration: '- # partners from different sectors who collaborate on a project, including those from the community, NGO, etc.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: '- # testimonials researcher gives to legislatures when considering a piece of legislation
- # times article is cited in policy document or piece of legislation
- research submissions to public dockets for regulatory rule-making

8. Other Areas: Although the number of times an article is cited by another publication is important, understanding the impact of our research beyond this traditional measure is equally important to provide a total view of impact as well as rich context for that citation. However, to accomplish this, the NIH needs to provide resources for personnel to implement, monitor, and address these alternative metrics. There needs to be an additional budget item, beyond the budget max for the research, for this effort. Research dollars are already maxed out on many projects; we are often asked to do more with less. Role: Investigator/Researcher

Date Submitted: 8/5/2026

1. Rigor and Reproducibility: Measurable indicators should include, but are not limited to:
Independent replication of findings in external datasets or cohorts. Investigators should be encouraged to pool resources. Collaboration is key to avoid findings from single centers that are not reproducible.
Public sharing of analytic code and statistical protocols to allow transparency of what was done, particularly for clinical research.
Publication of well-conducted negative or confirmatory studies. Less emphasis on publication of positive studies, which further leads to publicationi bias.
Adherence to reporting guidelines (e.g., CONSORT, STROBE, PRISMA).
Correction of errors when identified, including retractions of publications if necessary.

Rewarding reproducibility would encourage researchers to prioritize robust science over novel but irreproducible findings.

However, NIH should avoid creating burdensome documentation requirements that divert investigators' time from conducting research. The change from the NIH biosketch template to requiring ScienCV formatted biosketches was one example of such a requirement.

2. Data, Software, and Model Sharing: Investigators should be able to provide persistent links (DOIs, GitHub repositories, data repositories) to allow for public sharing of analytic code and statistical protocols to allow transparency of what was done, particularly for clinical research. Shared resources often generate far greater scientific impact than a single publication because they enable future discoveries by many investigators.

NIH should support collaborative data access across institutions. Siloed research is not the most rigorous or reproducible research.

3. Training and Mentorship: Training and mentorship should be recognized as core measures of scientific impact because one of NIH's most enduring contributions is the development of the next generation of biomedical researchers. The impact of a scientist extends beyond their own publications and discoveries to the people they train, mentor, and sponsor, who in turn advance science throughout their careers.

As an NIH-funded early-career physician-scientist, my perspective on mentorship is informed by my own lived experience. I was the child of immigrants and a first-generation college graduate, and I have

experienced firsthand how access to opportunity is often shaped by circumstances beyond one's control. I also know the transformative impact that mentors and sponsors can have in opening doors that otherwise might have remained closed. These experiences have shaped my approach to academic medicine and reinforced my belief that current faculty/research PIs have a responsibility not only to train future scientists, but also to recognize potential, invest in others, and create opportunities for them to succeed.

My own mentorship has centered on clinical research, where I have worked with medical students, residents, fellows, and junior faculty. Through projects supported by foundation awards and my NIH K23 award, trainees have presented research at regional and national scientific meetings, published peer-reviewed manuscripts, and continued into successful academic careers. Equally important has been serving as a sponsor by introducing trainees to collaborators, encouraging them to pursue ambitious opportunities, and helping them build the professional networks that sustain long-term scientific careers. It has been especially meaningful to mentor trainees who, like me, are first-generation college graduates, international medical graduates, or individuals from backgrounds that have historically faced barriers to careers in medicine and biomedical research.

NIH should therefore evaluate mentorship using meaningful outcomes rather than simple counts of trainees. Examples include evidence that trainees have developed independent research skills, presented their work at scientific meetings, published peer-reviewed research, obtained research funding, or advanced into careers that contribute to biomedical science and health care. Evaluations should also recognize sponsorship, interdisciplinary mentorship, and sustained commitment to trainee development.

At the same time, expectations should be appropriate for career stage. Early-career investigators have had fewer years to establish mentoring relationships, and therefore should not be expected to demonstrate decades of trainee outcomes. Instead, evaluation should focus on evidence of thoughtful mentorship practices and meaningful contributions to trainee development relative to opportunity.

Recognizing mentorship as a component of scientific impact would reinforce NIH's long-standing investment in building a strong, innovative, and sustainable biomedical research workforce. The discoveries that improve health tomorrow will depend not only on today's research, but also on today's trainees becoming tomorrow's scientific leaders.

4. Collaboration: NIH should ask investigators to describe their intellectual contributions to team science. Modern biomedical research increasingly depends on collaboration across institutions, disciplines, and countries. These collaborations improve scientific rigor by testing whether findings are reproducible in different populations. Important to the idea of multidisciplinary collaboration is INTERNATIONAL collaboration. For example, I recently completed a study with well regarded investigators in my field who are based in Europe. Each group analyzed its own patient cohort using harmonized methods, and we compared results across populations. Neither institution transferred patient-level data, as per the legal data use agreements at each site, but together we produced substantially stronger evidence than either group could have generated independently. Evaluations should recognize this type of collaboration as a marker of scientific impact. We should not be discouraged from international collaboration, if the expertise of tour collaborators is warranted. The NIH

should avoid paperwork that puts up barriers to international collaboration. Such scientific collaboration is fundamental to rigorous biomedical research and should be rewarded rather than discouraged.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: Foundational science often has delayed impact and may not immediately generate high citation counts or clinical applications. Supporting foundational research preserves the pipeline of discoveries that ultimately lead to new diagnostics and therapies. Careers and downstream research are also being supported. Short-term productivity metrics should not disadvantage high-risk, high-reward science whose greatest impact may emerge years later. It is also important to recognize that sudden terminations or delays in awards causes downstream effects that last over years and potentially decades.

7. Public Impact: The ultimate measure of NIH-supported research is its ability to improve the health and well-being of the public. Accordingly, public health impact should be evaluated based on measurable improvements in health, evidence-based communication, and the translation of scientific discoveries into policies, clinical practice, and interventions that benefit patients and communities.

Improving the health of the public means improving the health of ALL people. Achieving that goal requires recognizing that disease burden, access to care, and health outcomes are not distributed equally across the population. Many communities experience disproportionately high rates of disease because of longstanding differences in access to healthcare, preventive services, environmental exposures, socioeconomic conditions, and other social determinants of health. Research that identifies these disparities, seeks to understand their underlying causes, and develops interventions to reduce them is ESSENTIAL to NIH's mission of improving health for the entire nation.

Scientific impact should therefore include research that advances health equity by ensuring that discoveries are relevant to the populations most affected by disease. This includes conducting studies in populations that have historically been underrepresented in biomedical research, developing interventions that are effective across diverse communities, and generating evidence that helps clinicians and policymakers reduce avoidable differences in health outcomes. Focusing on populations that face the greatest barriers to health is not at odds with improving health for everyone; rather, it is often the most effective way to improve the health of the population as a whole.

Public impact should also recognize investigators who communicate science responsibly to clinicians, patients, policymakers, and the public. Accurate, accessible communication is essential for translating research into practice, maintaining public trust in science, and ensuring that scientific discoveries ultimately improve health. Measures of public impact should emphasize evidence-based educational activities, contributions to clinical guidelines and public health recommendations, development of patient and clinician educational resources, and demonstrated improvements in healthcare delivery or health outcomes. Popularity on social media or media attention alone should not be considered evidence of scientific impact.

Finally, NIH should continue to value a biomedical research workforce that brings diverse perspectives and experiences to scientific discovery. Diversity in backgrounds, disciplines, life experiences, and scientific approaches strengthens research by fostering innovation, challenging assumptions, broadening

the questions that are asked, and improving the relevance of research to the populations NIH serves. Evaluation of public health impact should recognize investigators who build inclusive research teams, engage meaningfully with the communities affected by their research, and produce science that is applicable across the diversity of the U.S. population.

8. Other Areas: As an NIH-funded early-career physician-scientist, I encourage NIH to recognize that scientific impact is created not only by individual discoveries, but also by the activities that make those discoveries rigorous, reproducible, and useful. Collaboration, dissemination through peer-reviewed publications and scientific meetings, sharing of data and analytic tools, and mentorship should be viewed as central components of scientific impact rather than secondary activities. The United States has become a global leader in biomedical research because it has fostered openness, collaboration, and scientific exchange. This necessarily includes international collaborations, as well as supporting researchers' ability to attend conferences to further collaborate and disseminate results, and support researchers in publishing their findings in peer reviewed journals. Outside of research funding, we do not have alternative means to support our attendance at conferences or publications in journals that charge publication fees. Removing our ability to include such items in grant budgets does a huge disservice not just to us but to scientific research in this country overall. NIH's evaluation framework should reinforce these strengths while avoiding unnecessary administrative burdens that reduce the time investigators can devote to conducting high-quality research.

1. Rigor and Reproducibility: Current and proposed indicators of rigor share a common weakness: they measure whether a practice occurred, not whether it constrained anything. Pre-registration is the clearest example. It is easy to count and easy to satisfy without a single analytic decision being bound by it. If NIH adopts registration as an indicator, the predictable unintended consequence is decorative registration — plans written loosely enough to accommodate any result, filed to satisfy a checkbox.

I would suggest three indicators that are equally countable but substantially harder to game.

1. Presence and content of a numbered deviation log. A registered plan that produced no deviations is either trivially simple or not being read honestly. What distinguishes bound work is a public, itemised record of where the analysis departed from the plan and why. This is machine-checkable: does a deviation log exist, is it numbered, does each entry state the registered specification, the change, and the rationale?

2. Whether the registered primary outcome is reported regardless of direction. The indicator is the ratio of registered analyses to reported analyses, and whether the registered primary endpoint appears in the abstract when it returns a null. A registration that produced a null primary result and a paper that leads with a secondary finding is a detectable pattern.

3. Advance declaration that all outcome branches are publishable. In a recent pre-registered analysis of county-level Medicare fee-for-service preventable hospitalizations across 3,061 counties (OSF registration DOI 10.17605/OSF.IO/9U4AE), I declared in the registration that all four possible outcome branches — material, mechanical, robust/null, and ambiguous — were publishable before any model was fit. This costs nothing to state, is verifiable against the frozen registration, and removes the author's own exit route from a null.

On unintended consequences, I want to name one from direct experience. That study's registered primary contrast returned a null. Its most substantive finding was unregistered and unfavourable to my own work: three of the four highest-ranked predictors partially re-measured the outcome, because inpatient-setting encounters were counted inside the outcome definition — a fact documented only in an appendix of the source methodology, not in any variable label or data dictionary. Reporting it reduced spatially blocked model performance from R^2 0.321 to 0.236 and reordered the attribution ranking more

than the registered question had. Disclosing this made the paper harder to place, not easier. Under any indicator that counts registrations, deposits, or publications, that study is indistinguishable from one where the registration changed nothing. Self-correction is currently paid for entirely by the researcher who performs it, and no existing metric can see it. If NIH wants a single indicator worth building, it is this one.

2. Data, Software, and Model Sharing: The current standard is availability: data are deposited, code is posted, a statement appears in the manuscript. Availability is necessary but it is a weak indicator, because it is satisfied by deposits that no one can execute and that no one has checked against the paper's claims. I would propose shifting the measured quantity from availability to verifiability, and offer three concrete, implementable indicators.

1. Proportion of numeric claims in the manuscript machine-checked against the deposited data. In the study referenced above I deposited two executable verification programs alongside the dataset: one that recomputes every shared figure in the analysis reports directly from the data, and one that parses the report text and checks every numeric claim in the prose against the underlying dataset, flagging any mismatch. Both passed with no mismatches. This is not exotic tooling — it is a few hundred lines of Python — but it converts "the data are available" into "the claims in this paper have been mechanically checked against the data." The indicator is the fraction of reported numbers under automated verification, which a repository can compute.

2. Cryptographic binding of the dataset and feature set at registration. My registration records two SHA-256 hashes, one fixing the analytic dataset and one fixing the feature list, both checkable against the deposited files. This makes silent substitution of the data between registration and publication detectable by anyone, at essentially zero cost. Repositories could compute and display this automatically.

3. Machine-readable derivation provenance for every variable, not just labels. The contamination described above was undetectable from variable names and would have remained undetectable from any ordinary data dictionary. It was visible only in an appendix describing how the outcome measure was constructed. The measurable requirement is that shared datasets carry derivation formulas and source-code composition at a level sufficient to detect overlap between a feature and the outcome. As secondary analysis of administrative and claims data becomes more common, and as machine learning makes feature counts larger, this failure mode will become more frequent, not less — and post-hoc explanation methods will faithfully rank the contaminated variables at the top.

On unintended consequences: any indicator based on counting deposits or download volumes will reward the deposit of many low-value datasets and disadvantage fields where a single well-documented dataset represents years of work. Weighting by verification and reuse, rather than by count, avoids this.

3. Training and Mentorship: Existing indicators count trainees. A more informative measure is whether trainees can independently reproduce work they did not perform. I taught graduate research methods as an adjunct for twelve years and currently supervise doctoral research. In my experience the single most transferable skill is not statistical technique but the discipline of pre-specifying an analysis and reporting deviations from it — and it is almost never assessed. A measurable indicator: the proportion of trainees who have registered an analysis plan and published a deviation log before completing their degree.

4. Collaboration: Team science is increasingly multinational, and NIH-funded work frequently depends on investigators and institutions in the countries where data are collected. Credit for those contributions is systematically under-recorded, and it is measurable.

I have directed research teams across six countries and worked with more than fifty partner organisations. In that setting the recurring pattern is that in-country investigators design instruments, negotiate government access, secure ethics approval, and collect and clean the data, then appear in acknowledgments rather than authorship, or in middle positions that no metric registers.

Three implementable indicators:

Authorship distribution relative to data origin. For studies using data collected outside the US, the proportion of first and senior authorships held by investigators based in the country of data collection. This is computable from existing metadata and is already tracked in some bibliometric work.
Completeness and machine-readability of CRediT statements. CRediT exists but is applied inconsistently and rarely audited. The indicator is whether every listed author has at least one assigned role, and whether the statement is deposited in structured form rather than as prose.
Whether data-collection partners appear as authors at all. A binary, checkable field.

On unintended consequences: any indicator that counts collaborators, institutions, or co-authors will reward gift authorship and large consortia over genuine contribution. Distribution and role-completeness are harder to inflate than headcount.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: Publication and citation counts are poor proxies for whether findings changed anything, and the most consequential outcomes of applied health research are currently uncounted.

Two examples from my own work. Findings from a task-shifting evaluation of community health workers in Burkina Faso were adopted by the national government and incorporated into programme policy. Evidence from an adolescent sexual and reproductive health programme in Kenya contributed to revision of the national adolescent reproductive health policy. Neither appears in any citation-based metric, and neither would register under any indicator NIH currently uses.

Suggested indicators:

Citations in policy documents, clinical guidelines, and government technical reports, tracked with the same infrastructure now used for scholarly citations. The technical capability already exists commercially; what is missing is that it does not count toward anything.
Time from publication to first documented guideline or policy incorporation. This measures whether the research reached the people who act on it, and it rewards accessibility and clear reporting rather than novelty.
Explicit inclusion of non-US and low-resource settings. NIH-funded evidence is frequently applied in health systems that produce no indexed literature of their own, and any tracking built only on US and

European policy corpora will systematically under-count it.

On unintended consequences: altmetric and media-mention indicators are already available and should be resisted as impact measures. They reward controversy and volume, and they are trivially manipulable in ways that policy citation is not.

8. Other Areas: The RFI asks for considerations of feasibility across career stages, disciplines, and institution types. I would ask NIH to consider a group the phrase "institution types" does not quite reach: researchers with no institution at all.

I am an independent researcher. The pre-registered study described in my earlier responses was designed, built, analysed, and written without institutional affiliation, library access, departmental support, or funding. Every open-science practice NIH wishes to reward — registration, data deposit, verification tooling, transparent reporting of a null — was available to me at no cost, and I used all of them. That is worth stating plainly: open-science indicators are more feasible for unaffiliated researchers than almost any other marker of scientific standing.

The obstacles sit elsewhere, and they will distort whatever indicators NIH builds:

Article processing charges are borne personally. An indicator rewarding open-access publication penalises exactly the researchers for whom open science is otherwise cheapest.
Verification and replication work earns nothing. There is no mechanism by which someone who checks another group's deposited data and finds an error receives credit. An ORCID-linked, citable record of verification contributions would be a specific and implementable start.
Registration infrastructure is open to anyone; institutional review is not. Independent researchers working with public secondary data can register and deposit but often cannot access an IRB. Any indicator conditioning on institutional review excludes this population by construction.

This is not only a fairness argument. Replication and verification are precisely the activities that require no institutional resources, and they are going undone in a system where they earn nothing. A population capable of performing them exists and is currently invisible to every metric NIH uses.

136. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/5/2026

1. Rigor and Reproducibility: I agree that scientific research needs to be rigorous. However, the definition of what constitutes rigor is not clear. Clarifying that definition will be critical to utilizing it as any sort of standard to compare research practice against. Reproducibility of research findings has always been a fundamental element of the scientific method. The goal of any Methods section of published work is provide enough detail that another scientist could replicate the approach and check their findings against others using the same approach. The current model of 'publish or perish' in the tenure-track system within universities does put a damper on publishing replication studies, as these are often not reviewed well when submitted for publication. However, how many replication studies are necessary for any given finding? Is 3 enough? Is 1,000 enough? How much research funding needs to go toward reproducibility before it is considered a waste of taxpayer money? And how closely does a replication study's finding need to be to the original finding to be considered 'reproduced'? Further, in the event where many groups publish findings on a similar topic, but use different methods, how does one determine which study is the original against which the others are compared? And who determines what the 'gold standard' is in any field of study? These are the practical challenges to implementing the ideals which this initiative seems to promote.

2. Data, Software, and Model Sharing: Data, software and model sharing are great ideals. Many areas of scientific research have been pushing these ideals for the past 20 years or more. However, there is currently not incentive to do so, besides recognition by colleagues that some ideal has been upheld. Instead, there is a competing ideal which our society seems to favor; that is the ideal that keeping things proprietary or protecting them with IP makes them more valuable, which can then financially incentivize researchers in the event that they may be able to license their data, software or models to industry, or start their own company to utilize the approach for financial gain. It seems that our society values the proprietary for-profit model more than it does the free sharing of knowledge. For ideal of sharing to be incentivized, one would need some certainty of financial benefit to offset the incentive of protecting ideas for financial benefit.

3. Training and Mentorship: Though there are many great NIH policies and programs that support training and protect trainee time for workforce development, the barrier to entry is quite large. Successful acquisition of fellowship funding through the existing F30/31/32 models is seemingly still based on reputation of PI or Institute rather than inherent quality and potential for growth of the trainee. On a slightly different topic, the changes made over the past 18 months to immigration and visa

applications has greatly reduced the number of high quality trainees who are able to join the scientific training that our country has to offer, thus reducing the future research workforce.

4. Collaboration: Recognition of team-based research needs to be implemented at the institution level so that researchers are rewarded for such collaboration in the form of high confidence of securing tenure and promotion. Additionally, the NIH needs to provide well-funded opportunities that are specifically targeted to researchers who are engaged in multi-institutional research, or who would like to. To often, the will and the interest is strong between researchers to collaborate, but the mechanisms to support the work does not exist or is not sufficient to carry out the work. This disincentives researchers from this ideal, causing them to pursue smaller, single-PI funding mechanisms.

5. Entrepreneurship and Translation: This ideal would seem to be contrary to the one listed previously regarding "Data, Software, and Model Sharing". The SBIR/STTR program is already a great program. Investing more resources into that program would be great! Additionally, I think it is necessary to provide even earlier pilot funding to researchers who are developing their ideas for translation to market but haven't yet formed a business.

6. Foundational Scientific Exploration: Agreed. There should be a well-supported mechanism for high-risk/high-reward proposal. Over the years, the R21 mechanism has become less likely to be funded, as it seems the reviewers tended to review these applications as if they were R01s, especially in the expectation that there would be strong preliminary findings. I think this reviewer bias was natural, because these have typically been reviewed in the same panels as R03 and R01 submissions. In an entire review panel's agenda, a minority of proposals would be R21s, and they seemed to not get sufficient focus. I would recommend that the review of R21 proposals (or similar high-risk mechanism) should occur in it's own focused panel, with very explicit instructions given to reviewers to not treat the proposals as if they were R01s.

7. Public Impact: I agree that there should be more benefit given to research that can demonstrate translation into real-world public impact. NIH has not been known as the federal agency which funds applied translational work, but rather has been generally known as the home for basic science discovery research. My own work has been easier to fund with industry-sponsored research agreements or with donor support than with NIH support, because my work is in the realm of human health benefiting from sport.

8. Other Areas: If the NIH wants to continue to be seen as the world-leader in biomedical scientific research, it is critical that it's reputation as a purely scientific entity be maintained. Because the NIH exists as a government-funded entity, there has always been risk that it's decisions will be overly influenced by the non-scientific perspectives of government officials or elected politicians. Over the last several months, announcements regarding executive orders or NIH policy statements have seemingly indicated that political appointees would be in positions to approve or deny funding for grant proposals which the non-government scientific experts reviewed favorably. These announcements have also seemed to suggest that previously awarded scientific projects could have their funding rejected by political appointees because they no longer match the current administration's priorities. This would utterly destroy the NIH's reputation as a scientific entity. There are historical examples in other countries of similar politicization of science completely ruining the otherwise strong research community. Perhaps the most poignant example of this was during the 1930's in the Soviet Union when political appointees destroyed the use of science in that country. One exceptional case was Trofim Lysenko, who rejected the

widely accepted principles of Mendelian genetics and drove agricultural decisions based on political ideals, rather than science. The loss of scientific principles in the Soviet Union led to the country falling several decades behind the rest of the world. The NIH needs to carefully manage its position not only within the government, but within the apolitical scientific community.

137. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Academic Institution

Date Submitted: 8/5/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: Data are very siloed. Creating an easily searchable database of all large datasets generated through NIH funding would be helpful. And there should be an incentive for particpating.

3. Training and Mentorship: Existing programs are onerous (T32 applications should be streamlined to encourage applications) and underfunded. There should be more support for program directors and less of a salary gap for trainees. Tracking trainees beyond their training program would be important.

4. Collaboration: Institutional promotional committees need to be educated to recognize team science. Increase funding fro program projects and create new mechanisms for collaborative projects.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: Basic research has suffered the last few years because of the uncertainty of the funding environment. We are losing promising young researchers so we need to create a stable pathway. Having competitions for specific high-risk high yield programs could help.

7. Public Impact: N/A

8. Other Areas: N/A

138. Doug Brugge

I am responding: On behalf of myself

Name: Doug Brugge

Name of Organization: University of Connecticut School of Medicine

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/6/2026

1. Rigor and Reproducibility: Regarding reproducibility, the best way to incentivize more replication of prior research is to provide funding mechanisms that support such efforts. Currently, the incentives are against replication because NIH favors, quite strongly, innovation and originality. A program announcement that only funds replication would be one possible way to encourage it.

As to rigor, I think the review process at NIH, and I have served on over 45 study sections, including chair one and as a standing member on two, could be improved by incentivizing the most qualified reviewers to serve. As it currently stands, reviewing is largely a thankless job that consumes a lot of time. How about some advantage in the review process for reviewers, or higher compensation or a reward of an R03 after service on 20 panels?

2. Data, Software, and Model Sharing: NA

3. Training and Mentorship: Expand the K award programs to offer more awards?

4. Collaboration: In my field, public health, we collaborate all the time across disciplines already

5. Entrepreneurship and Translation: How about follow up funding to R01 funded research that explicitely focuses on translation into real world impacts?

6. Foundational Scientific Exploration: NA

7. Public Impact: I am confident that in public health, much of our research has real world impact, the challenge is documenting that. I think two things are needed.

One is to develop reliable and standardized metrics by which these impacts can be measured. Scientific impact is easily assessed by publications, citations and reads, but nothing like that exists, as far as I know, for real world impact. So, fund development of metrics.

Secondly, at the end of a research study, there is no funding to document this sort of impact. Either add on funding to do so or requiring that budgets include funding for this purpose, perhaps in the final year of the grant, a bit like requirements for dissemination, might help.

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Not Applicable

Role: Other

Role - Other: Over my long career I can check off participation in 7 of the proposed roles.

Date Submitted: 8/6/2026

1. Rigor and Reproducibility: This process will not work unless anonymity is provided for those challenging well known researchers or long accepted principles. Or - the replication process is reserved for established researchers who don't need grant support for research. There goes the citation index. On occasions where I examined such issues as bias of perceptual attention, restriction of range of response, bias of focus of response, repeated construct bias, I was published and then characterized as having no original thoughts of my own but only attacking others' research, faking data, using questionable stimulus manipulations, undermining a publishing journal by showing that some alterations in my own methods would produce slightly but not totally different outcomes, showing that a reliable outcome I was predicting and replicating, only required half of participants to show the "reliable direction of outcome" to obtain significant results. And - an extensive review of methods article was accepted for publication by the editor of a well-known methods journal with the codicil of the editor that it could end my career and that of my co-author in the general area of the research. The world of research is much more vicious now than it was when I was starting my career. Now a pretext and the misuse of findings to support that pretext is a common part of science.

2. Data, Software, and Model Sharing: Based on my previous comments what might the incentive be to be abused or misused politically for not supporting a current version of authorized reality.

More importantly perhaps is that the current context of science does not support the time and financial dollars needed to support replication and its nuances.

3. Training and Mentorship: N/A

4. Collaboration: AI can run simulations, e.g., what is the financial impact of limiting highly successful investigators/labs to N grants or N dollars, but AI is easily biased by existing biased information and cannot be trusted.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

6. Foundational Scientific Exploration: I recommend using the so-called tire tracks approach, which identifies major discoveries and advances in the use and application of science, and looks backwards at how research enabled these contributions to society, medicine, or business. A major advantage of this method is that it recognizes that research is cumulative and can take many years, and may involve missteps and corrections as well. This method is probably most useful when the research is fast moving, as in computational research or some areas of bioscience. Other sciences are slower moving because they receive little funding, or require human RCTs, or involve processes that enfold over long periods. https://cccblog.org/2016/07/27/the-tire-tracks-diagram-corrected-and-humanized-by-national-academy-workshop-report/

1. Rigor and Reproducibility: **Response on Rigor and Reproducibility**

NIH should strengthen policies and infrastructure that make biomedical research reproducible by design rather than as an optional post-publication activity. We recommend the following measurable and feasible approaches:

1. **Open-source code and model release.** Investigators should be encouraged, and when appropriate required, to release source code, model architectures, training configurations, and inference pipelines through publicly accessible repositories. Measurable indicators include the proportion of funded projects with publicly available code, complete environment specifications (e.g., containerized environments), version-controlled repositories, and executable workflows.

2. **Standardized data-sharing mechanisms.** When participant privacy and consent permit, de-identified datasets, benchmark cohorts, or standardized synthetic datasets should accompany publications. For restricted clinical data, NIH should encourage secure data enclaves or federated evaluation platforms. Success metrics could include the percentage of studies providing reusable datasets or approved mechanisms for independent external validation.

3. **Standardized APIs for AI models.** For projects developing machine learning or foundation models, NIH should require or strongly encourage deployment of standardized application programming interfaces (APIs) that enable independent researchers to evaluate models on external datasets without requiring access to proprietary code or sensitive training data. This would facilitate reproducibility while protecting patient privacy and intellectual property. Metrics could include API availability, documentation quality, version control, uptime, and the number of independent validation studies completed.

4. **Reproducibility and sustainability as required closeout criteria.** Every federally funded research project should undergo a reproducibility and sustainability assessment before grant closeout. Similar to financial and scientific reporting requirements, investigators should demonstrate that the project's primary outputs are reproducible through documented code, accessible software, appropriate data-sharing mechanisms, comprehensive documentation, and, where applicable, externally accessible APIs. In addition, projects should include a **maintenance and sustainability plan** describing how software,

APIs, and associated resources will be maintained after the award period, including bug fixes, security updates, dependency management, versioning, and long-term repository hosting. NIH could establish a reproducibility checklist with measurable indicators, such as successful execution of the computational workflow, availability of required artifacts, API functionality, repository accessibility, and evidence that an independent evaluator can reproduce the reported results.

Embedding reproducibility and long-term maintenance into grant closeout would create strong incentives for sustainable research practices, improve transparency, accelerate independent validation, and maximize the long-term value of federally funded research investments. To ensure feasibility across institution types and career stages, NIH should provide dedicated funding mechanisms for software engineering, data curation, cloud infrastructure, API hosting, and long-term maintenance of open-source repositories and research software beyond the initial project period.

2. Data, Software, and Model Sharing: NIH should expand its data-sharing policies to recognize that modern biomedical research depends not only on data, but also on reusable software, computational workflows, and AI models. Effective sharing requires that these resources remain accessible, interoperable, and maintainable beyond the initial funding period.

NIH should establish centralized infrastructure (or regional centers) dedicated to the long-term stewardship of federally funded research software, datasets, models, and APIs. Similar to national data repositories or coordinating centers, this Research Software and AI Sustainability Center would provide repository hosting, API management, cloud infrastructure, security monitoring, dependency updates, version control, user support, and software preservation. Such a center would reduce duplication across projects, ensure continuity after grants end, and maximize the long-term return on federal investments.

By treating data, software, AI models, and their supporting infrastructure as long-term scientific assets, NIH can maximize the return on federal research investments, improve reproducibility, foster collaboration, and accelerate biomedical discovery. A centralized logistics and sustainability center would ensure that valuable federally funded resources remain accessible, functional, and secure for the broader research community long after the original project has concluded.

3. Training and Mentorship: NIH should broaden its evaluation of training and mentorship beyond traditional metrics such as publications and grant funding to recognize activities that build a sustainable, interdisciplinary, and translational biomedical workforce. Training should equip researchers with the skills needed for modern biomedical science, including data science, artificial intelligence, software engineering, reproducible research, team science, entrepreneurship, and regulatory science.

Establish measurable mentorship outcomes. NIH should evaluate training programs using standardized indicators such as trainee retention, career progression, interdisciplinary collaborations, leadership development, transition to independent funding, and contributions to team science. Evaluations should also include trainee satisfaction and long-term career tracking.
Implement long-term assessment of NIH-supported trainees. NIH should establish a centralized system to longitudinally track the career trajectories of trainees supported through NIH awards (e.g., 5, 10, and 15 years after training). Success metrics should extend beyond academic appointments to include

leadership positions, scientific productivity, entrepreneurship, technology commercialization, clinical translation, public service, mentorship of future investigators, and contributions to open science. These longitudinal outcomes would provide a more meaningful assessment of the long-term return on NIH investments in workforce development.
Recognize open science and research software contributions. Training programs should incentivize the development and maintenance of open-source software, datasets, AI models, and reproducible workflows. Contributions to community resources, software documentation, benchmarking, and data curation should be recognized as valuable scholarly outputs alongside publications.
Support experiential and cross-disciplinary training. NIH should encourage programs that integrate computational sciences, engineering, biomedical research, and clinical practice through cross-disciplinary mentoring, industry partnerships, internships, and collaborative projects. Exposure to regulatory science, implementation science, and commercialization will better prepare trainees for translating research into practice.
Provide sustained mentorship incentives. Effective mentorship requires significant time and effort but is often undervalued. NIH should recognize mentorship excellence in funding decisions and provide dedicated support for faculty who consistently demonstrate successful trainee development, interdisciplinary mentoring, and workforce diversity.
Develop centralized training infrastructure. NIH should establish national training and mentorship hubs that provide shared educational resources, standardized curricula, online learning platforms, mentoring networks, career development resources, and access to computational infrastructure. These centers would reduce duplication across institutions, expand opportunities for investigators at resource-limited institutions, and ensure equitable access to high-quality training.
Require workforce development plans and outcomes. Every federally funded training grant—and research grant supporting trainees—should include a workforce development plan with measurable milestones and report outcomes at grant closeout. Metrics could include trainee career advancement, mentorship quality, reproducible research practices, software and data contributions, interdisciplinary collaborations, and community engagement. These grant-level outcomes should also feed into NIH's centralized longitudinal trainee tracking system to continuously evaluate and improve the effectiveness of federal training investments.

By systematically measuring both short-term training outcomes and long-term career impact, NIH can better understand which training models produce the greatest scientific and societal return, enabling evidence-based improvements to workforce development programs while strengthening the future biomedical research enterprise

4. Collaboration: Evaluation should extend beyond first- and senior-author publications to acknowledge leadership in data generation, software development, AI model development, project coordination, clinical implementation, regulatory activities, and shared infrastructure. Standardized contributor taxonomies should be incorporated into grant reporting and career evaluations.

Rather than simply counting collaborators or institutions, NIH should assess measurable outcomes such as jointly funded grants, shared intellectual property, co-developed software and datasets, successful multicenter validation studies, technology adoption, and sustained partnerships beyond a single funding cycle.

Many impactful collaborations require years to mature. NIH should provide mechanisms to sustain successful collaborative networks, shared research infrastructure, and coordinating centers beyond the duration of individual research awards. Long-term support for data platforms, software ecosystems, and collaborative governance will maximize the return on federal investments and reduce duplication across projects.

5. Entrepreneurship and Translation: Track long-term translational outcomes. NIH should establish a centralized system to longitudinally assess the downstream impact of federally funded innovations, including follow-on investment, regulatory approvals, commercialization milestones, healthcare adoption, patient outcomes, startup sustainability, job creation, and economic impact. These data would enable NIH to identify funding mechanisms and translational models that produce the greatest public benefit.

Support translational infrastructure. NIH should expand access to innovation hubs, incubators, regulatory science expertise, manufacturing resources, clinical validation networks, and implementation science programs that help investigators bridge the gap between laboratory discoveries and real-world deployment.

6. Foundational Scientific Exploration: N/A

7. Public Impact: Recognize contributions to public resources. Federally funded projects that produce openly available datasets, software, AI models, educational materials, clinical guidelines, benchmarking resources, and public repositories should receive recognition for creating infrastructure that enables future scientific discovery and broad community benefit.

Evaluate economic and workforce impact. NIH should measure downstream outcomes such as startup creation, technology licensing, job creation, workforce development, commercialization, industry partnerships, and regional economic growth resulting from federally funded research.

8. Other Areas: N/A

142. Sindy KY Tang

I am responding: On behalf of myself

Name: Sindy KY Tang

Name of Organization: Stanford University

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/7/2026

1. Rigor and Reproducibility: NIH should expand the concept of rigor and reproducibility to encompass the complete measurement chain from biospecimen collection to reported result. For many cellular and functional assays, particularly those involving living or time-sensitive specimens (e.g., ex vivo cell activation tests), reproducibility is determined not only by experimental design but also by the interval and conditions between collection, processing, stabilization, transport, data acquisition, and analysis. Differences in these pre-analytical steps can substantially alter the measured biological signal and limit reproducibility across laboratories and clinical sites.

A key opportunity is to support technologies and validation frameworks that make time-sensitive biological measurements robust to realistic multicenter research workflows. These could include methods for decentralized specimen processing and stabilization, standardized transport conditions, automated or simplified sample handling, and approaches that separate the time and location of specimen collection from specialized downstream analysis.

Importantly, reproducibility should be evaluated at the individual-sample level, not only through aggregate measures such as cohort means or correlations. Strong population-level correlation can coexist with substantial deviations in individual measurements, including deviations large enough to alter biological or clinical classification. Useful quantitative indicators could therefore include sample-level bias and limits of agreement relative to a reference condition, preservation of classification or decision thresholds, robustness across defined time and temperature conditions, and reproducibility across sites, operators, instruments, and reagent lots.

Analytical reproducibility should be considered part of the same measurement chain. For complex datasets, NIH should encourage methods that preserve a traceable path from raw data through quality control, analysis, and the reported endpoint. This would make it possible to determine whether disagreement across studies arises from biology, specimen handling, instrumentation, batch effects, or analytical decisions.

A useful future NIH priority would therefore be the development and cross-site validation of end-to-end reproducibility platforms for complex biological measurements, with success defined by preservation of sample-level measurement fidelity from specimen collection through final analysis.

2. Data, Software, and Model Sharing: NIH should distinguish between data that are merely available and data that are genuinely re-analysis ready. Large amounts of valuable biomedical data have been generated through NIH-supported studies, but their future value can be limited when differences in instruments, assay configurations, reagent panels, batches, quality-control criteria, analytical methods, or reporting conventions make datasets difficult to compare or re-analyze together.

This challenge is particularly apparent in experimental data such as flow cytometry. Raw data from multiple studies may remain available, yet different laboratories may have used different marker panels, cytometers, population-identification strategies, gating conventions, quality-control rules, and thresholds. As a result, historical datasets that could otherwise support replication, validation, pooled analyses, or new biological questions may be difficult to synthesize objectively.

NIH should incentivize preservation of the raw data and metadata required for future re-analysis, including information about specimen collection and processing, assay configuration, instrumentation, reagents, batch, quality-control rules, and analytical procedures. A useful measure of scientific impact would be whether an independent investigator can reconstruct a reported endpoint from archived primary data and subsequently apply an updated or standardized analytical workflow.

NIH should also support development of computational and AI-enabled frameworks for retrospective cross-study re-analysis and auditing. Such tools could apply explicit analytical protocols across heterogeneous current and archived datasets, accommodate differences in measurement configurations, identify batch- or analysis-associated discrepancies, compare standardized analyses with historical manual analyses, flag results requiring expert review, and retain complete provenance of every analytical decision. The goal should not simply be automated prediction, but transparent and reproducible analysis that allows investigators to understand how each result was generated.

Measures of impact could include successful reproduction of published endpoints from raw data, number and diversity of independent datasets that can be analyzed using a common framework, external cross-laboratory validation, identification of previously unrecognized sources of analytical variability, and demonstrated reuse of archived datasets for cross-study validation or synthesis.

Such investments would increase the return on existing NIH-funded datasets while creating infrastructure for future studies to be designed for reproducibility and interoperability from the outset.

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: NIH should recognize technologies that transform fragile, expert-dependent research measurements into robust and deployable measurement systems as an important form of translational impact.

Many promising biomarkers and functional assays perform well in specialized academic laboratories but are difficult to implement in multicenter studies or routine clinical settings because they depend on fresh specimens, narrow processing windows, highly trained operators, specialized laboratory infrastructure, or immediate local analysis. These logistical constraints can prevent otherwise informative

measurements from progressing from discovery studies into large clinical trials, longitudinal cohorts, community-based research, or eventual clinical use.

NIH could incentivize technologies that address these barriers across the full workflow. Examples include methods that preserve biological measurements during delayed analysis and transportation; simplified or automated sample-processing systems that reduce operator dependence; approaches that allow specimen processing to occur near the participant while specialized measurement or analysis occurs centrally; and computational systems that maintain consistent quality control and interpretation across sites.

Translation should be assessed not only by patents, licensing, company formation, or regulatory milestones, but also by demonstrated improvement in deployability and measurement reliability. Relevant indicators could include extension of allowable specimen-processing or analysis windows, preservation of sample-level measurements during shipping, reduction in specialized infrastructure or operator requirements, successful implementation at multiple external sites, agreement across instruments and laboratories, and preservation of performance under realistic rather than idealized laboratory conditions.

NIH could specifically support cross-site studies that evaluate whether an assay developed in an expert laboratory can retain quantitative measurement fidelity when deployed in decentralized or multicenter settings. This type of translational validation bridges an important gap between proof-of-concept assay development and broad clinical implementation.

A future funding priority focused on technologies that enable robust translation of complex biological measurements from specialized laboratories into multisite and decentralized settings could accelerate the clinical utility of promising functional biomarkers while simultaneously improving rigor and reproducibility.

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

8. Other Areas: Measurement Science and Assay Harmonization

NIH should consider measurement science and assay harmonization as a distinct dimension of scientific impact. Biomedical research depends on the ability to generate measurements that are reliable not only within one laboratory or experiment, but also across laboratories, studies, instruments, operators, batches, and time.

Differences between studies are often attributed to biological heterogeneity when part of the disagreement may instead arise from specimen handling, assay implementation, instrumentation, reagent variation, batch effects, or analytical interpretation. Conversely, imposing a single assay protocol on all laboratories may be impractical and can make valuable historical datasets effectively unusable. There is therefore a need for technologies and reference frameworks that can both reduce avoidable measurement variability prospectively and account for unavoidable heterogeneity retrospectively.

NIH could support an integrated measurement-science framework with two complementary goals. First, prospective measurement stabilization and standardization should make sensitive biological assays reproducible under realistic multicenter conditions, including delays, transportation, different operators, and decentralized specimen collection. Second, retrospective analytical harmonization should make current and archived datasets generated with different assay configurations more re-analyzable, auditable, and comparable.

This could include development of reference materials and benchmark datasets; quantitative sample-level stability criteria; cross-site and cross-instrument validation studies; interoperable metadata describing specimen handling and assay conditions; standardized quality-control frameworks; and transparent computational tools capable of applying common analytical principles across heterogeneous datasets.

NIH could assess the impact of such work through measures including reduction in inter-site measurement variability, successful reproduction of results across independent laboratories, preservation of individual-sample measurements under realistic handling conditions, successful re-analysis of independently generated or historical datasets, and demonstration that data from multiple studies can be objectively compared or synthesized.

Dedicated investment in measurement science and assay harmonization would address an important gap between experimental rigor, data science, and translation. It would improve confidence in new studies while also increasing the scientific value of prior NIH investments by making existing data more useful for validation, replication, and new discovery.

4. Collaboration: Building and Measuring Collaborative Scientific Ecosystems: A Pilot Framework for Advancing Team Science and Scientific Impact

Executive Introduction and Background
The National Institutes of Health (NIH) is to be applauded for seeking input on future approaches to measuring collaborative science and scientific ecosystems. This Request for Information reflects NIH's continued leadership in advancing evidence-based approaches to understanding, evaluating, and strengthening modern biomedical research.

Traditional measures, including publications, citations, grant funding, patents, and clinical outcomes, remain fundamental indicators of scientific productivity and impact. However, these measures primarily assess the results of scientific activity rather than the organizational capabilities, collaborative behaviors, scientific networks, and research environments that enable discovery.

Over the past decade, NIH, the National Academies of Sciences, Engineering, and Medicine (NASEM), the National Cancer Institute (NCI), the Clinical and Translational Science Awards (CTSA) Program, and other Team Science initiatives have emphasized the importance of strengthening interdisciplinary collaboration and developing more effective approaches for evaluating collaborative research. These efforts have advanced the science of collaboration and provide a strong foundation for further understanding the organizational conditions that consistently produce high-performing scientific teams and sustain scientific impact.

We recommend that NIH complement, not replace, traditional outcome measures with an evidence-based framework that also evaluates the collaborative scientific ecosystem supporting research. The proposed Framework for Measuring Collaborative Scientific Ecosystems integrates leading indicators of collaborative capacity with lagging indicators of scientific outcomes to provide a more comprehensive understanding of scientific performance.

The framework is founded on three principles:
1. Traditional scientific outcomes remain essential and should continue to serve as the foundation for evaluating research productivity and impact.
2. Collaborative capacity can be measured through organizational capabilities, scientific networks, leadership, governance, collaborative behaviors, and workforce competencies that enable and incentivize effective Team Science.
3. Evidence should be drawn from multiple complementary sources to provide a comprehensive understanding of collaborative biomedical research.

We propose that NIH evaluate the Framework for Measuring Collaborative Scientific Ecosystems through a phased pilot conducted across multiple Institutes and Centers, scientific disciplines, career stages, and organizational settings. The pilot would provide practical experience, strengthen the evidence base, and assess the feasibility, reliability, administrative resiliency, predictive value, and any potential unintended consequences associated with implementation.

Building upon NIH's longstanding leadership in Team Science, this approach provides a practical pathway for strengthening Scientific Portfolio Stewardship, advancing organizational learning, and informing future guidance for evaluating collaborative scientific ecosystems through evidence-based implementation and continuous refinement.

1. Framework for Measuring Collaborative Scientific Ecosystems
Biomedical research has become increasingly collaborative, interdisciplinary, data-intensive, and translational. Traditional measures of scientific productivity, including publications, citations, grant funding, patents, and clinical outcomes, remain essential indicators of scientific success. However, these measures primarily assess the results of scientific activity rather than the organizational capabilities that enable discovery. As such, they function primarily as lagging indicators, reflecting achievements after they occur.

To better understand, strengthen, and sustain modern biomedical research, NIH should also consider leading indicators that assess the collaborative capacity supporting successful Team Science. These indicators evaluate the capabilities, behaviors, relationships, leadership, and organizational conditions that create an environment where scientific innovation can flourish before traditional outcomes become evident.

The proposed Framework for Measuring Collaborative Scientific Ecosystems (Figure 1 in attached PDF version of this Response) integrates leading and lagging indicators into a complementary approach for evaluating both scientific outcomes and the collaborative environment that produces them. The framework recognizes that modern biomedical discovery is increasingly generated through interconnected scientific ecosystems composed of investigators, multidisciplinary teams, collaborative behaviors, shared infrastructure, leadership, governance, institutional policies, incentive structures, recognition of collaborative contributions, technology platforms, and collaborative scientific networks.

Leading Indicators: Building Collaborative Scientific Capacity

Leading indicators evaluate whether an organization is developing the collaborative capabilities necessary to support sustained scientific excellence. The framework proposes four complementary dimensions.

> Individual Competencies assesses the scientific, technical, leadership, and collaborative capabilities that enable investigators to participate effectively in interdisciplinary research. These competencies may be evaluated using existing workforce development measures, competency assessments, education, and professional development activities.

> Collaborative Behaviors examines observable practices that advance Team Science, including data sharing, mentoring, knowledge exchange, shared decision-making, resource sharing, and cross-disciplinary problem solving. These behaviors provide evidence of how collaboration functions within research environments and may be assessed through structured interview analysis, direct observations, and complementary team analytic methods.

> Social Network Analysis (SNA) is an established quantitative, evidence-based methodology for measuring and analyzing collaborative relationships, patterns of connectivity, interdisciplinary interactions, and knowledge flows that support scientific collaboration. SNA provides objective measures of how investigators, teams, and organizations collaborate and helps assess the health of collaborative scientific networks over time.

> Scientific Ecosystems assesses the organizational environment that enables collaboration. This includes governance, leadership support, policies, incentives, shared infrastructure, technology platforms, workforce development, and organizational culture. Evaluating these conditions provides insight into an organization's collaborative capacity, readiness for Team Science, and ability to sustain scientific innovation over time.

Lagging Indicators: Measuring Scientific Results and Impact

Lagging indicators continue to provide the primary evidence of scientific achievement and long-term mission success.

> Scientific Portfolio Outcomes include measures of scientific innovation, translational progress, research productivity, workforce development, stewardship of scientific resources, and effective use of shared infrastructure.

> Patient and Public Impact reflects the ultimate purpose of biomedical research through improvements in health outcomes, public benefit, scientific advancement, equitable access to innovation, and return on public investment.

These outcome measures remain essential but become more informative when interpreted alongside the leading indicators that help explain how collaborative scientific success is achieved.

Recognition of Contributions to Team Science

Modern biomedical discovery increasingly depends on contributions that extend beyond traditional measures of authorship and principal investigator roles. Collaborative leadership, mentoring, data stewardship, development of shared research infrastructure, cross-disciplinary coordination, scientific facilitation, and contributions to collaborative networks all play important roles in advancing Team Science. Expanding recognition of these diverse contributions would better reflect how modern collaborative science is conducted while reinforcing behaviors that strengthen scientific ecosystems.

A Complementary Measurement Approach

The proposed framework is intended to complement, not replace traditional approaches for evaluating scientific productivity. By integrating leading indicators of collaborative capacity with lagging indicators of scientific outcomes, NIH can develop a more complete understanding of how collaborative scientific ecosystems contribute to discovery, translation, and public health impact.

This multidimensional approach provides opportunities to strengthen organizational learning, improve Scientific Portfolio Stewardship, identify opportunities to strengthen collaboration, and evaluate investments in Team Science. Because collaborative scientific environments differ across Institutes and Centers, the framework is intended for validation through a phased pilot that can assess feasibility, reliability, and predictive value before broader implementation.

2. Multiple Sources of Evidence

A fundamental principle of the Framework for Measuring Collaborative Scientific Ecosystems is that a comprehensive understanding of modern biomedical research is achieved through the integration of multiple complementary sources of evidence. Scientific collaboration reflects the interaction of individual capabilities, team dynamics, organizational culture, leadership, governance, infrastructure, and scientific outcomes. Together, these factors provide a balanced understanding of collaborative scientific performance and the conditions that enable successful Team Science.

The framework integrates qualitative and quantitative evidence to provide a comprehensive view of how collaborative scientific ecosystems function, support scientific discovery, and contribute to long-term scientific success. Each source of evidence offers unique insight into scientific performance, and together they provide a richer understanding than any single measure alone.

Proposed Evidence Sources

Quantitative Measures

> Quantitative measures provide objective evidence of scientific activity, collaborative capacity, and research outcomes. Examples may include bibliometric indicators, grant activity, collaboration metrics, shared publications, data-sharing metrics, utilization of shared scientific resources, translational outputs, organizational performance indicators, and other validated measures appropriate to the scientific environment.

Qualitative Measures

> Qualitative measures provide context for quantitative findings and help explain the organizational conditions that influence collaborative scientific performance. Examples may include interviews, focus groups, structured observations, case studies, after-action reviews, expert assessments, and other validated qualitative methods appropriate to the scientific environment. Together, these sources provide insight into collaborative experiences, leadership effectiveness, organizational culture, emerging practices, and the factors that contribute to successful Team Science and collaborative scientific ecosystems.

Social Network Analysis

> Social Network Analysis (SNA) is an established quantitative, evidence-based methodology for

measuring and analyzing collaborative relationships, patterns of connectivity, interdisciplinary interactions, and knowledge flows that support scientific collaboration. SNA provides objective measures of how investigators, teams, and organizations collaborate by identifying patterns of connectivity, boundary-spanning interactions, knowledge exchange, and the overall health of collaborative scientific ecosystems. These measures complement traditional scientific outcomes by providing evidence of the collaborative capacity that enables discovery, innovation, and long-term scientific impact.

Leadership Assessment
> Leadership plays a critical role in shaping collaborative scientific environments. Leadership assessments evaluate how vision, governance, decision-making, incentive structures, and organizational support foster Team Science and strengthen Scientific Portfolio Stewardship. These assessments provide insight into the leadership practices that encourage collaboration, recognize diverse scientific contributions, promote rigorous and transparent scientific practices, and create the organizational conditions necessary to sustain effective Team Science and collaborative scientific ecosystems.

Organizational Data
> Organizational data provide evidence regarding the environment in which scientific research is conducted and the organizational conditions that enable successful Team Science. Examples may include governance structures, institutional policies, resource allocation, shared infrastructure, workforce characteristics, training investments, technology platforms, incentive structures, recognition practices, and other organizational indicators appropriate to the scientific environment. Together, these data provide insight into organizational readiness, collaborative capacity, leadership support, and the conditions that sustain collaborative scientific ecosystems and long-term scientific excellence.

Each source of evidence contributes a unique perspective on collaborative scientific performance. No single measure can fully capture the complexity of modern scientific ecosystems. Integrating complementary sources of evidence provides a more comprehensive understanding of scientific performance, collaborative capacity, organizational effectiveness, and the conditions and incentives that support scientific excellence while reducing reliance on any individual measure. For example:

> Quantitative measures provide objective evidence of scientific activities, collaborative capacity, performance, and outcomes.
> Qualitative measures provide context for those findings by capturing organizational experiences, culture, leadership practices, and collaborative behaviors.
> Social Network Analysis illustrates how investigators, expertise, and knowledge are connected across collaborative scientific networks.
> Leadership assessments evaluate how vision, governance, decision-making, and organizational support foster Team Science and collaborative scientific ecosystems.
> Organizational data demonstrate how governance, institutional policies, infrastructure, resources, incentive structures, and recognition practices contribute to collaborative scientific environments.

Together, these complementary sources of evidence provide a more complete understanding of scientific performance, organizational capability, collaborative capacity, and the factors that enable successful Team Science. Integrating multiple sources of evidence also strengthens interpretation, supports

informed decision-making, and helps identify potential unintended consequences across diverse scientific environments.

Value of Multiple Sources of Evidence
Integrating multiple sources of evidence strengthens organizational learning, supports informed decision-making, and provides a more comprehensive understanding of collaborative scientific ecosystems. This multidimensional approach enables leadership to recognize organizational strengths, strengthen collaboration, evaluate investments in Team Science, encourage rigorous and transparent scientific practices, and continuously enhance the scientific ecosystem.

This approach aligns with the principles of Scientific Portfolio Stewardship by providing leadership with evidence that supports strategic decision-making across the research enterprise while complementing established measures of scientific productivity and impact. By recognizing diverse scientific contributions and reinforcing collaborative behaviors, the framework encourages the capabilities required for modern Team Science while preserving flexibility across scientific disciplines, career stages, institution types, and organizational missions.

3. Proposed Phased Pilot Implementation Framework
The proposed framework provides NIH with an opportunity to advance the evaluation of collaborative biomedical research through a structured pilot implementation. Conducting a pilot across multiple Institutes and Centers, scientific disciplines, career stages, institution types, and organizational settings would generate practical experience, strengthen the evidence base, and support the continued evolution of measures and incentives for collaborative scientific ecosystems.

The primary objective is to evaluate leading indicators that complement traditional measures of scientific productivity while providing additional insight into the organizational capabilities, collaborative behaviors, scientific networks, leadership practices, and ecosystem conditions that contribute to long-term scientific success and Scientific Portfolio Stewardship.

The pilot is intended to support organizational learning, evaluate the practical application of the framework, and inform future NIH guidance for measuring collaborative scientific ecosystems. Pilot implementation would assess the feasibility, usefulness, consistency, and applicability of the proposed measures across diverse scientific environments. The pilot would also examine relationships among leading and lagging indicators, evaluate implementation considerations, identify potential unintended consequences, and determine where flexibility may be appropriate across scientific disciplines, career stages, institution types, and organizational missions. Findings from the pilot would help refine the framework, identify effective implementation practices, and strengthen evidence-informed approaches that complement existing methods for evaluating scientific productivity and impact.

Proposed Pilot Phases
The proposed pilot consists of five sequential phases designed to support continuous learning, evaluation, and refinement.

Phase 1 – Framework Preparation

Conduct a review of existing evidence and leading practices; engage scientific and organizational stakeholders; identify candidate indicators; and develop the initial evaluation framework, implementation guidance, and data collection strategy.

Phase 2 – Pilot Design
Select participating Institutes, Centers, or research programs that represent diverse scientific disciplines, organizational structures, career stages, institution types, and research missions; establish baseline measures; define evaluation objectives; prepare implementation guidance; and orient participating organizations to the pilot framework and evaluation approach.

Phase 3 – Pilot Implementation
Implement the framework by collecting evidence across the proposed leading and lagging indicators, including individual competencies, collaborative behaviors, scientific networks, scientific ecosystem characteristics, scientific portfolio outcomes, and patient and public impact. Multiple complementary sources of evidence, including quantitative measures, qualitative assessments, Social Network Analysis, leadership assessments, and organizational data – would be examined together to provide a comprehensive understanding of collaborative scientific performance, organizational capability, collaborative capacity, and the organizational conditions that support scientific excellence.

Phase 4 – Evaluation and Learning
Evaluate pilot findings to assess the usefulness, consistency, feasibility, and practical application of the proposed measures. Examine relationships among leading and lagging indicators, identify implementation challenges and potential unintended consequences, assess flexibility across diverse scientific environments, capture lessons learned, and refine the framework and implementation guidance based on evidence gathered throughout the pilot.

Phase 5 – Guidance and Broader Application
Use the knowledge gained through the pilot to refine the framework, develop NIH guidance, establish recommended practices, and identify implementation strategies that support broader adoption of collaborative scientific ecosystem measures, where appropriate, across NIH.

Benefits and Implementation Considerations
The proposed framework is intended to complement existing evaluation approaches while remaining sufficiently flexible for use across diverse scientific environments. Because collaborative research differs by career stage, scientific discipline, organizational mission, institution type, and organizational context, pilot implementation across multiple Institutes and Centers will help determine which measures provide meaningful insight, which are broadly applicable, and where flexibility may be appropriate. This phased approach allows NIH to evaluate feasibility, administrative burden, consistency, predictive value, and potential unintended consequences before broader implementation.

The pilot is intended to inform future NIH guidance by identifying effective implementation practices, strengthening evidence-informed approaches to Scientific Portfolio Stewardship, and demonstrating how complementary sources of evidence can enhance understanding of collaborative scientific ecosystems while complementing established measures of scientific productivity and impact.

4. Recommendations to NIH

As biomedical research continues to evolve toward increasingly collaborative, interdisciplinary, and data-intensive models, NIH has an opportunity to complement existing measures of scientific productivity with approaches that also assess the collaborative capabilities and organizational conditions that enable scientific discovery. Based on the proposed Framework for Measuring Collaborative Scientific Ecosystems, we respectfully recommend that NIH consider the following actions:

1. Continue using traditional scientific outcome measures as the foundation for evaluating scientific productivity, scientific impact, and public benefit.
2. Expand scientific evaluation to include leading indicators that assess collaborative capacity, including individual competencies, collaborative behaviors, scientific networks, leadership practices, and the broader scientific ecosystem that supports Team Science and scientific excellence.
3. Adopt multiple sources of evidence approach that combines quantitative measures (including Social Network Analysis), qualitative assessments, leadership assessments, and organizational data to provide a more comprehensive understanding of collaborative scientific performance, organizational capability, and the conditions that support collaborative scientific ecosystems.
4. Conduct a phased pilot implementation across multiple Institutes and Centers, scientific disciplines, career stages, institution types, and organizational settings to evaluate the feasibility, usefulness, flexibility, and practical application of the proposed framework; strengthen the evidence base; identify effective implementation practices; and assess potential unintended consequences before broader adoption.
5. Use findings from the pilot to refine the framework, inform future NIH guidance, strengthen Scientific Portfolio Stewardship, and support evidence-informed approaches that complement established methods for evaluating scientific productivity and impact.

The proposed framework is intended to build upon NIH's longstanding leadership in Team Science by providing an evidence-informed approach for understanding not only the outcomes of scientific research but also the collaborative capabilities and organizational conditions that contribute to sustained scientific excellence. By integrating leading and lagging indicators through multiple sources of evidence, NIH can advance a more comprehensive approach to evaluating collaborative scientific ecosystems while strengthening Scientific Portfolio Stewardship, organizational learning, and patient and public benefit.

Building and Measuring Collaborative Scientific Ecosystems: A Pilot Framework for Advancing Team Science and Scientific Impact

Executive Introduction and Background

The National Institutes of Health (NIH) is to be applauded for seeking input on future approaches to measuring collaborative science and scientific ecosystems. This Request for Information reflects NIH's continued leadership in advancing evidence-based approaches to understanding, evaluating, and strengthening modern biomedical research.

Traditional measures, including publications, citations, grant funding, patents, and clinical outcomes, remain fundamental indicators of scientific productivity and impact. However, these measures primarily assess the results of scientific activity rather than the organizational capabilities, collaborative behaviors, scientific networks, and research environments that enable discovery.

Over the past decade, NIH, the National Academies of Sciences, Engineering, and Medicine (NASEM), the National Cancer Institute (NCI), the Clinical and Translational Science Awards (CTSA) Program, and other Team Science initiatives have emphasized the importance of strengthening interdisciplinary collaboration and developing more effective approaches for evaluating collaborative research. These efforts have advanced the science of collaboration and provide a strong foundation for further understanding the organizational conditions that consistently produce high-performing scientific teams and sustain scientific impact.

We recommend that NIH complement, not replace, traditional outcome measures with an evidence-based framework that also evaluates the collaborative scientific ecosystem supporting research. The proposed **Framework for Measuring Collaborative Scientific Ecosystems** integrates leading indicators of collaborative capacity with lagging indicators of scientific outcomes to provide a more comprehensive understanding of scientific performance.

The framework is founded on three principles:

1. **Traditional scientific outcomes remain essential** and should continue to serve as the foundation for evaluating research productivity and impact.
2. **Collaborative capacity can be measured** through organizational capabilities, scientific networks, leadership, governance, collaborative behaviors, and workforce competencies that enable and incentivize effective Team Science.
3. **Evidence should be drawn from multiple complementary sources** to provide a comprehensive understanding of collaborative biomedical research.

We propose that NIH evaluate the Framework for Measuring Collaborative Scientific Ecosystems through a phased pilot conducted across multiple Institutes and Centers, scientific disciplines, career stages, and organizational settings. The pilot would provide practical experience, strengthen the evidence base, and assess the feasibility, reliability, administrative resiliency, predictive value, and any potential unintended consequences associated with implementation.

Building upon NIH's longstanding leadership in Team Science, this approach provides a practical pathway for strengthening Scientific Portfolio Stewardship, advancing organizational learning, and informing

future guidance for evaluating collaborative scientific ecosystems through evidence-based implementation and continuous refinement.

1. Framework for Measuring Collaborative Scientific Ecosystems

Biomedical research has become increasingly collaborative, interdisciplinary, data-intensive, and translational. Traditional measures of scientific productivity, including publications, citations, grant funding, patents, and clinical outcomes, remain essential indicators of scientific success. However, these measures primarily assess the results of scientific activity rather than the organizational capabilities that enable discovery. As such, they function primarily as **lagging indicators**, reflecting achievements after they occur.

To better understand, strengthen, and sustain modern biomedical research, NIH should also consider **leading indicators** that assess the collaborative capacity supporting successful Team Science. These indicators evaluate the capabilities, behaviors, relationships, leadership, and organizational conditions that create an environment where scientific innovation can flourish before traditional outcomes become evident.

The proposed **Framework for Measuring Collaborative Scientific Ecosystems** (*Figure 1.)* integrates leading and lagging indicators into a complementary approach for evaluating both scientific outcomes and the collaborative environment that produces them. The framework recognizes that modern biomedical discovery is increasingly generated through interconnected scientific ecosystems composed of investigators, multidisciplinary teams, collaborative behaviors, shared infrastructure, leadership, governance, institutional policies, incentive structures, recognition of collaborative contributions, technology platforms, and collaborative scientific networks.

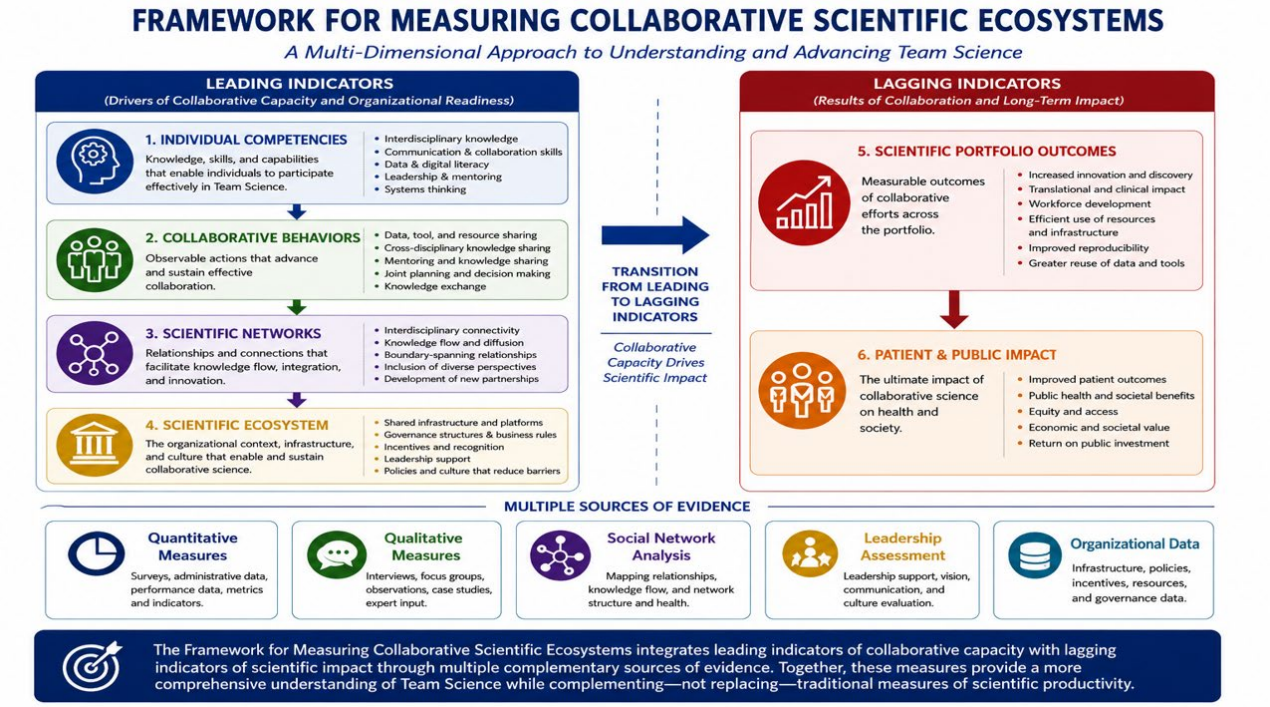

***Figure 1**. Framework for Measuring Collaborative Scientific Ecosystems*

Leading Indicators: Building Collaborative Scientific Capacity

Leading indicators evaluate whether an organization is developing the collaborative capabilities necessary to support sustained scientific excellence. The framework proposes four complementary dimensions.

- **Individual Competencies** assesses the scientific, technical, leadership, and collaborative capabilities that enable investigators to participate effectively in interdisciplinary research. These competencies may be evaluated using existing workforce development measures, competency assessments, education, and professional development activities.
- **Collaborative Behaviors** examines observable practices that advance Team Science, including data sharing, mentoring, knowledge exchange, shared decision-making, resource sharing, and cross-disciplinary problem solving. These behaviors provide evidence of how collaboration functions within research environments and may be assessed through structured interview analysis, direct observations, and complementary team analytic methods.
- **Social Network Analysis (SNA)** is an established quantitative, evidence-based methodology for measuring and analyzing collaborative relationships, patterns of connectivity, interdisciplinary interactions, and knowledge flows that support scientific collaboration. SNA provides objective measures of how investigators, teams, and organizations collaborate and helps assess the health of collaborative scientific networks over time**.**
- **Scientific Ecosystems** assesses the organizational environment that enables collaboration. This includes governance, leadership support, policies, incentives, shared infrastructure, technology platforms, workforce development, and organizational culture. Evaluating these conditions provides insight into an organization's collaborative capacity, readiness for Team Science, and ability to sustain scientific innovation over time.

Lagging Indicators: Measuring Scientific Results and Impact

Lagging indicators continue to provide the primary evidence of scientific achievement and long-term mission success.

- **Scientific Portfolio Outcomes** include measures of scientific innovation, translational progress, research productivity, workforce development, stewardship of scientific resources, and effective use of shared infrastructure.
- **Patient and Public Impact** reflects the ultimate purpose of biomedical research through improvements in health outcomes, public benefit, scientific advancement, equitable access to innovation, and return on public investment.

These outcome measures remain essential but become more informative when interpreted alongside the leading indicators that help explain how collaborative scientific success is achieved.

Recognition of Contributions to Team Science

Modern biomedical discovery increasingly depends on contributions that extend beyond traditional measures of authorship and principal investigator roles. Collaborative leadership, mentoring, data stewardship, development of shared research infrastructure, cross-disciplinary coordination, scientific

facilitation, and contributions to collaborative networks all play important roles in advancing Team Science. Expanding recognition of these diverse contributions would better reflect how modern collaborative science is conducted while reinforcing behaviors that strengthen scientific ecosystems.

A Complementary Measurement Approach

The proposed framework is intended to **complement, not replace traditional approaches for evaluating scientific productivity.** By integrating leading indicators of collaborative capacity with lagging indicators of scientific outcomes, NIH can develop a more complete understanding of how collaborative scientific ecosystems contribute to discovery, translation, and public health impact.

This multidimensional approach provides opportunities to strengthen organizational learning, improve Scientific Portfolio Stewardship, identify opportunities to strengthen collaboration, and evaluate investments in Team Science. Because collaborative scientific environments differ across Institutes and Centers, the framework is intended for validation through a phased pilot that can assess feasibility, reliability, and predictive value before broader implementation.

2. Multiple Sources of Evidence

A fundamental principle of the **Framework for Measuring Collaborative Scientific Ecosystems** is that a comprehensive understanding of modern biomedical research is achieved through the integration of multiple complementary sources of evidence. Scientific collaboration reflects the interaction of individual capabilities, team dynamics, organizational culture, leadership, governance, infrastructure, and scientific outcomes. Together, these factors provide a balanced understanding of collaborative scientific performance and the conditions that enable successful Team Science.

The framework integrates qualitative and quantitative evidence to provide a comprehensive view of how collaborative scientific ecosystems function, support scientific discovery, and contribute to long-term scientific success. Each source of evidence offers unique insight into scientific performance, and together they provide a richer understanding than any single measure alone.

Proposed Evidence Sources

Quantitative Measures

- Quantitative measures provide objective evidence of scientific activity, collaborative capacity, and research outcomes. Examples may include bibliometric indicators, grant activity, collaboration metrics, shared publications, data-sharing metrics, utilization of shared scientific resources, translational outputs, organizational performance indicators, and other validated measures appropriate to the scientific environment.

Qualitative Measures

- Qualitative measures provide context for quantitative findings and help explain the organizational conditions that influence collaborative scientific performance. Examples may include interviews, focus groups, structured observations, case studies, after-action reviews, expert assessments, and other validated qualitative methods appropriate to the scientific environment. Together, these sources provide insight into collaborative experiences, leadership effectiveness, organizational culture, emerging practices, and the factors that contribute to successful Team Science and collaborative scientific ecosystems.

Social Network Analysis

- **Social Network Analysis (SNA)** is an established quantitative, evidence-based methodology for measuring and analyzing collaborative relationships, patterns of connectivity, interdisciplinary interactions, and knowledge flows that support scientific collaboration. SNA provides objective measures of how investigators, teams, and organizations collaborate by identifying patterns of connectivity, boundary-spanning interactions, knowledge exchange, and the overall health of collaborative scientific ecosystems. **These measures complement traditional scientific outcomes by providing evidence of the collaborative capacity that enables discovery, innovation, and long-term scientific impact.**

Leadership Assessment

- Leadership plays a critical role in shaping collaborative scientific environments. Leadership assessments evaluate how vision, governance, decision-making, incentive structures, and organizational support foster Team Science and strengthen Scientific Portfolio Stewardship. These assessments provide insight into the leadership practices that encourage collaboration, recognize diverse scientific contributions, promote rigorous and transparent scientific practices, and create the organizational conditions necessary to sustain effective Team Science and collaborative scientific ecosystems.

Organizational Data

- Organizational data provide evidence regarding the environment in which scientific research is conducted and the organizational conditions that enable successful Team Science. Examples may include governance structures, institutional policies, resource allocation, shared infrastructure, workforce characteristics, training investments, technology platforms, incentive structures, recognition practices, and other organizational indicators appropriate to the scientific environment. Together, these data provide insight into organizational readiness, collaborative capacity, leadership support, and the conditions that sustain collaborative scientific ecosystems and long-term scientific excellence.

Each source of evidence contributes a unique perspective on collaborative scientific performance. No single measure can fully capture the complexity of modern scientific ecosystems. Integrating complementary sources of evidence provides a more comprehensive understanding of scientific performance, collaborative capacity, organizational effectiveness, and the conditions and incentives that support scientific excellence while reducing reliance on any individual measure. For example:

- **Quantitative measures** provide objective evidence of scientific activities, collaborative capacity, performance, and outcomes.
- **Qualitative measures** provide context for those findings by capturing organizational experiences, culture, leadership practices, and collaborative behaviors.
- **Social Network Analysis** illustrates how investigators, expertise, and knowledge are connected across collaborative scientific networks.
- **Leadership assessments** evaluate how vision, governance, decision-making, and organizational support foster Team Science and collaborative scientific ecosystems.

- **Organizational data** demonstrate how governance, institutional policies, infrastructure, resources, incentive structures, and recognition practices contribute to collaborative scientific environments.

Together, these complementary sources of evidence provide a more complete understanding of scientific performance, organizational capability, collaborative capacity, and the factors that enable successful Team Science. Integrating multiple sources of evidence also strengthens interpretation, supports informed decision-making, and helps identify potential unintended consequences across diverse scientific environments.

Value of Multiple Sources of Evidence

Integrating multiple sources of evidence strengthens organizational learning, supports informed decision-making, and provides a more comprehensive understanding of collaborative scientific ecosystems. This multidimensional approach enables leadership to recognize organizational strengths, strengthen collaboration, evaluate investments in Team Science, encourage rigorous and transparent scientific practices, and continuously enhance the scientific ecosystem.

This approach aligns with the principles of Scientific Portfolio Stewardship by providing leadership with evidence that supports strategic decision-making across the research enterprise while complementing established measures of scientific productivity and impact. By recognizing diverse scientific contributions and reinforcing collaborative behaviors, the framework encourages the capabilities required for modern Team Science while preserving flexibility across scientific disciplines, career stages, institution types, and organizational missions.

3. Proposed Phased Pilot Implementation Framework

The proposed framework provides NIH with an opportunity to advance the evaluation of collaborative biomedical research through a structured pilot implementation. Conducting a pilot across multiple Institutes and Centers, scientific disciplines, career stages, institution types, and organizational settings would generate practical experience, strengthen the evidence base, and support the continued evolution of measures and incentives for collaborative scientific ecosystems.

The primary objective is to evaluate leading indicators that complement traditional measures of scientific productivity while providing additional insight into the organizational capabilities, collaborative behaviors, scientific networks, leadership practices, and ecosystem conditions that contribute to long-term scientific success and Scientific Portfolio Stewardship.

The pilot is intended to support organizational learning, evaluate the practical application of the framework, and inform future NIH guidance for measuring collaborative scientific ecosystems. Pilot implementation would assess the feasibility, usefulness, consistency, and applicability of the proposed measures across diverse scientific environments. The pilot would also examine relationships among leading and lagging indicators, evaluate implementation considerations, identify potential unintended consequences, and determine where flexibility may be appropriate across scientific disciplines, career stages, institution types, and organizational missions. Findings from the pilot would help refine the framework, identify effective implementation practices, and strengthen evidence-informed approaches that complement existing methods for evaluating scientific productivity and impact.

Proposed Pilot Phases

The proposed pilot consists of five sequential phases designed to support continuous learning, evaluation, and refinement.

Phase 1 – Framework Preparation

Conduct a review of existing evidence and leading practices; engage scientific and organizational stakeholders; identify candidate indicators; and develop the initial evaluation framework, implementation guidance, and data collection strategy.

Phase 2 – Pilot Design

Select participating Institutes, Centers, or research programs that represent diverse scientific disciplines, organizational structures, career stages, institution types, and research missions; establish baseline measures; define evaluation objectives; prepare implementation guidance; and orient participating organizations to the pilot framework and evaluation approach.

Phase 3 – Pilot Implementation

Implement the framework by collecting evidence across the proposed leading and lagging indicators, including individual competencies, collaborative behaviors, scientific networks, scientific ecosystem characteristics, scientific portfolio outcomes, and patient and public impact. Multiple complementary sources of evidence, including quantitative measures, qualitative assessments, Social Network Analysis, leadership assessments, and organizational data – would be examined together to provide a comprehensive understanding of collaborative scientific performance, organizational capability, collaborative capacity, and the organizational conditions that support scientific excellence.

Phase 4 – Evaluation and Learning

Evaluate pilot findings to assess the usefulness, consistency, feasibility, and practical application of the proposed measures. Examine relationships among leading and lagging indicators, identify implementation challenges and potential unintended consequences, assess flexibility across diverse scientific environments, capture lessons learned, and refine the framework and implementation guidance based on evidence gathered throughout the pilot.

Phase 5 – Guidance and Broader Application

Use the knowledge gained through the pilot to refine the framework, develop NIH guidance, establish recommended practices, and identify implementation strategies that support broader adoption of collaborative scientific ecosystem measures, where appropriate, across NIH.

Benefits and Implementation Considerations

The proposed framework is intended to complement existing evaluation approaches while remaining sufficiently flexible for use across diverse scientific environments. Because collaborative research differs by career stage, scientific discipline, organizational mission, institution type, and organizational context, pilot implementation across multiple Institutes and Centers will help determine which measures provide meaningful insight, which are broadly applicable, and where flexibility may be appropriate. This phased approach allows NIH to evaluate feasibility, administrative burden, consistency, predictive value, and potential unintended consequences before broader implementation.

The pilot is intended to inform future NIH guidance by identifying effective implementation practices, strengthening evidence-informed approaches to Scientific Portfolio Stewardship, and demonstrating how complementary sources of evidence can enhance understanding of collaborative scientific ecosystems while complementing established measures of scientific productivity and impact.

4. Recommendations to NIH

As biomedical research continues to evolve toward increasingly collaborative, interdisciplinary, and data-intensive models, NIH has an opportunity to complement existing measures of scientific productivity with approaches that also assess the collaborative capabilities and organizational conditions that enable scientific discovery. Based on the proposed **Framework for Measuring Collaborative Scientific Ecosystems**, we respectfully recommend that NIH consider the following actions:

1. **Continue using traditional scientific outcome measures** as the foundation for evaluating scientific productivity, scientific impact, and public benefit.
2. **Expand scientific evaluation** to include leading indicators that assess collaborative capacity, including individual competencies, collaborative behaviors, scientific networks, leadership practices, and the broader scientific ecosystem that supports Team Science and scientific excellence.
3. **Adopt multiple sources of evidence approach** that combines quantitative measures (including Social Network Analysis), qualitative assessments, leadership assessments, and organizational data to provide a more comprehensive understanding of collaborative scientific performance, organizational capability, and the conditions that support collaborative scientific ecosystems.
4. **Conduct a phased pilot implementation** across multiple Institutes and Centers, scientific disciplines, career stages, institution types, and organizational settings to evaluate the feasibility, usefulness, flexibility, and practical application of the proposed framework; strengthen the evidence base; identify effective implementation practices; and assess potential unintended consequences before broader adoption.
5. **Use findings from the pilot** to refine the framework, inform future NIH guidance, strengthen Scientific Portfolio Stewardship, and support evidence-informed approaches that complement established methods for evaluating scientific productivity and impact.

The proposed framework is intended to build upon NIH's longstanding leadership in Team Science by providing an evidence-informed approach for understanding not only the outcomes of scientific research but also the collaborative capabilities and organizational conditions that contribute to sustained scientific excellence. By integrating leading and lagging indicators through multiple sources of evidence, NIH can advance a more comprehensive approach to evaluating collaborative scientific ecosystems while strengthening Scientific Portfolio Stewardship, organizational learning, and patient and public benefit.

Date Submitted: 8/7/2026

1. Rigor and Reproducibility: As a biostatistician and methodologist, I have been particular concerned about the lack of rigor within "data science." This field has no theoretical basis, and no standards. there may be as many 600 "guidelines" but none are comprehensive and none effectively promote rigor, reproducibility and transparency. The field has evolved to serve themselves with improved computational techniques to save time and space. Similar issues attach to software engineering. Letting data drive any endeavor is a terrible idea. to move forward, we have to return to the fundamentals-theory, theory, theory. The problem with prediction is that there is no theory; as a result, we have returned to some 19th century understanding of philosophy of science. I have commented elsewhere on the misuse of the EHR in clinical research; I have also belied the lack of transparency in a recent paper and proposed a comprehensive framework for reproducibility and transparency as well as an audit procedure using curated AI queries--all of which can be automated as a digital tool to review research prior to publication. For funding, a tool like this could be utilized as a condition of funding. Overall, empirical research has gone too far in the direction of external validation with little or no though given to internal validity. I am also a strong proponent of simulation to assess the robustness of assumptions and theoretical propositions. Replication, in my opinion, has killed progress in clinical research. Now we are using meta-analysis to indemnify the baisses inherent in the replications. No thanks! The first action to take is to require 2 semesters of philosophy of science, not targeting bioethics which are important, but not the key problem. Trained researchers have misguided faith in the RCT and its replicants. Coming from social science to medicine, I was horrified at the lack of knowledge regarding the scientific endeavor. Decades of overvaluing the RCT has led to a dearth of skill in actual research. Now with data driving research and no theory, as well as unreliable data sets designed to track billing and not patient experience, are we really surprised we can't replicate results? If decades of pediatric cancer research with 80% of all NIH money cannot undertake research to reduce chemotherapy dosing and prevent horrific side effects, something is wrong with our research and funding mechanisms.

2. Data, Software, and Model Sharing: I can't agree with a replication approach to validation. Again, it misses the importance of theory and internal validation. You can never get to causality from replication. In fact, you can't really get anywhere because all it really takes is one counterexample to upend your research. As I described above, I am working on a comprehensive framework with AI auditing to support confirmation of results. Yes, all coding should be posted on GitHub or equivalent but more often than not, you find numerous problems with the code after the paper is published. i suggest demonstrating

validation via in silico (simulation testing) of your model and data. Yes, use alternate data sets but not for replication-rather for exploration via simulation to understand failure points and edges. We just completed this type of effort in a recent paper (abstract attached).

3. Training and Mentorship: Training and mentorship is incredibly time consuming and requires a mutli-year commitment. I have to applaud the new ASU Medical School for diving into the deep end and deciding every MD will also be a biomedical engineer. I am sure they will find, however, without deep mentorship in extant start-ups and with experienced developers/founders-the technical training only goes so far. Trainees must be embedded into MedTech ecospheres that extend beyond one community or university. founders (engineers) are notoriously ignorant of basically everything else they need to know about commercializing their tech. In addition, many are looking for lifelong careers for a single science project not business opportunities. In the Irvine Tech Hub, we are embedding MBAs, regulatory specialists, trial specialists etc. to educate founders. Beyond the founders, traditional training in biostats, data science, or regulatory science will not serve biomedical engineering. Even the bioscience side has huge gaps, for example, purchasing an enzyme for animal studies that works but can't be translated clinically because the company doesn't want the liability associated with their enzyme. WHAT? More biomedical engineers will not make the workforce you need for translation. So counting them won't help. I recommend supporting partnerships where start-ups are funded a trainee and assigned multiple projects or components to expand their applied skillset. The number of translated projects and investor funded projects from those partnerships would also be a metric to consider.

4. Collaboration: One of the best collaborations I have observed is the Pediatric Cardiac Research and Learning Collaborative. The group sets guidelines for clinical practice, engages patients and families, test new treatments and is well-poisiotned to evaluate new cardiac devices, as well as hold their own the with FDA (thus reducing costly and time-consuming replication). the group are the experts, they understand the theory, they can explain the science supporting the device or intervention, they engage patients and their families to ensure their work is patient and family first. 90% of the time, research is clinician-focused--what they want or need (and heaven help us -what they need for tenure and promotion) not what the patient wants or needs; not what the health system or the payor could benefit from. Personally, I target the latter in all my consults. what good does it do to have a slightly more accurate treatment but it requires in-patient surgery where the existing tx is outpatient? Let's refocus research on the big issues--reducing the cost of Medicaid not providing more and more elaborate treatments for already very expensive patients. Let's move 90% of hospital activity to the home--let's target devices that do that. Let's stop rampant replication of single institution findings where the noise is always larger than the signal. Let's engender research and learning collaboratives that meet all the requirements of effective research and learning consortia. Let's offer them funding to "solve" big health system issues and not only micro improvements. Let's incentivize these collabs to solve problems and NOT COLLECT DATA! All that data led only to career making papers but no real knowledge. Does cooling actually help a TBI? 20,000 patients later and we don't know. There are so many problems out there to address, let's incentivize collabs to address them.

5. Entrepreneurship and Translation: Oh goodness! the NIH mission may need to be revamped away from cool science projects with tons of promise or promoting academic careers, towards patient centered problems or reducing health system costs. 20 years of genomics and we are only now starting to integrated genome sequencing to target infections. And it's expensive and the lab work can only be done by one university with no plans to democratize it or bring down the cost. It's a public good

monopolized by a private university. How do we explain that? I would encourage the NIH to skip the science projects completely because from my observation the funding of these has been diverted to sustain a 20-year academic career with R01 grants and zero, zero, zero translation.

6. Foundational Scientific Exploration: Let a thousand flowers bloom! Open the doors to research that hasn't spent a decade being primed in an NIH grant machine. Revamp the grant application to work backward from the vision of the translation to impact (and commercialization, if possible). we need to incentivize foundational scientific exploration to align with the biggest problems we have today not the esoteric whims of highly specialized researchers who are not targeting major problems. the one-step-at-a-time approach only incentivized academic careers not impact. My favorite example is related to a young investigator how really identified an impactful treatment but simply refused to translate it before she received additional grant money to test it in related populations. first, this example shows how hesitant investigators are to translate their work; second, it shows her misguided reliance on external validation; third it shows her commitment to herself and her academic career over the patients she could have helped. I cant forget this example because it was so egregious in my view. going forward, this researcher will likely not get r01 money because her research is not foundational and the novelty of is quickly eroding. this doesn't preclude her being clinically impactful and seeking out private partnerships to enhance her impact. However, her academic career comes first. I also saw another investigator who had lived on r01s for 20 years derisking his medtech. by the time he was ready to commercialize, investors said "no thanks."

We have to define: foundational to what? To 300 year old specialties? I encourage you to rethink your entire approach to research and replace the solipsism with problem solving. we are too used to thinking science moves ahead by some quirk or step by step process. it can move ahead all sorts of ways but never based on someone putting their career ahead of the problem. Cool science projects for science's sake in my view must target problems, otherwise, we are just supporting somebody's interest regardless of its overall value to and impact on the public (who pay for this research).

7. Public Impact: Obviously, I believe this should come first, second, and third. I work extensively with clinicians who look at changing clinical practice as a modest one-step-at -a-time endeavor that more often than not serves them and not the patient. Does a patient need remote monitoring? What does it actually do for them, specifically. I guarantee you that the clinician hasn't given it a second of thought. For the clinician it only provides a lot more information that they absolutely don't need, won't use, and can only be integrated into the EHR in summary data or notes. The whole endeavor is to ping a patient to make an appointment-they won't be automating recommended adjustments to their treatment plan because hospitals require a "human in the loop" which at this stage means "make an appointment." We are also too incremental in our envisioning of patient-centered care. We think about it in steps-push them onto a digital platform, integrate telehealth, navigate towards some automation, take 5 years to complete. NIH should not fund anything where patients are not a key stakeholder in the research, not just an afterthought-full stop. Never. designing treatments and interventions and improvements in delivery or care must come from the patient's needs first. However, don't get me wrong-I work in peds so I have the luxury of early, early intervention planning and prevention. More funding and faster funding (and FDA approval) for game changing diagnostics and treatments should be the top pediatric target. Surgeons want to cut not prevent. I recently consulted on a grant application for epilepsy which was attempting to use qEEG to better predict time to surgery for Sturge-Weber Syndrome. I suggested

very strongly that they align with the major research that is looking to predict as early as possible in the pathway of the disease not fix it at the margins. We are simply not training our clinicians to solve big problems and when they do get exposed through journal club or collaboration, their immediate approach is replication. It's safe, its easy, its publishable. NIH will never break that horrific approach without a completely different incentive structure. Medicine is now overtly creating two classes of clinicians-researchers and non-researchers. This is akin to universities who have researchers who don't teach and a teaching corps of underpaid service workers. My suggestion is that no NIH money should be granted to any elite research group unless they are also training multiple young investigators outside of their own institution. This not only prevents the elite research group from hoarding but also limits their ability to exploit their fellows and residents (which they do). By taking steps like these, we are asking researchers to include people from excluded communities. in turn, those trained can better hone their research to solve their local community problems.

Description: Abstract of a current paper under review on transparency.

A Bias-Aware Analytic Framework for Real-World Data with AI-Audited Workflows: Application to Opioid Ordering in Pediatric Oncology

T. Morphew, H. Pease, M. Fotier, Z. Kain and L. Sayrs (2026)

Background The growing use of computational modeling of real-world data (RWD) in clinical research introduces significant risks for data scientists already managing inconsistency, unexamined bias, and analytical opacity. Without the formal theory supporting biostatistical models and despite more than 600 guideline-based checklists for data quality and transparency reporting in observational RWD, reliance on *ad hoc* model specification and verification is still the norm. No structured guidance exists to help clinicians and researchers systematically assess and manage the risks generated by computational results using RWD. In this paper, we propose a framework that reflects a rigorous, bias-aware methodology for complex analyses of RWD. We also propose the curated use of a large language model (LLM) supporting AI-generated code-auditing to ensure data quality. Our structured hierarchical approach coupled with AI-auditing is the first phase in the development of full-stack automation of RWD analytic validation.

Methods Our analytic framework spans 10 domains across three analytic phases. Each domain includes prespecified criteria governing verification with potential biases, mechanisms, and mitigation strategies systematically mapped throughout. Phase 1 entails *Specification* (Domains 1–4: objectives and estimands, data inputs and outputs, cohort and filters, and variable coding); Phase 2:*Modeling* (Domains 5–7: model testing, diagnostics, and reasonableness checks); and Phase 3: *Robustness and Interpretation* (Domains 8–10: missing data handling, temporal and stratified checks, and scope boundaries). We utilize specific prompt-directed large language model (LLM) auditing of model elements to ensure data quality. The methodology is illustrated with examples from an empirical characterization of inpatient opioid data from Cerner *Real World* (2014–2021).

Results The Cerner RWD data base contained 16,734 pediatric cancer patients (76,395 encounters) across 55 U.S. health systems. During the specification phase, total daily dose could not be estimated with sufficient validity from Cerner RWD, and "as-needed" orders, warranted empirically supported exclusion. The modeling phase revealed residual variability in opioid ordering attributable primarily to patient-level differences within health systems (ICC=19.9%) rather than between health systems (ICC=2.0%). Temporal analysis revealed a downward trend in morphine and fentanyl ordering trajectories from 2017-onward. We then utilized curated prompting to enforce an AI-generated coding requirement to produce valid likelihood ratio tests across the prespecified model sequence accounting for temporal trends.

Conclusions The 10-domain framework provides a structured, reproducible mechanism for governing RWD analyses, supporting transparent exposure definition, systematic bias assessment, prespecified analytic decision-making, and auditing via curated AI prompting. To our knowledge, this is the first structured framework to 1) identify analytic metrics at risk for unreliability; 2) incorporate AI-audited workflows in RWD research; and 3) demonstrate utility in a large multi-institutional real-world data base. The approach reflects the initial development in automating of RWE data analytics.

1. Rigor and Reproducibility: Maybe there could be an intramural branch at NIH dedicated to replicating studies that have the potential to be very impactful, and therefore, must be verifiably accurate. There could be a signifier (think social media "verified check") on PubMed that is displayed on papers that have been independently verified at NIH or other institutions.

2. Data, Software, and Model Sharing: Continuing to require that data/repositories/etc. that are produced using NIH grants be made publicly accessible is important. As we move into the age of AI writing most code that biologists use, it may be appropriate to require NIH grant awardees to also make their code publicly available upon publication of a project it is used in.

3. Training and Mentorship: This needs to be taken seriously at the level of university hiring practices and grant application review. If the primary investigator of a grant (excluding training grants) does not specify how they are going to involve trainees in conducting the project, it should be considered less favorably because it was not well thought out regarding the inclusion of trainee development.

4. Collaboration: Do not implement the grant cap proposed earlier this summer if you truly value collaboration. Investigators will be much less likely to work with other labs in any kind of formal capacity if writing a grant with other investigators directly takes away from their ability to fund their own lab. Since there is a constant cycle of trying to get money to fund science and doing science to get money, it is not realistic to assume that investigators will prioritize collaborating with other labs if there is no money involved because that informal collaboration work takes away the resources and personnel required to work on projects that will allow the lab to keep bringing in money.

5. Entrepreneurship and Translation: Generally, most biosciences researchers are either entrepreneurially-minded or they're not. Having resources available to support investigators who are motivated to study directly translatable questions or work in the drug development pipeline is great, but for those of us who do science for the advancement of knowledge and enjoyment of learning about the world, any attempts to force these people to abandon their studies and engage instead in an entrepreneurial agenda will be met with opposition.

6. Foundational Scientific Exploration: There needs to be more money set aside for grants that can be given to investigators with a proven track record of producing innovative and quality science using the traditional, "safer" funding mechanisms and who could therefore be reasonably trusted to explore meaningful questions with longer, more unstructured funding. Constant progress reports are a hindrance

to being able to work on anything in a timely manner and prioritize "successful results" over following the data naturally and trying bold ideas even if they don't work. If researchers are punished for not having positive results, they don't dare to study anything risky.

7. Public Impact: In the grant awarding process, include a section for applicants to discuss their involvement in science communication, policy, and other public engagement efforts. This requires reviewers to deliberately change their criteria for assessing a productive investigator.

8. Other Areas: Many of these areas can be addressed by reviewers and upper level members within each institute deciding to "put their money where their mouth is". If these topics are truly valued by NIH, making these changes only requires people to make a conscious effort to reward investigators who already do these things but are limited in how much time and resources they can expend on these other pursuits, as they are currently not rewarded by NIH.

SIR BRIEFINGS

Scholarly Integrity Review

Measuring and Rewarding Scientific Impact:

An Ethical, Interprofessional Response to NIH RFI NOT-OD-26-087

Author: **Annette Greer, PhD, MSN, RN, FNAP** — Founder, Scholarly Integrity Review LLC

Personal capacity; affiliation used only for identification. Not an ECU or BSOM institutional response.

Response window: June 18, 2026 – August 19, 2026.[1]

Version: Publication-ready draft after SIR internal audit x 3 (source verification, bias review, audience-impact assessment).

[1]National Institutes of Health. Request for Information on Measuring and Rewarding Scientific Impact. Notice NOT-OD-26-087. Released June 18, 2026. https://grants.nih.gov/grants/guide/notice-files/NOT-OD-26-087.html

Executive summary

NIH's Request for Information on Measuring and Rewarding Scientific Impact rightly recognizes that biomedical research is now a collaborative, interdisciplinary enterprise, and that publication counts and citation metrics are a poor proxy for the mission of enhancing health, lengthening life, and reducing illness.[2] The reform opportunity is real. So is the risk: any new indicator can become a new gaming target, and metric change without structural incentive change will not produce more rigorous or more trustworthy science.

This briefing offers a source-anchored, interprofessional response grounded in three convergent literatures — responsible metrics (**Leiden Manifesto**, **DORA**, **CRediT**),[345] team science (**National Academies 2015, 2025**),[67] and rigor and reproducibility (**Ioannidis 2005**, **Begley & Ellis 2012**, **NASEM 2017**, **NIH R&R Initiative**).[891011] It draws on the **IPEC 2023 Core Competencies** and Cochrane evidence on interprofessional collaboration to name what team-science measurement actually requires when the "team" includes nurses, social workers, pharmacists, community researchers, and patients — not only principal investigators.[1213]

Core recommendation. NIH should adopt a two-track indicator system: (1) an individual-level **Contribution Portfolio** anchored in CRediT roles, verifiable data/software/model deposits, mentorship

outcomes, and reproducibility events; and (2) a team-level **Public-Impact Trajectory** anchored in health-outcomes linkage, evidence uptake, community/practitioner engagement, and independent replication. Both tracks must be paired with narrative context, career-stage calibration, and an explicit anti-gaming and equity review — otherwise the reform risks recreating h-index harms in new dress.

1. Why this RFI matters now

The RFI is issued alongside NIH's Replication and Reproducibility Initiative and its Plan to Drive Gold Standard Science.[14][15] It names seven target areas: rigor and reproducibility; data, software, and model sharing; training and mentorship; collaboration; entrepreneurship and translation; foundational scientific exploration; and public impact.[16] Two decades of published evidence support the diagnosis:

- **Preclinical irreproducibility is well documented.** Begley and Ellis reported that only 11% of 53 landmark preclinical oncology findings could be reproduced by an experienced industry team; Ioannidis showed on statistical grounds that most published findings can be expected to be false under common design conditions.[17][18]
- **Individual metrics reward the wrong things.** The Leiden Manifesto and DORA both conclude that journal impact factors and citation counts are poor proxies for scientific quality and misalign incentives with research missions.[19][20]
- **Team science is the norm, not the exception.** The National Academies concluded in 2015, and reaffirmed in 2025, that biomedical research increasingly requires interdependent expertise across disciplines, sectors, and career stages — with attribution challenges that individual metrics cannot solve.[21][22]

[22]National Academies of Sciences, Engineering, and Medicine. The Science and Practice of Team Science. Washington, DC: National Academies Press; 2025. https://www.nationalacademies.org/read/29043/chapter/4

- **Public trust is fragile but recoverable.** Pew Research found that 76% of U.S. adults have a great deal or fair amount of confidence in scientists to act in the public's best interests in 2024 — up from pandemic lows, but with sustained concerns about communication, humility, and policy overreach.[23] Metrics that ignore public impact and transparency will not repair that trust.

2. Ethical grounding: measurement is a moral act

Choosing what to count is a value statement about what science is for. Three ethical commitments should govern any new NIH indicator set.

2.1 Human accountability before algorithmic ranking

Leiden Manifesto Principle 1 is unambiguous: quantitative evaluation should support — not supplant — qualitative, expert assessment.[24] Every proposed indicator should have a named human decision-maker responsible for its use, with authority to override the number when context demands. This mirrors interprofessional ethics: teams are accountable, algorithms are not.[25]

2.2 Transparency, reproducibility, and honest failure

NASEM's **Fostering Integrity in Research** frames research integrity as a shared responsibility across investigators, institutions, journals, and sponsors, and treats transparency as constitutive of rigor rather than an add-on.[26] Indicators must reward negative results, pre-registration, failed replications, and corrections — not only positive discoveries.

2.3 Equity across career stages, disciplines, and institution types

The RFI explicitly asks for indicators that are feasible across career stages, disciplines, and institution types.[27] Early-career investigators, minority-serving and rural institutions, community-engaged and clinical-education researchers, and interprofessional non-physician scientists (nurses, social workers, pharmacists, allied health) will be disproportionately harmed by any metric set that presumes MD/PhD principal-investigator norms.

3. What "collaboration" must mean in an interprofessional biomedical enterprise

The RFI names collaboration as one of seven indicator areas but leaves the term open.[28] In modern biomedical research, collaboration is not simply co-authorship across departments; it is interprofessional and inter-sectoral, and it operates under a competency framework that the workforce already uses to teach and assess team behavior.

IPEC 2023 Core Competencies (Version 3) define four domains — values and ethics, roles and responsibilities, communication, and teams and teamwork — that shape how modern health-professions teams learn to work together and how team performance can be observed.[29] Cochrane evidence on practice-based interprofessional collaboration interventions shows small-to-modest improvements in adherence to practice guidelines, healthcare processes, and use of resources, with the strongest signal coming from structured team routines rather than one-off training.[30]

Implication for NIH. Team-science indicators should draw on this existing, validated competency architecture rather than invent parallel scales. Contribution attribution should be structured (CRediT), reproducibility should be team-attributable (not only PI-attributable), and collaboration quality should be observable through team routines, decision logs, and shared data/software deposits — not through survey self-report alone.[31][32]

4. Recommended measurable indicators, by RFI area

For each area, SIR proposes candidate indicators that satisfy the citation and evidence rigor standard: they are observable, verifiable, resistant to trivial gaming, and feasible for early-career and non-R1 investigators. Each is paired with a named benefit and a named unintended consequence to be actively monitored.

RFI Area	Candidate indicator	Watch-out
Rigor & Reproducibility	Independent replication attempts documented per lab per 5-year period; pre-registration rate; open protocol deposit rate; corrections and retractions handled transparently.	Do not create incentives for shallow "confirmatory" replications; require methodological independence.
Data, Software & Model Sharing	FAIR-compliant deposit rate at time of publication; downstream reuse counts (data citations, package installs); computational reproducibility receipts.	Reuse counts favor mature fields — pair with narrative context; protect participant privacy in data-sharing metrics.
Training & Mentorship	Trainee independence outcomes at 5 and 10 years (grants, first-author work, retention in research); mentee-reported climate and integrity indicators; documented mentoring plans.	Do not penalize mentors whose trainees leave academia for equally valuable public-impact roles.
Collaboration	CRediT-based contribution portfolios; team composition diversity (disciplines, professions, institution types); documented team routines and decision logs.	Avoid rewarding "author inflation"; use CRediT roles rather than raw co-author counts.
Entrepreneurship & Translation	Verified translation events (licensed technology, guideline adoption, policy citation, deployed clinical decision-support); post-translation safety and equity monitoring.	Do not conflate patents filed with public health benefit delivered; require outcome linkage.
Foundational Exploration	High-risk portfolio share at institution level; time-to-first-independent-award for exploratory investigators; documented negative-result publication.	Protect small-lab and non-R1 exploratory work; do not concentrate high-risk funding in a few elite sites.
Public Impact	Guideline citation; measurable population health signal linked to funded lines of work; community/patient-partner co-authorship and governance; independent media and educator reuse.	Guard against political capture of "impact"; adopt bias review, not popularity, as a proxy.

5. A two-track measurement model

Track A — Contribution Portfolio (individual). An investigator-level, career-stage-calibrated portfolio combining verified CRediT roles across published outputs, verifiable data/software/model deposits, mentorship outcomes, independent replication events (both attempted and successful), and a narrative

that names contribution to team science and public impact.[3][3][4][3][5] Institutions review the portfolio holistically; NIH samples it for validation.

Track B — Public-Impact Trajectory (team/line of work). A team- or program-level trajectory that follows a research line into practice: guideline uptake, changes in clinical or policy standards, community-partner co-governance, patient-reported benefit where measurable, and equity of that benefit across populations.[3][6][3][7] The unit of analysis is the research question, not the individual.

Why two tracks. A single composite score would recreate the h-index harm the RFI is trying to escape. Two independent tracks preserve individual accountability and team accountability without collapsing them into each other. NIH review committees can weight the tracks differently by mechanism (fellowships weight Track A; centers and consortia weight Track B).

6. Named risks and unintended consequences

- **Goodhart's Law.** Every metric becomes a target. Any new indicator should be paired with a stated tolerance for gaming behavior and a scheduled review at 3 and 5 years, with authority to sunset indicators that no longer measure what they claim.
- **Equity harms.** Reproducibility investment favors well-resourced labs. Data-sharing infrastructure favors large centers. Translation metrics favor commercially attractive lines of work. Each area needs an equity offset that protects early-career, minority-serving, rural, and non-physician-led science.[3][8]
- **Political capture of "public impact."** "Public impact" can be defined narrowly to reward politically convenient work. NIH should bind public-impact indicators to independent scientific and

[3][3]Brand A, Allen L, Altman M, Hlava M, Scott J. Beyond authorship: attribution, contribution, collaboration, and credit. Learned Publishing. 2015;28(2):151-155. CRediT — Contributor Roles Taxonomy (ANSI/NISO Z39.104-2022). https://credit.niso.org/

[3][8]National Institutes of Health. Request for Information on Measuring and Rewarding Scientific Impact. Notice NOT-OD-26-087. Released June 18, 2026. https://grants.nih.gov/grants/guide/notice-files/NOT-OD-26-087.html

community review, not to the sitting administration's policy agenda. This is a durable-institution question, not a partisan one.[3940]

- **Erosion of foundational exploration.** Basic and high-risk work has slow, uncertain public impact by design. Any indicator system that penalizes slow trajectories will hollow out the pipeline that produced the discoveries the RFI now wants to reward.[4142]
- **AI-enabled metric inflation.** Generative tools can now produce plausible-looking outputs, citations, and contribution claims. NIH should require verifiable deposit and identifier-resolvable attribution (ORCID, ROR, DOI) before any indicator is credited, and should treat unverifiable AI-authored outputs as unattributed.[4344]

7. Implementation approach

- **Pilot before mandate.** Pilot the two-track model in 2–3 ICs across mechanism types (R01, K, U54, T32) for a full cycle before scaling.[45]
- **Publish an anti-gaming register.** For each indicator, publish the known gaming behaviors, the monitoring plan, and the sunset trigger. This inverts the h-index history in which harms were named only after damage.
- **Anchor in existing standards.** Use CRediT (ANSI/NISO Z39.104-2022), FAIR principles, and the existing Data Management and Sharing Policy as the technical backbone.[464748]

- **Interprofessional review panels.** Include nursing, social work, pharmacy, allied-health, patient/community, and non-physician scientific reviewers on panels that assess team-science and public-impact indicators. IPEC competencies can structure that review.[4950]
- **Sunset the composite.** Do not publish a single institutional or investigator ranking derived from the new indicators. The Leiden Manifesto's warning against composite league tables applies with special force here.[51]

8. Direct response to the RFI's core questions

Specific measurable indicators: See Section 4 table and the two-track model in Section 5.

Implementation approaches: Section 7. Pilot, anti-gaming register, anchor in CRediT/FAIR/DMS policy, interprofessional panels, no composite ranking.

Potential benefits: Better alignment between reward structure and NIH mission; explicit recognition of team-based and interprofessional contributions; verifiable, sharable evidence of rigor; recovered trust through transparent public-impact linkage.[52]

Unintended consequences: Section 6. Goodhart's Law, equity harms, political capture, erosion of foundational exploration, AI-enabled metric inflation.

Feasibility across career stages, disciplines, and institution types: Two-track separation lets NIH weight tracks by mechanism, protecting early-career, non-R1, community-engaged, and interprofessional-non-physician investigators from being scored on the same rubric as senior R01 PIs.[535455]

Measurement in science is not administrative housekeeping. It is a public covenant about what we agree to reward. If NIH measures narrowly, it will teach the next generation to work narrowly. If NIH measures well — rigor, transparency, team contribution, mentorship, honest failure, and verifiable public impact — it will restore what the h-index era eroded. That is the reform this RFI has the chance to deliver, if the new indicators are paired from day one with the humility to sunset them when they stop serving the mission.

Author note

Author. Annette Greer, PhD, MSN, RN, FNAP. Founder, Scholarly Integrity Review LLC. Faculty, Brody School of Medicine at East Carolina University.

Capacity. This SIR Briefing is submitted in personal capacity. ECU/BSOM affiliation is used only for identification; the response is not an institutional ECU or BSOM comment.

Competing interests. The author leads Scholarly Integrity Review LLC, which reviews citations, sources, methods, and manuscripts for academic clients, and Integrity Document Services. No NIH funding was used to prepare this briefing; no ECU library or database access was used to anchor claims in this document.

Method. Sources were drawn from primary NIH notices, National Academies consensus reports, peer-reviewed scholarship, and standards-body documents. Each load-bearing claim is footnoted to an identifier-resolvable source. Draft passed SIR internal audit x 3: (1) source verification, (2) bias review, (3) audience-impact assessment.

Description: Alzheimer's Association Responses to NIH RFI on Measuring and Rewarding Scientific Impact

Jay Bhattacharya, MD, PhD
Director
National Institutes of Health
9000 Rockville Pike
Bethesda, Maryland 20892

August 10, 2026

Re: Request for Information on Measuring and Rewarding Scientific Impact (Notice Number: NOT-OD-26-087)

Dear Dr. Bhattacharya,

The Alzheimer's Association and the Alzheimer's Impact Movement (AIM) appreciate the opportunity to respond to the Request for Information on Measuring and Rewarding Scientific Impact.

The Alzheimer's Association is the leading voluntary health organization in Alzheimer's care, support, and research. The Alzheimer's Impact Movement, a separately incorporated advocacy affiliate, is a nonpartisan, nonprofit organization and works to make Alzheimer's a national priority.

Today there are an estimated 8.6 million Americans with the biomarkers of Alzheimer's disease and symptoms, including 4.4 million Americans with dementia due to Alzheimer's and 4.2 million with mild cognitive impairment (MCI) due to Alzheimer's.[1] Yet only two treatments are available that change the underlying biology of Alzheimer's and slow cognitive decline, and the treatments are only for people with mild cognitive impairment or mild dementia. People with moderate or severe Alzheimer's dementia have no therapeutic options, save drugs to lessen symptoms. Furthermore, research advances have made it possible to detect Alzheimer's biomarkers in individuals without symptoms - which might be the most effective time to intervene - but they also have no therapeutic options. Therefore, the Alzheimer's Association and AIM applaud the National Institutes of Health's (NIH) efforts to drive new incentives toward scientific progress.

The Alzheimer's Association and AIM fully support the expansion of the types of non-traditional metrics proposed in concept. The exact metrics, however, may prove challenging to develop, and the evaluation of these contributions must be balanced. For example, teaching an online course is not the same as an in-person course in a medical school lab; how is that evaluated? If a metric is the number of individuals trained for the workforce and they subsequently leave the field, how is that evaluated? How are shared datasets and subsets valued? We would be pleased to work with NIH to explore these issues and ultimately drive scientific progress.

[1] Alzheimer's Association. (2026). *2026 Alzheimer's Disease Facts and Figures.*

Thank you for the opportunity to comment. The Alzheimer's Association and AIM would be glad to serve as a resource to NIH as it considers these important issues and how they relate to individuals living with Alzheimer's and related dementias. Please contact Laura Thornhill, Director, Regulatory Affairs, at 202-638-7042 or lthornhill@alz-aim.org if you have questions or if we can be of additional assistance.

Sincerely,

Robert Egge
Chief Public Policy Officer, Alzheimer's Association
President, Alzheimer's Impact Movement

Maria C. Carrillo, Ph.D.
Chief Science Officer, Alzheimer's Association

1. Rigor and Reproducibility: Rigor and reproducibility in genomics need to separate two things that current NIH metrics tend to blur: statistical reproducibility (same data, same code, same result) and biological replicability (independent data, same conclusion). Single-cell genomics is especially vulnerable here because upstream choices like normalization, batch correction, and dimensionality reduction can silently change downstream findings without anyone noticing. NIH's push for gold standard science would benefit from treating these as distinct, separately measurable indicators rather than folding them into a single "reproducibility" bucket.

On causal research specifically, rigor should be defined by whether a paper explicitly states its causal assumptions (no unmeasured confounding, faithfulness, etc.) rather than by which algorithm it uses. Work applying causal discovery to single-cell perturbation data shows that causal claims from observational genomic data require sensitivity analyses and transparent assumptions, not just methodological novelty. A concrete indicator NIH could adopt is something like an "assumption disclosure checklist," similar to CONSORT or STROBE guidelines but built for computational and causal methods.

A few other measurable indicators worth proposing:

Require papers to report whether their false discovery rate control has any theoretical guarantee, rather than relying on nominal p value thresholds. Many high throughput pipelines currently lack this, and p value free frameworks like Clipper show it's possible to validate FDR control without assuming a specific data distribution.

Track whether code and data pipelines are version pinned and containerized (tagged Git releases, fixed random seeds), since single-cell integration methods are highly sensitive to software drift.

Create a "replication readiness score" combining code and data availability, documented random seeds, benchmarking against simulated ground truth, and pre-registration for hypothesis driven studies.

As AI tools become embedded in every stage of biomedical research, from literature synthesis to code generation to result interpretation, NIH needs explicit guidelines for when and how AI outputs can be trusted rather than treating them as neutral productivity gains. A useful evaluation framework would

require researchers to disclose which parts of an analysis involved AI assistance, benchmark AI generated code or annotations against a known ground truth before relying on them, and report an error rate rather than assuming correctness. For single-cell genomics specifically, AI based cell type annotation or gene function prediction tools should be evaluated the same way any other statistical method is evaluated, meaning held out validation, calibration checks, and sensitivity to input perturbations, rather than accepted purely because a large model produced them. NIH could incentivize this by funding independent benchmarking of AI tools used in biomedical pipelines, similar to how new statistical methods are benchmarked, and by requiring grant applications and publications to state what human verification step was applied to any AI generated result before it entered the paper.

On incentives and infrastructure, NIH should fund benchmarking and replication work as its own grant category, not just novel method development. Right now, careful benchmarking papers are undervalued relative to flashy new methods, even though they're what actually let the field trust a result. Supporting shared, well characterized reference datasets with known ground truth would also help, since realistic simulators are essential for testing whether a method's reproducibility claims actually hold before publication. Tenure and grant review criteria should give explicit credit for benchmarking papers, replication studies, and negative results, which is really the core ask behind NIH moving past raw publication and citation counts.

On feasibility, early career researchers and smaller institutions often don't have the compute or data infrastructure to run large scale replication studies. NIH could offset this with shared cloud compute credits or consortium access earmarked for reproducibility verification work. Reproducibility and benchmarking work is also time intensive and mostly invisible on the tenure clock right now, so study sections and review criteria need to treat it as a real scientific contribution rather than service work.

2. Data, Software, and Model Sharing: Data, software, and model sharing in computational biology needs incentives that go beyond simply posting code to a repository, because a public GitHub link with no maintenance, documentation, or usage tracking does little to advance reproducibility. Statistical software for genomics, like FDR control frameworks or single-cell analysis tools, only delivers value if other researchers can actually install it, run it on their own data, and get comparable results. That means the measurable indicators NIH adopts should capture usability and maintenance, not just existence.

A few concrete indicators worth proposing:

Track software usage and adoption through metrics like downloads, Bioconductor or CRAN install counts, or citations of the software itself as distinct from citations of the associated paper. Right now a method paper gets citation credit while the underlying tool, which took far more sustained effort to build and maintain, gets none.

Require a minimal reproducibility package for any tool tied to a publication, meaning example data, a working vignette, and version pinned dependencies, so a new user can reproduce the paper's core result within a fixed time budget, say under an hour.

Score data sharing not just on deposit but on documentation completeness, meaning whether metadata, processing scripts, and quality control steps are included alongside raw data. A dataset dropped into a

repository without its generating code is much less useful for validation than one with a full computational trail.

For models specifically, including statistical or machine learning models trained on genomic data, require versioned model releases with reported performance on held out or independent benchmark datasets, not just performance on the training cohort.

On incentives, NIH should treat long term software maintenance as a fundable activity in its own right, separate from new method development grants. Maintaining a widely used single-cell analysis tool for five years after publication is real scientific labor, yet it is currently invisible in grant renewals and promotion packets. NIH could create a distinct award mechanism, similar to how some funders support research software engineers, that explicitly funds bug fixes, dependency updates, and user support rather than only new algorithmic contributions.

NIH should also recognize data and software curators and maintainers as contributing authors or acknowledge them through a formal contribution taxonomy, similar to CRediT, so that promotion and tenure committees can see this work reflected in a researcher's record. Institutions vary widely in how they weigh software contributions, so NIH endorsing a standard contribution statement across grant applications and biosketches would help normalize this across career stages and institution types.

A potential unintended consequence is that overly rigid sharing requirements could disadvantage early career researchers or smaller labs without dedicated engineering support, so any mandate should be paired with infrastructure funding, such as shared institutional repositories or centralized deposition services, rather than pushing the full compliance burden onto individual investigators. Large data intensive genomics studies also raise data sharing complications around patient privacy and consent scope, so indicators for data sharing need to allow for controlled access tiers rather than assuming all data can or should be fully public.

Finally, NIH could fund the creation of well characterized benchmark datasets with known ground truth for common genomic tasks, since having a shared gold standard is what actually lets independent groups verify that a tool or model works as claimed, rather than relying on each paper's own internal validation.

1. Rigor and Reproducibility: Rigor and Reproducibility

Reproducible and replicable research is the operational foundation upon which the biomedical research enterprise derives its credibility and public value. NIH's Replication and Reproducibility Initiative arrives at a critical inflection point, one in which the complexity and scale of modern biomedical research have outpaced the infrastructure, incentives, and norms required to sustain it. The following comments draw on direct operational experience supporting large-scale NCI data-generating programs, where reproducibility planning, validation frameworks, and quality assurance are contractual requirements and critical to support the NIH's mission. We offer specific, implementable recommendations across four areas: computational standards, treatment of negative and replication studies, metrics and recognition structures, and dedicated funding mechanisms.

Computational Reproducibility Standards

The reproducibility crisis in biomedical science is, in substantial part, a computational reproducibility crisis. The RFI also asks about causal rigor, including standards for causal inference and study design; these merit parallel NIH attention and are outside the scope of these four recommendations, which focus on computational reproducibility specifically. Analyses that cannot be re-executed because of undocumented software environments, proprietary dependencies, or absent version control cannot be validated, replicated, or built upon. NIH should address this directly and systematically with the four following steps.

First, NIH should require computational pipeline validation plans as a deliverable for all data-generating grants, analogous to the existing Data Management and Sharing Plan requirement. These plans should specify pre-defined acceptance thresholds for key quality metrics, document the software environment (including version-pinned dependencies), describe the validation dataset and approach, and define the human review process for automated outputs. Without such a plan, there is no systematic mechanism to verify that an analysis can be independently re-executed, that results reported at publication match what the pipeline produces, or that automated outputs have undergone human review prior to dissemination. In our experience supporting federal informatics programs, the development of a formal bioinformatic pipeline validation plan, including defined acceptance criteria, structured testing against a mock dataset, and human review of flagged outputs was essential to building confidence in novel

analysis products. This model to define criteria, validate against a gold standard or acceptance threshold, and document the process is broadly applicable and should be a standard deliverable, not an optional practice.

Second, NIH should invest in centralized validation resources and reference standards for high-priority assay types and computational methods, modeled on programs like ENCODE or Genome in a Bottle. These initiatives produced validated reference datasets and benchmarking protocols that individual research groups could adopt without recreating the validation infrastructure from scratch. The absence of such resources forces independent groups to develop their own gold standards, causing a duplication of effort that introduces variability across studies. In our own bioinformatics work, developing and validating novel pipelines for emerging technologies, such as spatial transcriptomics, required substantial investment in constructing validation benchmarks simply because the fundamental resources do not exist for this type of work. NIH-funded, community-maintained validation resources of this kind would lower the barrier for reproducible pipeline development across the field.

Third, NIH should require a documented, reproducible environment specification as a condition of data deposition and publication for computational and AI-based research. Containerized environments such as Docker or Singularity are the most reliable implementation for most work and should be the default. NIH should define approved alternatives for cases where containerization is not feasible, including work involving controlled-access data, licensed or proprietary software dependencies, export-controlled materials, or long-term maintenance constraints, provided the alternative achieves equivalent reproducibility. The environment in which an analysis was run is as much a part of the methods as the algorithm itself; without a documented specification, computational reproducibility is aspirational rather than achievable.

Finally, NIH should consider piloting concordance-based submission standards for data deposition into shared repositories, analogous to the platform concordance testing used in clinical trial settings. Under this model, research groups seeking to contribute data of a specific type to an NIH data common would validate their pipelines against a standard reference set. Concordance with defined thresholds would be a prerequisite for submission. This would establish baseline comparability across contributed datasets, a prerequisite for meaningful meta-analysis and cross-study replication.

Treatment of Negative and Replication Studies

The current incentive structure penalizes researchers who pursue replication studies or report null results, regardless of the scientific rigor with which those studies were conducted. This creates a systematic bias in published literature and undermines the self-correcting function of science. NIH should act on several fronts. NIH should explicitly recognize and reward investigators who publish rigorous replication and null-result studies during grant renewals and progress report evaluations. A well-conducted replication study that confirms or fails to confirm a high-impact finding is a valuable contribution to the field and should be treated as such. Providing equal weight to null and replication findings, rather than treating them as evidence of unproductivity, would shift researcher incentives in a meaningful direction. NIH should work with journals and preprint servers to establish structured pathways for publishing null replication findings, including standardized reporting formats that make

these studies discoverable and citable. The absence of such pathways means that failed replications frequently go unpublished, creating an invisible correction record that cannot be accessed by the broader community.

NIH should also consider funding standing replication cohorts; small, continuously funded teams whose explicit mission is to independently reproduce high-impact findings in priority disease areas. Success metrics for these teams should be defined by completion rate and concordance, not by novel publication output. This would provide a systematic, rather than ad hoc, mechanism for evaluating the replicability of landmark findings before they advance to clinical translation.

Metrics and Recognition Structures

Metrics shape behavior. If NIH wants reproducible research, it must measure and reward the practices that produce it.

NIH should develop and track a reproducibility practice index for funded investigators with structured measures of whether key reproducibility practices were followed; protocol preregistration, version-controlled code availability, standardized SOPs, complete methods reporting, and validated data QC thresholds. This index could function similarly to an H-index in concept but would track rigor practices rather than citation counts and could be factored into competitive renewal scoring.

NIH should introduce "Reproducibility Badges" on Biosketches as a formal NIH designation for investigators whose published protocols have been independently verified or whose computational pipelines have been successfully re-executed by a third party. This creates a visible, career-relevant signal that rigor is recognized and valued, particularly important for early-career investigators who face pressure to prioritize novelty over reproducibility. It is also the natural complement to the replication cohort concept and incentivizes to seek third party verification. NIH should ensure that badge criteria are attainable across institution types, including smaller institutions and disciplines without mature, shared validation infrastructure, and should provide implementation guidance and tooling support to prevent the program from inadvertently advantaging well-resourced groups.

The NIH should consider tracking independent validation of published findings, such as external reproductions, successful cross-site implementations, and secondary analyses using deposited data as a distinct positive impact metric separate from citation counts. A finding that has been independently validated across multiple sites and datasets represents a qualitatively different and higher level of scientific confidence than one that has been frequently cited but not yet reproduced. For early-career investigators, documenting independent validation of their published methods and findings during tenure review and career advancement processes would create a meaningful incentive structure at the institutional level.

Finally, NIH should incentivize the creation of reusable research infrastructure, for example, validated assays, reference datasets, and standardized workflows as a scoreable output. Grants that produce infrastructure enabling others to reproduce findings should receive scoring recognition, and dedicated funding mechanisms (e.g., R21-scale awards) should be available specifically for infrastructure

development of this kind. In our experience, SOP-driven quality frameworks such as the comprehensive suite of validated operating procedures governing clinical trial abstraction and quality assurance, provide exactly this kind of reusable infrastructure; documented, version-controlled, and subject to annual review. The value of that infrastructure compounds across the programs that adopt and adapt it.

There is established precedent within the federal ecosystem for holding recipients of government funds accountable for the quality of their work through recurring, on-the-record evaluation. Through the Contractor Performance Assessment Report (CPAR) system, federal contractors are formally rated on performance at regular intervals, and those ratings persist as part of the entity's record, following the organization across future funding opportunities. This creates a durable, portable accountability signal; consistent quality is rewarded with continued opportunity, and lapses in quality carry forward-looking consequences. NIH should consider extending an analogous principle to the reproducibility and rigor of federally funded research. A recurring, on-the-record assessment of an investigator's or institution's adherence to reproducibility practices that persist as part of their funding record rather than resetting with each new award would align incentives with long-term scientific reliability. The key features worth adopting are the periodic cadence, the persistence of the record over the life of the funded entity, and the direct linkage between demonstrated rigor and future funding competitiveness.

Dedicated Funding Mechanisms

Two funding mechanisms merit specific consideration. First, NIH should establish Independent Replication Supplements. Dedicated supplemental awards to pay independent, third-party laboratories to replicate landmark or high-impact findings before those findings advance to clinical stages or inform major funding priorities. This would create a systematic pre-translation check without requiring primary investigators to shoulder the replication burden.

Second, NIH should consider Institutional Replication Core incentives. Overhead or infrastructure funding for universities and research institutions that establish and maintain dedicated internal replication cores. These cores would audit and validate high-stakes findings internally before public dissemination, providing a first-line quality check that benefits both the investigator and the broader field, and creating institutional ownership of reproducibility as a value, not just a mandate.

2. Data, Software, and Model Sharing: Data, Software, and Model Sharing

NIH's investment in data sharing has produced extensive repository infrastructure and a policy framework that, on paper, requires investigators to make their data available. What it has not consistently produced is reuse. The gap between deposition and reuse is where the return on NIH's data investment is being lost, and closing it requires action on four fronts: measuring what actually matters, governing for reusability from the point of study design rather than the point of deposit, reducing the regulatory complexity that drives investigators toward conservatism, and funding the people and infrastructure that make shared resources usable over time.

These comments draw on operational experience building and running data sharing pipelines and harmonization infrastructure for NIAID and NCI programs and on the work established specifically to help federal clients navigate the regulatory environment governing biomedical data. We reference this

experience because several of the recommendations below arise directly from repeatedly encountering the same issues across programs.

1. Measure Reuse, Not Deposition

The single most consequential change NIH could make is to shift its measurement of data sharing success from a count of deposits to a measure of downstream reuse. A deposited dataset that no one accesses represents a compliance event, not a scientific contribution.

Develop a Data Sharing Impact Score. NIH should track the metrics that reflect actual scientific value: the number of derivative publications using a deposited dataset, the number of unique investigators who have accessed it, the number of independent replication or validation attempts it enabled, and the number of downstream studies that incorporated it into larger analyses. This score should appear on investigator profiles and be factored into competitive renewal scoring.

Weight external and independent reuse more heavily than internal reuse. A dataset used exclusively by the generating laboratory and its immediate collaborators has not entered the scientific commons in any meaningful sense. The measure of a dataset's value is whether investigators with no prior connection to the generating team can find it, understand it, and use it. Reuse metrics must distinguish clearly between these cases, for example, by factoring generators' and users' geographical location and co-authorship history.

Credit widely adopted software and models on the same basis. Investigators whose shared tools achieve broad adoption by other NIH-funded projects or clinical research networks have delivered substantial scientific value. A computational method adopted by fifty downstream studies has arguably contributed more than a well-cited but unused publication, yet the current incentive structure recognizes only the latter.

Two mechanisms make this tractable using infrastructure that already exists:

Elevate data and software citations to parity with journal citations. Persistent identifiers for datasets and open-source software are already well-supported. NIH should treat citations tracked through these identifiers with the same administrative weight as traditional publication citations in the NIH Biosketch and in review. This is a low-cost policy change with immediate signaling value.

Establish a Data Utility Index tied to future funding eligibility. This index would measure how frequently an investigator's previously funded datasets are actively used in external, independent publications. Tying a portion of renewal competitiveness to demonstrate utility of prior data outputs would create a direct and durable incentive to produce data others can use.

Anticipate gaming. Any reuse-based metric will be gamed if implemented naively. Reuse counts inflated by self-citation, by consortium partners, or by trivially derivative analyses would undermine the metric's validity. The mitigations are straightforward but must be designed from the start: weight for independence from the generating team, require that reuse be traceable to a persistent identifier rather

than self-reported, and audit a sample of claimed reuse events. NIH should also avoid disadvantaging investigators in fields where the potential for reuse, for example due to low number of researchers, is inherently small. The metric should be normalized against field-level or data-type-level baselines rather than applied as a raw count.

2. Govern for Reusability at the Point of Design, Not the Point of Deposit

The most expensive moment to harmonize data is after it has been collected. The cheapest is before it is collected at all. Current NIH policy engages data sharing primarily at the back end of the research lifecycle, through Data Management and Sharing Plans reviewed for compliance and deposition requirements enforced at publication. This is backwards from both a cost and a quality standpoint. By the time data arrives at a repository in a nonstandard format, the harmonization required to make it interoperable is labor-intensive, error-prone, and often scientifically lossy.

Move common data elements from the back end to the front end. NIH has invested substantially in CDE infrastructure through the NIH CDE Repository and, in the cancer domain, through Cancer Data Standards Registry and Repository (caDSR). That investment is not being fully realized, for two reasons. First, CDE adoption is treated as an optional best practice rather than a design requirement. Second, the practical barrier to adoption is high: with tens of thousands of CDEs available, no investigator can reasonably be expected to know which element best fits a given data capture need. Placing that navigation burden on the individual researcher guarantees inconsistent adoption.

Two changes would address this directly.

Fund tooling that makes CDE selection and mapping easy enough to become default behavior. This is a solvable technical problem. For example, sentence embedding models accurately and rapidly map source data elements to appropriate CDEs. Thus, the barrier to CDE adoption is a tooling gap, not a fundamental scientific one, and NIH is well positioned to close it.

Align clinical trial funding expectations with use of approved, community-developed CDEs where fit-for-purpose, enforced through the statistical analysis plan review process, with documented exceptions where no appropriate element exists or where domain-specific standards apply. For clinical research, the enforcement mechanism already exists. Statistical analysis plans are reviewed and approved by governing bodies, and data collection standards can be reviewed at that same gate. If a study's data capture instruments are required to use approved CDEs as a condition of protocol approval, the data arrives in a reusable format by construction and costly retrospective harmonization becomes unnecessary. NIH should pilot this requirement in a defined program area and measure the downstream reduction in harmonization cost, which we expect would be substantial.

Establish governance parity for software and model artifacts. Current DMS Plan requirements are oriented toward datasets and largely do not address model artifacts. As machine learning methods become central to biomedical discovery, this is an increasingly consequential gap. A published model with no documented training data provenance, no version-controlled code repository, and no held-out validation benchmark cannot be evaluated, reproduced, or responsibly reused. NIH should require, for

any model published with NIH support: documentation of training data provenance, a version-controlled and publicly accessible code repository, and at minimum one held-out validation benchmark reported against a defined test set. The discipline is not burdensome in our experience when adopted at the outset, but in practice, it is nearly impossible to retrofit.

Add a data sharing readiness review at grant review. Before a data-generating study is funded, reviewers should assess whether the proposed data model, formats, and deposition target are realistic for reuse by investigators outside the generating team. This is a distinct question from whether the DMS Plan is technically compliant. A study that plans to deposit a nonstandard, sparsely documented dataset into a general-purpose repository can be fully compliant and still not promote data reuse.

Verify data sharing rather than accepting attestation. Annual grant progress reviews should include data sharing progress, verified rather than self-reported. Reporting a dbGaP accession number or BioProject ID is evidence that a record was created, not that data are accessible. NIH should implement verification mechanisms, such as cross-checking repository access records and controlled-access approval lists against grantee reports, to confirm that data have actually been released and are actually reachable by qualified external requestors who have completed applicable data use agreements. We believe the gap between reported and actual accessibility is, in our operational experience, meaningful and underappreciated.

3. Reduce the Regulatory Complexity That Suppresses Sharing

Regulations governing patient-derived data are essential. They protect participant privacy, honor the terms under which participants consented, and sustain public trust in biomedical research. They are also, in aggregate, extraordinarily difficult to navigate, and that difficulty is itself suppressing the reuse of exactly the high-value datasets NIH most wants reused.

We want to be precise about the nature of the problem, because it is frequently mischaracterized. The issue is not simply that there are many rules. It is that the applicable authority stack is scenario-dependent, the scenarios are not enumerated anywhere authoritative, and the prioritization among conflicting authorities is not documented. In our experience, the correct authority stack for a given dataset depends on a set of distinctions that are not obvious and are frequently not known to the investigator:

Funding pathway. Data generated under NIH funding, data generated externally but analyzed under NIH funding, data generated under NIH funding but analyzed externally, and data generated in collaboration with NIH under a services-in-kind agreement are each governed differently. In the mixed cases, which award's expectations take precedence is a real question with a real answer, and it is not intuitive.

Generation versus analysis. An award covering analysis carries expectations that may differ from those attached to the award that generated the data, and both may apply in sequence.

Repository ownership. Whether a system is operated on behalf of NIH, qualifies as an NIH Controlled Access Data Repository, or is external to NIH determines an entirely different compliance regime, with

different security expectations and different review processes for sensitive data.

Requestor role. Access rules differ materially for senior-level PIs, non-senior investigators and lab members, students and citizen scientists, developers supporting a data system under NIH funding, and NIH program staff exercising oversight. Each of these categories has a distinct approval pathway.

Institutional and national location. Collaboration with investigators at the same institution, at a different U.S. institution, and at an international institution each trigger different requirements, with additional restrictions applying to entities based in countries of concern.

Emerging product types. Tools and AI models used for scientific management or reuse, animal models, and biospecimens raise authority questions that existing policy addresses incompletely.

The behavioral consequence of this complexity is predictable and damaging. When a researcher is uncertain whether they are permitted to share a dataset, the rational default is to not share it. Regulatory ambiguity produces conservatism, and conservatism suppresses reuse. NIH is very likely losing more data sharing to uncertainty than to actual prohibition. We would encourage NIH to treat this as a first-order priority rather than a background condition, and we offer two recommendations.

Sponsor an authoritative, maintained decision-support tool for data use authorities. A researcher should be able to describe the characteristics of their dataset and their intended use (data type, funding pathway, consent scope, repository, requestor role, recipient institution and location) and receive a clear determination of which frameworks apply and what adherence requires. This tool should be developed, it should be authoritative, and it should be centrally maintained rather than reconstructed independently by every institution and program that needs one. The alternative, which is the status quo, is that thousands of investigators each make an individual, uninformed, risk-averse judgment.

Pursue holistic, cross-agency harmonization of data sharing authorities. A decision-support tool makes a complex environment navigable, but it does not make it simpler. The deeper fix is for NIH, in coordination with other HHS components and relevant regulatory bodies, to systematically review where data sharing authorities overlap, conflict, or impose duplicative requirements without corresponding protection benefit, and to consolidate where possible. Consent-scope constraints on retroactive sharing of existing datasets deserve particular attention: a great deal of high-value legacy data is effectively stranded by consent language written before secondary reuse was contemplated, and NIH should develop clear, generalizable guidance on what is and is not permissible in these cases rather than leaving each institution to reach its own conservative conclusion. This is slow institutional work. It is also the highest-leverage action available, because every subsequent data sharing initiative is built on top of this substrate.

4. Fund the Infrastructure and the People Who Sustain It

Shared data does not maintain itself, and the current funding model consistently underwrites the work that determines whether shared resources remain usable.

Fund research software engineers and data stewards explicitly. NIH should permit, and in some cases require, grants to budget for dedicated data stewards or research software engineers whose role is to ensure that shared data, code, and models are well-documented, FAIR-compliant, and genuinely reusable. Without this, data sharing too often means depositing a raw data dump with minimal or even potentially inaccurate metadata.

Recognize data curation and harmonization as scientific work deserving career credit. Cleaning, standardizing, and contextualizing a dataset for reuse is not administrative overhead. It requires domain knowledge, methodological judgment, and a working understanding of how the data will be used downstream. Under current incentive structures, the people who do this work well receive little credit for it, and the field has a chronic shortage of them as a direct result. NIH should make curation and harmonization contributions visible and creditable through contribution taxonomies, through data citation, and through explicit recognition in review.

Create distinct funding pathways for long-term maintenance. Widely adopted software tools, APIs, repositories, and models require ongoing maintenance, hosting, dependency updates, and user support. The current model funds initial development and then withdraws support at precisely the point when adoption has made the resource most valuable to the community. NIH should establish maintenance-specific funding mechanisms and should recognize sustained stewardship of a community resource, not merely its initial release, as a creditable scientific contribution.

Establish pre-validated model repositories. NIH should incentivize deposition of AI and machine learning models into vetted, standardized repositories that run automated benchmarking to verify that a deposited model is accessible, executable, and performs as reported. This addresses a fast-growing problem: models that are nominally shared but cannot be loaded, run, or reproduced. Automated verification at deposit is far cheaper than discovery of the failure by a downstream user months later, particularly if that failure is not widely reported.

Track and publish an inventory of data sharing platforms across NIH. Institutions, intramural programs, and extramural awardees maintain data sharing platforms that are not systematically catalogued. NIH should track these platforms and make the inventory available, so that the agency and the community can understand what data exist, where they reside, and how they can be accessed. This is a prerequisite for the cross-study analysis NIH wants to enable, and it is directly analogous to what NCI's Clinical Trials Reporting Program provides for the clinical trial landscape: a single, authoritative, continuously maintained view of what exists.

Summary

The recommendation is a reorientation across four dimensions: measure reuse rather than deposition; govern for reusability at the point of study design rather than the point of deposit; reduce the regulatory complexity that drives investigators toward conservatism, beginning with authoritative documentation of the scenario-dependent authority stack; and fund the people and infrastructure that keep shared resources usable over time.

Each of these is implementable with mechanisms that largely already exist. NIH has the repositories, the CDE infrastructure, the persistent identifier systems, the review gates, and the policy authorities. What is missing is the alignment of incentives with the outcome NIH actually wants, which is not compliance but reuse. That alignment is what this RFI is positioned to create.

3. Training and Mentorship: Training and Mentorship

NIH's current indicators of training success are measured against an implicit model of the successful trainee: one who remains in academia, secures independent funding, and produces publications. That model describes a shrinking minority of the people NIH actually trains. The consequence is a systematic measurement failure. NIH trains a workforce that overwhelmingly goes on to careers in industry, government, federal contracting, public health, policy, and education. These professionals make substantial contributions to the biomedical research mission, yet their impact is largely unmeasured. Any meaningful effort to quantify training impact must begin by redefining what constitutes a successful outcome.

We offer comments in four areas: outcome measurement, mentorship quality and accountability, protected time verification, and infrastructure to support trainee career development beyond the training period. Our perspective is that of an organization performing biomedical informatics and data science work in direct support of NIH programs, staffed substantially by people with advanced scientific degrees who came through the NIH-funded “traditional” training pipeline (post-baccalaureate, graduate, and postdoctoral researchers in academic laboratories) and now advance the NIH mission from outside academia.

1. Redefine and Measure the Successful Outcome

Track long-term trainee outcomes, not trainee counts. The number of trainees supported under an award is an input measure rather than an output measure. Instead, NIH should track what happens to those individuals over time: career progression, achievement of research independence in their chosen settings, retention in scientific careers broadly defined, and whether they go on to mentor future scientists. A five-year and ten-year longitudinal assessment of these trainee outcomes would provide a far more meaningful measure of return on NIH’s training investment than simply counting the number of funded trainee positions.

Track mentorship lineage. The most durable output of excellent mentorship is not the trainee's own productivity but the future scientists they subsequently develop. NIH should track mentorship lineage as a distinct measure of impact by assessing whether trainees become mentors themselves and whether their mentees, in turn, achieve success. This captures the compounding effect that makes mentorship such a valuable investment, yet it remains entirely invisible in current metrics.

Build the metrics to recognize non-academic careers, which are the majority case. This is the central recommendation of this section. A researcher who leaves academia for industry, federal service, contracting, secondary education, policy, or the nonprofit sector has not failed the training pipeline. In many cases, they have entered precisely the role where their training delivers the most public value. Yet NIH's dominant success indicators, publication counts and independent funding, capture almost none of

this.

Consider what this invisibility costs. A researcher who completes a fellowship and accepts a role in industry, government, or federal science support does not appear in NIH's success metrics. However, a researcher who leaves academia entirely because no academic position was available appears in the same way. These are not the same outcome, and NIH currently has no way to distinguish them.

NIH should develop alternative outcome indicators that reflect the actual distribution of careers its trainees enter. Candidate indicators include years active in scientific work under a broad definition; patents and licensed technologies; technical reports, white papers, and standards contributions; invited talks and professional society leadership; software and data resources produced; and number of individuals subsequently trained or supervised. These indicators are measurable, and several are already tracked by the institutions employing these scientists.

The design of these indicators should not be done in isolation from the people they describe. NIH should convene scientists who followed non-academic paths to help define what meaningful contribution looks like in those settings, because academic reviewers may not be best positioned to evaluate them.

Anticipate the participation problem. Non-academic employers and alumni have no current obligation or incentive to report outcome data to NIH. As a result, any tracking system that depends on voluntary participation is likely to suffer from significant response bias, disproportionately capturing individuals with the strongest outcomes. NIH should design deliberate incentives for participation: small grants or supplements to institutions that maintain high-quality alumni tracking, formal recognition programs for organizations that report consistently, or integration of outcome reporting into existing federal reporting relationships where they already exist. Without an explicit incentive structure, a long-term outcomes dashboard will systematically underrepresent the very population it is designed to capture.

Create a Biomedical Informatics and Data Science pipeline indicator specifically. There is an acute and worsening workforce shortage in bioinformatics, clinical data science, and computational biology. NIH depends on this workforce to support nearly every modern data-intensive program it funds, yet it has no dedicated metric to track how many trainees enter these fields. NIH should establish such a measure and recognize placement in biomedical informatics and data science roles, in any sector, as a positively weighted training outcome.

This shortage is addressable, and one effective model is deliberately structured senior-to-junior technical pairing on real production work. In our own experience, pairing a senior analyst with a junior analyst on substantive, delivery-bound projects, rather than on training exercises, has produced both rapid skill development and genuine scientific output: original contributions across computational oncology, clinical data informatics, and multimodal analysis that the teams would not have produced in a traditional training-only structure. The mentorship was meaningful, and the outcomes were tangible, yet neither would likely have been achieved through a traditional training-only model. NIH should recognize applied, delivery-embedded mentorship models as legitimate, fundable approaches to workforce development, particularly in computational fields where the most valuable skills are acquired through hands-on experience.

2. Make Mentorship Quality Visible, Measurable, and Consequential

Mentorship quality is currently assessed almost entirely on the basis of self-reported mentoring plans. Yet the individuals best positioned to evaluate a mentor are their trainees themselves, and NIH does not systematically solicit or incorporate their feedback.

Institute anonymized, aggregate trainee feedback as a standard input to review. NIH should incorporate structured, fully anonymized feedback from graduate students and postdoctoral fellows into the evaluation of PIs and institutions. This feedback should assess key aspects of the training experience, including career development support, coaching in scientific rigor, inclusion, and the overall quality of the training environment. Results should be aggregated at the institutional level to protect trainees from retaliation while providing meaningful, actionable insights. Institutions that consistently receive poor mentorship feedback evaluations across multiple awards may have systemic issues, and NIH should have the ability to identify and address those patterns.

Pilot a Mentorship Quality Index. Building on that feedback, NIH should pilot a composite index that can be incorporated into institutional training grant renewals. We would recommend piloting this before broader implementation and being explicit about the risks. Any survey-based instrument invites manipulation, and mentorship quality is inherently difficult to capture in a single metric. However, the current alternative, in which mentorship quality is effectively unmeasured and unaccountable, is less effective. A well-designed pilot with a predefined evaluation period would allow NIH to determine whether the instrument provides a meaningful and actionable measure of mentorship quality.

Add a dedicated mentorship section to the Biosketch, and make it scoreable. PIs should document their mentoring approach, the concrete milestones achieved by past trainees, and the career trajectories those trainees followed. Making this a scored peer review criterion, rather than a narrative afterthought, would create a direct incentive for investigators to take mentorship seriously and would give reviewers something substantive to evaluate.

Establish a trainee contribution attribution standard for computational papers. Multi-author computational publications currently obscure individual contributions. NIH should require structured contribution statements that specify which analyses each trainee performed, rather than relying on author order as a proxy for contribution. This makes mentorship visible, makes trainee contribution creditable, and provides the raw material for evaluating both.

Reward mentors who produce interdisciplinary scientists and support diverse career paths. A mentor whose trainees successfully pursue careers in industry, government, and public policy, and who actively prepares them for those roles, is serving the NIH mission. Under current incentives, that mentor may be reviewed less favorable than those who retain trainees in academia. NIH should explicitly recognize mentors who support the full range of productive career destinations and should recognize collaborative mentoring models in which expertise is distributed across multiple investigators rather than concentrated in a single PI.

Reward audited mentoring excellence with tangible support. PIs with a demonstrated, verified record of exceptional mentorship should receive priority consideration for administrative supplements or extended award durations that protect dedicated mentoring time. Effective mentorship is time-intensive, and the current incentive structure expects investigators to perform it within the same fixed time budget used to produce the research outputs on which they are primarily evaluated. Until the incentive structure resolves that conflict, simply encouraging better mentorship is unlikely to produce meaningful change.

Measure participation in rigor and stewardship training directly. NIH should track trainee participation in formal mentoring plans, responsible conduct of research training, data stewardship, and reproducibility training as distinct indicators of the training experience. It should also evaluate whether these activities are effectively improving trainee knowledge, skills, and research practices rather than simply documenting participation. Reproducibility and data stewardship are learned behaviors, and the training period is when they are most efficiently instilled.

3. Verify Protected Time Rather Than Assuming It

Protected research time for trainees is currently enforced on an honor system, and the honor system is not proving effective. Trainees on T32 and K awards routinely report that clinical, teaching, or administrative obligations consume time that is nominally protected, and there is currently no mechanism for NIH to identify or monitor these situations.

Require annual reporting of actual versus required protected time. Trainees supported by protected-time awards should confidentially report, on an annual basis, the amount of protected research time they received against the time their award requires. This would represent a low-burden data collection effort with the potential to provide highly valuable insight into whether protected time commitments are being honored.

Attach consequences to persistent institutional shortfalls. Reporting without consequence changes nothing. Institutions that show consistent, verified shortfalls across multiple awards and multiple trainees should face defined consequences in future training grant competitions. The unit of accountability should be the institution rather than the individual PI, both to protect trainees from retaliation and because persistent protected-time erosion is typically an institutional resourcing problem rather than an individual failing.

Audit rather than attest. NIH should conduct periodic institutional audits of protected time protection, sampling across awards. The existence of an audit function, even at low sampling rates, changes institutional behavior in a way that self-attestation does not.

4. Support Trainee Development Beyond the Training Period

NIH's investment in a trainee currently ends when the appointment ends, at the critical point when the trainee's professional trajectory is being determined.

Invest in professional profile development during post-baccalaureate and postdoctoral fellowships. Before completing their appointments, trainees should be equipped with the professional infrastructure needed to sustain a long-term research identity, including persistent researcher identifiers, complete and maintained publication and contribution records, and a professional presence that allows their work to be found and their career trajectory to be trackable. This is a modest investment that pays for itself, both in long-term trainee outcomes and in NIH's own ability to measure them. A trainee who cannot be found five years later cannot be meaningfully included in those outcomes.

Fund publication and dissemination support for trainees after their appointment ends. In our experience, a substantial amount of work completed during training goes unpublished because the trainee departs before the manuscript is finished. This represents a direct loss of NIH-funded scientific output. NIH should establish a small, low-overhead mechanism to support peer-reviewed publication and white paper dissemination during the period following a trainee’s appointment, particularly for those entering settings without institutional publication support. The benefit is threefold: the science reaches the community, the trainee's professional development is advanced, and a durable link is maintained between NIH and a scientist now positioned in industry, government, or another sector where NIH benefits from having a relationship.

Summary

NIH cannot manage what it does not measure, and it is currently not measuring the majority of what its training investment produces. The highest-priority actions are to redefine the successful outcome to include the non-academic careers that many trainees enter, to institute anonymized trainee feedback as an accountability mechanism for mentorship quality, and to verify protected time rather than assuming it. Together these changes would give NIH an accurate picture of what its training investment produces and where it is being lost.

4. Collaboration: Collaboration

NIH has correctly identified that biomedical research has become team-based while the credit system remains individual. The standard response to this problem is to improve attribution at the point of publication, typically by adopting a contributor role taxonomy. We support that step and address it below. But we want to make a more fundamental argument first, because we think the publication-stage framing is diagnosing the problem too late.

By the time a multi-site study reaches manuscript preparation, the contribution record has already been lost. The information about who generated which samples, which laboratory ran which assay, which site enrolled which patients, which team harmonized which data elements, and which analyst produced which result exists in operational systems during the conduct of the study, and it is not carried forward. Authors then reconstruct contributions from memory, negotiation, and social convention, and a taxonomy applied at that point is formalizing a reconstruction rather than recording a fact.

The alternative is to treat contribution as provenance metadata, captured at the point of data generation and carried with the data through analysis, dissemination, and publication. This is technically achievable today, and we describe below how it works in practice in NCI programs we support. It would transform

contribution attribution from a negotiated social artifact into a queryable property of the scientific record.

Our comments address four areas: making contributions attributable through infrastructure, recognizing the enabling work that makes team science possible, structuring credit for multi-site and multi-PI science, and funding the collaboration phase itself.

1. Make Contribution Attributable at the Source

Adopt contributor role taxonomies, and adopt them as a requirement rather than an option. NIH should require use of CRediT or an equivalent contributor taxonomy for publications arising from multi-PI, center, and network awards, and should incorporate the resulting contribution records into the NIH Biosketch. Distinguishing conceptualization, methodology, software, data curation, formal analysis, validation, and project administration makes visible the work that first-and-last-author convention erases. The current system, in which position in an author list serves as a proxy for both the nature and the magnitude of contribution, systematically disadvantages methodologists, data scientists, software engineers, and clinical coordinators whose contributions do not map onto the conventional hierarchy.

This is a necessary but not a sufficient reform, for the reason stated above: a taxonomy applied at manuscript stage records what the author group agrees to record.

Build contributor attribution into data provenance. The durable solution is to tag contribution at the data element level, within the systems that operate multi-site science, and to carry that metadata forward automatically.

This is not hypothetical. In the Federal programs we support, the informatics infrastructure that enables multi-institutional research already tracks the provenance of data as an operational necessity. Data flowing from a national network of trial sites and specialized assay laboratories must be traceable to its source in order to be interpretable: an analyst needs to know which laboratory ran a given assay, under which protocol version, on samples from which trial and which site.

The insight is that the contribution record NIH wants already exists inside these systems, as a byproduct of running the science correctly. It is simply not being captured, retained, and propagated as an attribution artifact. Extending existing provenance metadata to include structured contributor information, and carrying it through harmonization into the released data package, is an incremental technical change with substantial downstream benefit:

Contribution is recorded as fact at the time of generation rather than reconstructed later.

Contributions travel with the data package at dissemination, so downstream users can see and cite the contributing sites and teams.

Contribution becomes machine-readable and therefore countable, which is precisely what NIH needs to build any credible collaboration metric.

Sites and laboratories that contribute data but do not author the primary manuscript become visible and creditable.

We would recommend NIH pursue this concretely: require that data packages released from network and consortium awards carry structured contributor metadata as a condition of deposition and fund the infrastructure work needed to generate it. The specification should be developed with the coordinating centers and informatics teams that operate these systems, because they are the ones who know what provenance is already being captured and what it would cost to extend it.

Develop a Network Contribution Index on that foundation. With structured contributor metadata in place, NIH can construct a credible index that credits each participating site and laboratory for what it contributed: samples and data generated, protocols contributed, patients enrolled, assays performed, analytic work delivered, and coordination effort supplied. Critically, this credit should be decoupled from who holds the prime award. Under the current structure, the prime awardee institution captures the institutional credit for a network's output while contributing sites, which may have generated most of the data, receive attribution only through authorship on the resulting papers, if at all.

Develop a Cross-Institutional Data Access metric. Track how frequently a dataset, tool, or resource developed under one award is used by investigators at other institutions. This operationalizes collaboration as an outcome rather than an intention, and it is measurable using persistent identifiers and repository access records that largely already exist.

Distinguish substantive interdisciplinary contribution from co-authorship inflation. A biostatistician who designed the core analytic strategy and a group that supplied one dataset have made contributions that differ in both kind and magnitude, and both currently appear as a name in a list. Structured contribution statements are the mechanism for separating them. Without this distinction, any collaboration metric based on co-authorship will reward author list length rather than collaborative substance and will be gamed accordingly within a single funding cycle.

2. Recognize the Enabling Work That Makes Team Science Possible

Multi-site science does not happen because investigators agree to collaborate. It happens because someone builds and operates the infrastructure that allows a hundred sites to produce comparable data, someone harmonizes that data into an analyzable form, someone maintains the platform on which the analysis runs, and someone coordinates the whole enterprise. That work is scientific work. It requires methodological judgment, domain knowledge, and substantial technical expertise. It is also, under current metrics, nearly invisible.

Fund collaboration infrastructure explicitly and recognize it as a scientific contribution. Shared data platforms, coordinating centers, harmonization hubs, biorepositories, and core facilities are the precondition for team science and are chronically underfunded relative to their importance. NIH should fund them as first-class scientific infrastructure and should recognize the people who build and run them accordingly.

Create recognition pathways for core facility and platform staff scientists. NIH should establish award tracks, citation mechanisms, or formal designations that credit core facility directors, coordinating center leads, staff scientists, and research software engineers whose infrastructure enables multi-center science. These individuals frequently appear as middle authors, when they appear at all, and are evaluated against productivity metrics designed for a role they do not hold.

Credit operational excellence as a collaborative contribution. Data integration, software development, project management, and reliable operational delivery are what convert a collaborative intention into a functioning multi-site program. NIH should credit investigators and teams who enable collaborative science through this work, and should evaluate collaborative outcomes, shared datasets, multicenter publications, and community resources, rather than emphasizing individual productivity alone.

Align tenure and promotion incentives with team science. NIH cannot reform university promotion committees directly, but it has considerable influence. Federal guidance urging institutions to formally recognize substantive middle-author contributions to high-impact team science as comparable to sole-PI work would give institutional advocates a lever they currently lack. Without this, NIH will continue to ask investigators to prioritize collaboration while their employers continue to promote on the basis of individual credit, and investigators will continue to respond rationally to the incentive that determines their careers.

3. Restructure Credit for Multi-PI and Multi-Site Awards

Split multi-PI credit equally by default. NIH should redesign multi-PI mechanisms so that project credit, institutional indirect cost recovery, and NIH portfolio tracking are attributed equally across PIs unless the team specifies otherwise. The current structure, in which one institution and one investigator are functionally the center of gravity regardless of the nominal equality of the multi-PI model, produces a persistent "dominant lab" dynamic that discourages genuine peer collaboration. Equal default attribution changes the negotiating baseline and any deviations from the baseline must be justified.

Recognize interdisciplinary collaboration that crosses sectors. Increasingly, the collaborations that produce translational impact span academia, healthcare delivery systems, government, and industry. NIH's metrics should recognize these collaborations rather than treating non-academic partners as adjuncts to an academic core. This is particularly relevant to informatics and data science, where the deepest operational expertise in running large-scale clinical data systems frequently resides outside academic institutions.

4. Fund the Collaboration Phase

Large team science projects fail or underperform for reasons that are established long before the award begins: the participating groups have not aligned on scientific aims, the data models are incompatible, the harmonization burden was never scoped, and the governance structure was improvised. NIH currently funds none of this preparatory work and then funds the full project on the assumption that it was somehow done.

Establish interdisciplinary bridge funding. NIH should offer small, fast, low-overhead awards specifically to fund the collaboration phase preceding a major team science project: cross-institutional scientific alignment, data model reconciliation, harmonization scoping, governance design, and pilot integration work. In our experience, the cost of failing to do this work up front is not that it goes undone; it is that it gets done during the funded project, consuming time and budget that was allocated to science, and often done under schedule pressure in ways that produce technical debt lasting the life of the program. A modest investment before the fact is dramatically cheaper than the same work performed reactively.

5. A Note on Shared Federal Knowledge Infrastructure

NIH funds an enormous volume of codebases, data resources, standard operating procedures, and technical documentation that is fragmented across institutes, programs, and awards, with no systematic mechanism for one program to discover and reuse relevant work produced under another. NIH should evaluate whether a shared, appropriately governed knowledge infrastructure built over these government-funded assets could reduce this fragmentation. The design challenges — data sensitivity, access authority, provenance, and the risk of presenting incorrect outputs confidently — are real and should be resolved before any deployment. We raise the concept as an opportunity worth evaluating, not a recommendation to implement immediately; the underlying problem, however, is real and worth solving.

Summary

The core recommendation is to move contribution attribution upstream: require that data packages released from network and consortium awards carry structured contributor metadata as a condition of deposition and fund the infrastructure to generate it. Adopting contributor taxonomies at publication is a necessary first step, but it formalizes a reconstruction of the contribution record rather than capturing the record itself. Alongside that, NIH should formally recognize the coordinating centers, data platforms, and harmonization infrastructure that make team science possible; restructure multi-PI and network credit so it is not concentrated at the prime institution; and fund the collaboration phase that precedes large team science awards, which currently goes unfunded and is therefore either skipped or performed at the expense of the science.

5. Entrepreneurship and Translation: Entrepreneurship and Translation

NIH's translation agenda is built on a pipeline model: discovery originates in academia, matures through translational funding, and passes to industry for commercialization and delivery. That model is real and it works. But it is unidirectional, and the assumption that innovation only ever flows in that one direction is costing NIH a substantial amount of innovation it could otherwise capture.

We make three arguments in this section. First, NIH's definition of a translational output is too narrow, and it systematically fails to credit the reusable tools, platforms, and data standards that enable large volumes of downstream science. Second, translation needs to be measured by adoption, not by the legal artifacts of commercialization. Third, and most substantively, NIH should build a return channel: a funding mechanism that allows innovative ideas originating in industry to be developed in academia and

matured back into practice. That channel does not currently exist, and its absence is a structural loss to the innovation ecosystem NIH is trying to foster.

1. Broaden What Counts as a Translational Output

Recognize reusable tools, platforms, and standards as primary translational outputs. A bioinformatics pipeline adopted by fifty downstream studies, a clinical data standard that makes cross-study analysis possible, or a data platform that enables a national research network has delivered translational value at a scale most individual products never reach. Under current metrics, none of this reliably registers. NIH's translational indicators are oriented toward patents, licenses, INDs, and spin-outs, and a widely adopted open research tool produces none of those artifacts while potentially advancing the mission more than any of them.

As a concrete example, NCI's Clinical Trials Reporting Program provides the authoritative national registry of NCI-supported cancer clinical trials, and its data standards, abstraction protocols, and reporting infrastructure are the substrate on which cancer trial reporting, regulatory compliance, and cross-center benchmarking depend. That infrastructure was translated in every meaningful sense: it moved from concept into operational use, it was adopted at scale, and it changed how the field works. It generated no patents. NIH should have a way to see and credit outputs of this kind, because at present it largely does not.

Recognize enabling technologies, diagnostics, and research tools, not just startups. Entrepreneurship in the biomedical context is frequently equated with company formation. Company formation is one path to impact, and NIH should continue to support it. But an investigator who produces a broadly usable diagnostic method, a validated assay, or an enabling technology adopted across the field has translated their discovery, whether or not a company resulted.

Define translation milestones by research type. A single definition of translation cannot serve basic science, clinical research, and methods development simultaneously. NIH should define appropriate milestones for each, and track investigator progress against the relevant set:

For basic research: a validated method, a licensed tool, a reagent or model system in broad community use, a mechanistic finding that enables a downstream therapeutic program.

For clinical research: a change in clinical practice guidelines, an FDA submission, an approved indication, incorporation of a finding into standard of care.

For methods and informatics research: adoption of a tool, pipeline, or standard by external groups; incorporation into a data commons or a national research infrastructure; measurable improvement in the speed or quality of downstream research.

The value of an explicit, type-specific milestone framework is that it lets NIH credit progress rather than only endpoints, and it prevents basic researchers from being penalized for being early in a pipeline that has not yet reached its terminus.

2. Measure Adoption, Not Legal Artifacts

Downstream adoption is the correct translational metric. Patents are an input to translation, not evidence of it. A large fraction of issued patents is never licensed, never practiced, and never reach a patient. NIH should measure the adoption of technologies in research, healthcare delivery, and clinical trials as the primary indicator, and treat patents, licenses, and IND filings as supporting evidence rather than as the measure itself.

Reward measurable progression toward translation. Validation studies, regulatory milestones, and advancement in technology readiness are all measurable, and all represent real progress that current metrics ignore because they precede the terminal commercialization event. Crediting progression rather than only completion changes investigator behavior at the margin, which is where the valley of death claims most projects.

Establish a Translational Impact Registry. NIH-funded discoveries that enter clinical use, receive regulatory clearance, achieve licensure, or are adopted as a research standard should be formally logged and credited back to the originating award and to the investigator's record. The absence of such a registry means that translational success, when it occurs, is often invisible in NIH's own portfolio data, particularly when it occurs years after the award closed and through intermediaries the original investigator never interacted with.

Pilot translational credit scoring in competitive renewals. Investigators who can demonstrate that prior work led to a licensed product, an initiated clinical trial, an adopted standard, or a documented change in practice should receive scoring recognition at renewal. This should be structured as a bonus rather than a requirement, so that basic researchers early in the translational arc are not penalized for the position they occupy in the pipeline.

Expand the Biosketch to reflect translational contribution. Issued patents, IND filings, licensed technologies, adopted standards, spin-out formation, and documented tool adoption should be formally counted as indicators of scientific impact alongside publications. Investigators currently have no structured place to report this work, and reviewers therefore have no structured way to weigh it.

Give positive review weight to translation training. PIs who have participated in commercialization and translation training, such as I-Corps, have made a deliberate investment in learning how to move work toward impact. Recognizing that participation in review costs NIH nothing and signals clearly that translation is valued.

Credit public-private partnerships that maintain scientific rigor. Partnerships that accelerate patient impact while preserving methodological integrity should be creditable outcomes. Our own experience supporting national-scale trial networks shows that effective public-private collaborations function only because multiple stakeholders operate as an integrated system and that integration is itself a translational achievement that is not credited anywhere.

3. Build the Return Channel: Industry-Originated, Academically Developed Innovation

This is our central recommendation, and we believe it identifies a structural gap in the innovation ecosystem that NIH is well positioned to close with the deep connections the NIH harbors.

The current flow is unidirectional. Scientists trained in NIH-funded academic environments move into industry, government, and federal contracting, carrying knowledge and methods with them. This is a large and continuous flow, and it is valuable. But there is no meaningful return channel. Ideas originating in industry, in the organizations doing applied biomedical work at scale, do not flow back into academia for development.

This is not because industry lacks ideas. Applied organizations operate against delivery commitments, and speculative development competes directly against contracted work for the same staff hours. An idea that would require six months of exploratory engineering to reach proof of concept, with genuine risk of failure, is very difficult to fund internally, regardless of its potential value. The idea is not built, published or transferred. It simply does not happen.

Academia has precisely the complementary profile. Academic environments are structured for exploratory work with uncertain outcomes. They have trainees who need substantive projects, faculty who are rewarded for novelty, and institutional tolerance for the possibility of failure. What they frequently lack is the applied problem context, the operational data, the delivery discipline, and the product maturation pathway to carry a proof of concept into practice.

These are complementary deficits, and they are not being matched. The result is a persistent, largely invisible loss: ideas that industry can conceive but cannot build, and academic capacity that could build them but never sees the problem.

We recommend NIH establish a bidirectional innovation mechanism. The structure we would propose:

A small, fast, R21-scale grant mechanism specifically for industry-originated problems developed in academic laboratories. The industry partner contributes the problem definition, the applied context, and where permissible the operational data. The academic partner performs the exploratory development. NIH funds the academic work. These awards should require minimal supporting data by design given that the value of the mechanism lies in funding work too early-stage to demonstrate feasibility.

Clear intellectual property structure established up front. This is the mechanism's central design challenge and its central risk. Industry participants will not contribute genuinely valuable ideas into an arrangement where their IP position is uncertain, and academic participants will not accept terms that suppress their ability to publish. The mechanism must resolve this explicitly: protect the originating party's core IP position while guaranteeing the academic team's right to publish the scientific results and disseminate the methods. This tension is real and cannot be papered over, but it is not novel, and workable frameworks exist in other public-private research contexts.

Career credit for the academic participants. Faculty and trainees who take on industry-originated

problems should receive recognized career credit for doing so, including promotion and tenure consideration, formal recognition in competitive renewal review, and/or with assistance with funding future publications or patents. Without this, the mechanism will attract only investigators with nothing to lose.

Milestone-linked incentives. Financial incentives tied to successful maturation milestones, such as validation, technology readiness advancement, and eventual deployment, would align both parties toward carrying the work through rather than abandoning it at proof of concept.

Deliberate resolution of the publication question. Open publication and dissemination should be a condition of participation, on a defined timeline that permits the industry partner to establish necessary protections first. NIH-funded work should enter the literature.

The mechanism would produce publishable science, train students on problems that have demonstrated real-world relevance, and generate innovations with a defined pathway into practice, because the industry partner has both the motive and the infrastructure to mature them. It also creates a durable connection between academic laboratories and the applied organizations that employ most of their graduates, which has independent value for both workforce development and translation.

A bounded pilot structure, for example a cohort of awards at the R21 scale with explicit evaluation criteria and IP protections built into the agreement terms from the outset, would allow NIH to test the mechanism and establish precedents before broader commitment. The mechanism is small-award-scale by design. And it addresses a gap that no current NIH mechanism addresses, because every existing translational mechanism assumes the idea originates in the academic laboratory.

4. Fix the Valley of Death Where It Actually Opens

Create a Phase 0 bridge mechanism. SBIR and STTR programs assume a level of technical maturity that many academic discoveries have not reached. A researcher with a promising finding and no minimum viable product is not competitive for SBIR and has no mechanism to become competitive. NIH should establish a dedicated pre-SBIR bridge award to mature a discovery to the point where commercial mechanisms become accessible. This is where a large number of viable translations quietly die.

Extend SBIR and STTR pathways for informatics and AI tools specifically. Biomedical informatics and AI tools developed under NIH awards frequently have clear clinical or commercial utility but face a regulatory and business development pathway that academic teams are unequipped to navigate. The technical work is done and the tool does not reach anyone. NIH should expand SBIR and STTR support tailored to software and data tools, including support for the regulatory pathway determination that software-as-a-medical-device products increasingly require.

Fund academic-to-industry trainee time splits. Graduate students and postdoctoral fellows should be able to split time legitimately between an academic discovery laboratory and a commercial or applied R&D environment with a transferable fellowship. This is currently difficult to arrange and frequently discouraged. It is one of the most efficient available mechanisms for transferring both knowledge and

people across the boundary, and it addresses the innovation flow problem from the workforce side.

Push institutions to standardize technology transfer. Institutional technology transfer processes vary enormously in speed, terms, and competence, and a researcher's ability to translate a discovery frequently depends more on which university employs them than on the merit of the discovery. NIH should use its considerable influence to encourage standardization and simplification of institutional tech transfer pathways, so that translation is rewarded rather than obstructed.

Summary

NIH should broaden what counts as a translational output to include the reusable tools, platforms, and standards that enable downstream science; measure translation by adoption rather than by patents and legal artifacts; establish registries and review mechanisms that make translational success visible and creditable; and address the valley of death with a pre-SBIR bridge mechanism and informatics-specific commercialization support.

Above all, NIH should recognize that the innovation pipeline it has built runs in only one direction. Industry conceives ideas it cannot afford to build; academia can build ideas it never sees. Constructing the return channel would cost relatively little, would produce publishable science and trained students, and would capture innovation that is currently being lost entirely.

6. Foundational Scientific Exploration: Foundational Scientific Exploration

NIH's difficulty in funding high-risk research is not a failure of intent. The agency has created mechanisms explicitly for this purpose and states priority clearly. The difficulty is that the surrounding system, peer review, career advancement, publication, and institutional promotion, is optimized to reward safety, and it exerts that pressure continuously on every actor in the system. Investigators, reviewers, and institutions respond rationally to the existing system. The aggregate outcome is a portfolio more conservative than anyone involved intends.

Correcting this requires acting on the specific mechanisms that produce conservatism rather than exhorting the participants to be bolder. We address four areas: the preliminary data paradox, the structural bias in expert peer review, the treatment of negative results, and the career risk borne by the investigator who takes scientific risks. We note that the barriers to bold work differ by sector, and that NIH's mechanisms should account for both.

1. Resolve the Preliminary Data Paradox

The R21 and DP2 mechanisms are the right instruments for exploratory research. In practice, they do not function as designed, for a reason that is well understood and rarely stated plainly: preliminary data is not formally required, but it is functionally required.

Reviewers, acting reasonably and in good faith, use preliminary data as the primary evidence that a proposed line of work is likely to succeed. An application with preliminary data is scored more favorably than one without. Investigators learn this quickly and respond by submitting work that is already

substantially de-risked. The mechanism intended to fund exploration ends up funding modestly extended versions of work already underway.

The paradox is structural. The riskiest proposals are, by definition, the least likely to have preliminary data. If strong preliminary evidence existed, the hypothesis would not be risky. A review process that treats preliminary data as the primary evidence of feasibility will therefore systematically select against exactly the work these mechanisms exist to fund.

We recommend NIH address this directly rather than through guidance to reviewers, which has been tried and has not worked.

Establish a distinct high-risk mechanism with its own study sections and its own criteria. A dedicated track, an R21-HR or equivalent, in which every application in the pool is speculative and preliminary data is explicitly excluded from consideration, would apply the criteria evenly across the whole pool. The essential feature is that applications compete against other speculative applications, not against de-risked ones. When a speculative proposal is scored in the same pool as a well-supported incremental one, it loses, and the reviewer has done nothing wrong.

A dedicated track has a further advantage for NIH: it makes the high-risk portion of the portfolio explicit and adjustable. NIH can set the proportion of funds allocated to speculative work deliberately, according to national scientific priorities, rather than discovering after the fact that the intended risk appetite was eroded by review dynamics.

Create a blinded review track. NIH should dedicate a defined percentage of funding to a review track that removes investigator identity and preliminary data entirely and evaluates the application solely on the significance of the question, the coherence of the reasoning, and the rigor of the proposed approach. This directly tests whether the idea can stand without the reputational and evidentiary scaffolding that normally carries an application through review. It also addresses, as a secondary benefit, the well-documented advantage that established investigators hold in conventional review.

Establish a High-Risk Research Designation with protected renewal criteria. Awards carrying this designation should be evaluated at renewal primarily on the rigor of the approach and the significance of the question pursued, explicitly not on publication productivity during the award period. An investigator who spends three years rigorously testing a bold hypothesis that proves incorrect has done what NIH asked them to do. Under current renewal criteria they will struggle, and every investigator watching them learns the relevant lesson.

Create an Early Career Exploratory Fund shielded from productivity metrics. Small awards, under $250,000, for early-career investigators pursuing genuinely novel hypotheses, evaluated at close solely on what was learned and what new questions the work opened. Early-career investigators face the sharpest version of the risk-aversion incentive, because a fallow period that a tenured investigator can absorb is career-ending for them. Shielding these awards from productivity evaluation is the goal of the mechanism.

2. Counterbalance the Conservatism of Expert Review

Peer review is simultaneously the strongest quality mechanism NIH has and a structural source of conservatism. Expert reviewers evaluate proposals using their own understanding of the field. That understanding is exactly what makes their judgment valuable, and it is also what makes them poorly positioned to evaluate work that would overturn it. Reviewers reward what they recognize as sound, and what they recognize as sound is, definitionally, the current paradigm. A proposal that would change how a field thinks will frequently be evaluated by the people most invested in how the field currently thinks. No individual reviewer needs to act in bad faith for this to produce a systematic bias toward the safe and familiar.

The counterweight to expert judgment is judgment from outside the expert community. We recommend NIH pilot a structured outsider review component, contributing a defined and limited portion of the total score, perhaps twenty percent, and scored against different criteria than the expert review:

Does the question matter? Will the answer move the field materially, independent of whether the field currently believes the answer is likely?

Is the reasoning coherent? Does the logical progression from premise to hypothesis to approach hold together?

Is there a reasonable path to the result? Not a likely positive result, but a design capable of producing an informative outcome either way.

Reviewers for this component should come from adjacent fields, from other disciplines entirely, or from applied and industry backgrounds. They will not be able to assess technical feasibility within the field, which is precisely the point: that assessment is what the expert panel provides. What outsiders can assess is whether the idea is interesting and whether the argument is sound, and those judgments are less contaminated by investment in the current paradigm.

NIH could also evaluate whether automated review support has a role in this component, given that language models can assess logical coherence and structural quality at scale and without disciplinary investment. We raise this only as an option worth studying, not as a recommendation to implement. The risks are significant, including the possibility that such systems reproduce rather than counteract existing bias, since they are trained on historical literature and would carry its assumptions forward. Any use would need to be carefully validated against human judgment before it influenced a real funding decision, and it should supplement rather than substitute for human review. The substantive recommendation stands independently: expert review needs a counterweight from outside the expert community.

Implement rapid-response speculative micro-grants. Standard grant cycles run nine to twelve months from submission to award. A researcher with a sudden, potentially paradigm-shifting idea must either abandon it or hold it for a year, during which the moment frequently passes. NIH should implement rolling, fast-tracked micro-grants that allow immediate testing of a speculative idea. The award sizes

would be small, the failure rate would be high by design, and both of those properties are appropriate to the purpose.

3. Make Negative Results a First-Class Scientific Output

Formalize negative results and productive failures as deliverables for high-risk awards. A documented account of what was attempted, what was found, why the hypothesis did not hold, and what the work rules out should be an acceptable, citable, and creditable output of an exploratory grant. NIH should define the format, require it, and count it.

The scientific logic is straightforward and we think under-appreciated. Exploratory research operates at the edge of knowledge, where hypotheses are more likely to be wrong than right. That is the definitional property of the work. A funding mechanism that treats a disproven hypothesis as a failed award is not funding exploration; it is funding confirmation. And the knowledge produced by a rigorous negative result is real: it closes off a line of inquiry, redirects the field, and prevents other groups from repeating the same effort.

Rigorously conducted negative findings can be decisive. As a clear example, a clinical trial evaluating adavosertib in heavily pretreated patients with advanced solid tumors reported that the agent did not deliver the anticipated survival benefit in that population (Kummar et al.; JCO Precision Oncology; 2026). The result was rigorous, it was published, and it was consequential. It can inform subsequent development decisions, and spare future patients an ineffective therapy. That is a valuable scientific contribution. Under conventional productivity metrics, it registers as a study failure.

Distinguish productive scientific risk from poor execution. This is the legitimate concern underlying reviewer conservatism and it deserves a serious answer rather than dismissal. Not every failed project is a valuable negative result. Some projects failed because they were badly designed, badly executed, and/or badly managed.

The distinction is assessable, and NIH should build explicit criteria for it:

Was the hypothesis rigorously tested? Was the study adequately powered, appropriately controlled, and executed with sufficient methodological quality that the negative result is trustworthy?

Was the data of high quality? A negative result from poor data is not a negative result; it is an absence of information.

Was the failure informative? Does the community now know something it did not know before?

Did the investigator pivot appropriately? When early data indicated the initial approach would not work, did the investigator recognize this and adapt, or continued to expend resources on an approach that data had already ruled out?

An investigator who rigorously disproves their own hypothesis and clearly documents what the field

should conclude has succeeded. An investigator who produces an uninterpretable result through poor design has not. Evaluating methodological rigor, data quality, and the agility of the pivot, rather than whether the hypothesis held, makes the distinction.

Support milestone-based funding. Bold ideas should be able to mature without requiring immediate positive results, and milestone-based release is the appropriate structure: funding advances at defined stages such as project plan, initial proof of concept, validation, and handoff to a larger mechanism or to a partner capable of maturing the work. This structure is well established in the startup and small-business funding world, where it has proven effective precisely because it manages risk without demanding certainty at the outset. It allows NIH to limit exposure to any single speculative bet while permitting the successful ones to continue.

Recognize foundational outputs before translational impact is visible. Foundational datasets, enabling technologies, and mechanistic insights that make future discoveries possible should be creditable outputs. Their value is frequently realized years later and by other groups, and a metric system that waits for downstream impact will fail to credit the people who made it possible.

4. Address Career Risk

Every recommendation above is undermined if the individual investigator still bears the career cost of a null result.

An investigator considering a bold project faces a clear calculation. If the speculative project fails and produces few publications, that weakens the next grant application and damages the tenure case. The safe project produces reliable output. NIH can create as many high-risk mechanisms as it likes; if this calculation holds, the strongest investigators will continue to route their most ambitious ideas into their safest proposals.

Establish institutional guidelines protecting junior faculty who take scientific risk. NIH should issue guidance urging promotion and tenure committees to formally credit rigorous high-risk work, including work that yielded a negative result, and to weigh it comparably to conventional productivity. NIH does not control tenure decisions, but it has substantial influence over institutional behavior and should use it.

Consider tying institutional incentives to this behavior. Institutions that demonstrably protect and promote faculty engaged in high-risk foundational research could receive favorable treatment in indirect cost recovery or in institutional training and infrastructure awards. This converts an exhortation into a financial incentive and institutional behavior responds to financial incentives far more reliably than guidance.

Engage the publishing ecosystem. Career risk is transmitted substantially through publication. If journals will not publish rigorous negative findings, an investigator, whose hypothesis fails, has no way to convert their work into the credential which their career requires. NIH should use its considerable leverage with publishers to establish accessible, indexed, and citable venues for rigorous negative results. Without this,

negative results as a grant deliverable produce a document that satisfies NIH and does nothing for the investigator's career.

Summary

NIH's exploratory funding is constrained by four mechanisms operating independently of anyone's intent: preliminary data functions as a de facto requirement in review, expert reviewers are structurally invested in the paradigms that bold work would overturn, negative results are treated as failure rather than knowledge, and the individual investigator bears the full career cost of scientific risk. Each is addressable through the mechanisms described above. The binding constraint is the last one: no mechanism for high-risk research will work if the investigators best positioned to do that work cannot afford to take the risk.

7. Public Impact: Public Impact

NIH's public impact is real, substantial, and largely unmeasured. NIH-funded research changes clinical practice, extends lives, generates economic activity, and produces the knowledge on which the health system operates. Evidence of this appears constantly, in news coverage, institutional communications, and the professional accounts of individual scientists. What it does not appear in is any central, structured, queryable record.

The consequence is that NIH cannot answer, with data, the question it is most often asked to answer: what has this investment produced for the American public? The agency can point to individual successes. It cannot systematically quantify them, trace them back to the awards that produced them, or use them to inform where to invest next.

This is a data infrastructure problem, and it is solvable. The information required exists. It is distributed across clinical guideline bodies, regulatory filings, publication databases, policy documents, patents, employment records, and health outcome data. Assembling it into a coherent, maintained, public-facing resource is precisely the kind of extraction, standardization, harmonization, and reporting work that NIH already funds routinely for scientific data. What is missing is the decision to apply that same discipline to NIH's own impact.

We highlight a few examples where this approach has had tangible benefits.

1. Public Impact Measurement Is a Solved Technical Problem Awaiting an Institutional Decision

During the SARS-CoV-2 pandemic, decision-makers at every level needed to know what proportion of the population had been infected. That information existed, scattered across seroprevalence studies conducted by different investigators, with different assays, different populations, and different reporting formats. Individually, no single study could answer the question, but the aggregate data could if combined in a usable way.

Seroprevalence data from studies across the country were harmonized into a common structure and surfaced through a public-facing dashboard (called SeroHub) that allowed researchers, public health

officials, and the public to see the actual state of population immunity, updated as new data arrived (Freedman et al; Sci Data; 2022). The result was that stakeholders responding to a fast-moving public health emergency could act on current, harmonized evidence rather than on outdated models or inference.

This lesson is parallel to NIH's desire to monitor public impact. The barrier to measuring NIH's public impact is not that the data does not exist, or that the technical methods are unavailable. It is that no one has been tasked with harmonizing it and no infrastructure has been funded to hold it. This is the same problem SeroHub solved, applied to a different domain.

The same is true of the infrastructure NIH already funds for other purposes. NCI's Clinical Trials Reporting Program maintains an authoritative national view of the cancer clinical trial landscape, supporting regulatory reporting compliance, accrual monitoring, and cross-center benchmarking, because the NCI knew it was necessary and funded the infrastructure to sustain it. NIH's public impact deserves the same treatment.

Recommendation: build a public-facing Research Impact Dashboard. Modeled conceptually on USASpending.gov but oriented toward health and scientific outcomes rather than obligations, this resource would allow the public, Congress, and NIH itself to see how research investments connect to health improvements, clinical practice change, economic activity, and workforce development over time. It would serve three distinct purposes simultaneously: it would build public trust through transparency, it would create genuine accountability infrastructure, and it would give NIH the evidence base to direct future investment toward what demonstrably works.

We would emphasize that this is a substantial and sustained data engineering undertaking, not a reporting exercise, and it should be resourced accordingly. It requires harmonizing heterogeneous sources, maintaining linkage between awards and downstream outcomes over multi-year lags, and sustaining the resource over time. These are known problems with known solutions, and NIH funds this class of work routinely.

2. Establish a Health Outcome Attribution Framework

The ultimate measure of NIH's mission alignment is whether funded research improved health. NIH should build a structured framework for documenting when a line of research contributed to a change in clinical guidelines, a reduction in disease burden, an improvement in diagnostic accuracy, or the availability of a new treatment, and for tracing that contribution back to the originating awards.

Attribution in biomedicine is genuinely difficult. The path from a funded study to a changed clinical outcome is typically long, indirect, and multiply determined, and any framework claiming clean causal attribution would be wrong. But the difficulty of perfect attribution is not an argument for no attribution. A framework that documents contribution transparently, with appropriate acknowledgment of shared credit and uncertainty, would be enormously more informative than the current state, which is effectively silence.

The clearest cases are traceable end to end, and NIH should start there. For example, an NCI precision oncology clinical trial network's findings in patients with BRAF V600E-mutated tumors contributed to an accelerated, tumor-agnostic FDA approval of dabrafenib plus trametinib for adult and pediatric patients with unresectable or metastatic solid tumors harboring that mutation who had progressed on prior treatment and had no satisfactory alternatives.

That is a complete chain: federal research investment, a trial network built to test biomarker-matched treatment across tumor types, an informatics infrastructure that made molecularly matched assignment possible at national scale, a rigorous clinical finding, a regulatory approval, and a treatment option now available to patients, including children, who previously had none. The scientific and clinical credit belongs to the investigators, the network, and the patients who enrolled. Our point is narrower and is about measurement: this chain is fully documentable, and NIH has no systematic mechanism for documenting it. Cases of this clarity should be captured as a matter of course, not reconstructed after the fact when someone needs an example.

Track societal and policy citation. NIH should develop metrics that capture when funded research is explicitly cited in clinical trial protocols, clinical practice guidelines, public health recommendations, regulatory submissions, federal or state policy documents, and government reports. These citations are direct evidence of real-world influence, they are machine-detectable at scale, and they are almost entirely untracked. This is among the lowest-cost, highest-yield measurement improvements available.

Measure contributions to clinical practice and healthcare delivery directly, including changes to guidelines, improvements in patient outcomes, and improvements in the efficiency or quality of care delivery.

3. Measure Equity of Impact

A finding that improves outcomes for some populations and not others has not delivered its full public value, and NIH should be able to see that in the data.

Require disaggregated reporting. Research outputs reporting clinical or population-level findings should include analyses disaggregated by relevant demographic and socioeconomic factors, and the availability of such disaggregated data should itself be counted as an enhanced impact indicator. This requires that the underlying data be captured in a structured, standardized form from the outset, which connects directly to the common data element recommendations we made in response to the data sharing question. Structured demographic capture in clinical research data, aligned to established standards such as the cancer-relevant USCDI+ data elements, is what makes population-level analysis possible at all. Where it is absent, no amount of downstream analytic effort can recover it.

Benchmark study cohorts against actual disease burden. NIH should measure how well the demographic composition of studied cohorts matches the demographic distribution of the disease in the population. A trial cohort that does not resemble the affected population produces findings of uncertain applicability to the people who most need them. This is measurable: trial accrual data is collected, and disease burden data exists. Reporting infrastructure of the kind NCI maintains for cancer trial accrual

demonstrates that the data required for this comparison is already being captured and simply needs to be analyzed and reported accordingly.

4. Recognize Public Goods and Community Engagement as Impact

Credit the creation of community resources. Public datasets, educational materials, open research infrastructure, and widely adopted community tools deliver diffuse public value that no publication metric captures. NIH should recognize these as impact outputs in their own right.

Reward genuine engagement across the research lifecycle. NIH should evaluate whether research involved patient advocates in study design, whether results were communicated back to affected communities in accessible language, and whether the research question itself emerged from community partnership. That last item is the most consequential and the most rarely achieved: research that answers a question the affected community actually asked is qualitatively different in public value from research that arrives at a community as a finished product.

Require plain-language summaries. Every funded publication should carry a plain-language abstract, on the order of 300 words, genuinely accessible to a non-specialist reader. Compliance should be tracked at the institutional level. This is a small requirement with a large cumulative effect on public accessibility and trust, and it is currently encouraged rather than required, which means it is inconsistently done and frequently done badly.

Add a public engagement section to progress reports. A dedicated section documenting outreach to non-academic stakeholders, patient advocacy organizations, community health settings, and the public would make this work visible and creditable. What is not reported is not valued, and what is not valued does not happen.

5. Measure Economic Impact Systematically

Standardize economic indicators. NIH should develop consistent metrics tracking commercialization outcomes, workforce development and job creation, cost savings to the health system, regional supplier and biotech ecosystem growth, and the enabling effect of NIH investment on subsequent private-sector research activity.

Count workforce development as economic impact. As we noted in response to the training question, NIH trains a scientific workforce that overwhelmingly enters industry, government, and applied settings, where it performs work of direct economic and scientific value. That workforce is an NIH product. It is also, at present, essentially uncounted in any assessment of NIH's economic return.

NIH should also evaluate creating a structured mechanism through which meritorious but unfunded proposals, with the originator's consent, become visible to other Institutes, federal agencies, foundations, and private-sector partners who may wish to support them. NIH generates far more scientifically vetted ideas than it can fund. At present, an idea that does not find support through its initial mechanism simply disappears. A public venue of this kind would both reduce the loss of good

ideas and make the breadth and seriousness of NIH-funded scientific thinking visible to the public. The design challenges are real and would need resolution before implementation, but the concept merits evaluation

Summary

The recommendations in this section reduce to a single argument. NIH's public impact is not primarily a communication problem. It is a measurement problem.

The impact is real. It is happening continuously. It is visible in fragments, in news coverage, in individual accounts, in the occasional traceable success story like a tumor-agnostic approval that gives children with a specific mutation a treatment they did not previously have. What is missing is the infrastructure to capture it systematically, attribute it credibly, and present it in a form that the public, Congress, and NIH itself can act on.

That infrastructure is buildable. NIH funds work of exactly this character routinely, for scientific data, for clinical trial reporting, and, when a public health emergency made it urgent, for national seroprevalence surveillance. The methods are established. The data sources exist. What is required is the decision to treat NIH's own impact as a dataset worth building, and to fund it accordingly. Anything that is not measured cannot be improved and cannot be defended. NIH's public impact deserves both.

8. Other Areas: About Essex Management. Essex Management is a federal contractor and member of the Emmes Group with over 15 years of experience supporting NIH and HHS agencies. Our work spans three integrated practice areas: Biomedical Informatics and Data Science (BIDS), which supports complex NIH data platforms, bioinformatics pipelines, and clinical informatics programs; Modern Technology and Engineering, which delivers cloud-native software development, data engineering, and FISMA-compliant infrastructure; and Program Strategy and Delivery, which supports scientific program operations, stakeholder engagement, and translational research coordination. Together, these capabilities have supported NIH programs including precision medicine clinical trials, immuno-oncology data commons, pediatric cancer registries, clinical trial management and reporting systems, real-world data platforms, and AI-enabled health informatics. We offer the following perspective to help inform the NIH’s initiative for Measuring and Rewarding Scientific Impact.

150. Brian Bauer

I am responding: On behalf of myself

Name: Brian Bauer

Name of Organization: University of Georgia

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/12/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: Funders already track policy citations as an impact indicator. The UK's National Institute for Health and Care Research uses the Overton database, which indexes more than 13 million policy documents from over 43,000 organizations, to monitor the policy impact of the research it funds. Altmetric indexes citations in policy as a separate category.

However, what these platforms currently report is an unweighted count. Tunn et al. (2025), evaluated both tools against 110 articles from an NIHR policy research unit, and found that the way citing documents were used as evidence varied considerably. At one end, a finding provided general background. At the other, it supplied the stated rationale for a specific clinical recommendation. The authors concluded that citation analysis alone cannot provide the complete picture. A count records both cases as one citation.

I recommend that NIH develop a weighted measure of policy citation, classifying each citation event on two dimensions. The first is role, or how load-bearing the citation is in the document, ranging from background mention through direct support for a stated recommendation. The second is fidelity, based on if the claim as stated in the policy document is supported by the claim as stated in the cited source. For example, a finding that supplies the rationale for a clinical guideline recommendation represents a different kind of uptake than the same finding listed among background references, and a misstated finding in that position is different again. A count cannot distinguish any of these.

Both dimensions are computable from Overton, GovInfo, and Federal Register text using large language model extraction of the citing passage and the source claim, followed by human adjudication of a

validation subsample to estimate error rates. Building the coding scheme and the labeled corpus could be agency-level work. Because the measure is defined per citation event, it aggregates to whatever unit is under evaluation. The same extraction would also show whether retracted findings continue to appear in policy documents after retraction, by joining the Retraction Watch database to the same corpora.

8. Other Areas: N/A

151. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Research Participant/Patient Advocacy Organization/Patient Advocate/Caregiver

Role: Research Participant/Patient/Advocate/Caregiver

Date Submitted: 8/12/2026

1. Rigor and Reproducibility: * Enforce data sharing policies
* Encourage data depository use and maintenance
* Provide training and incentives for data re-use/secondary data analysis
* Deprioritize funding of incremental improvements to evidence-based interventions. We don't need another study on the Diabetes Prevention Program in 50-59 women in rural Wyoming for instance--just reproduce and spread established findings from the DPP, as one example.

2. Data, Software, and Model Sharing: * Enforce current data sharing policies
* Encourage data depository use and maintenance
* Provide training and incentives for data re-use/secondary data analysis
* Utilize known repositories like GitHub, bioLINCC, dbGaP, and MIMIC rather than creating de novo or bespoke data repositories
* Use and promote the standards and resources promulgated by the Mobilizing Computable Biomedical Knowledge initiative

It does take substantial work by "data janitors" to clean and maintain data sets and help ensure that secondary users understand provenance, mode of collection, metadata, and other nuances. This work largely goes unfunded because it's not included in research grants and the grants run out when the data are ready for sharing and reuse

3. Training and Mentorship: In the same way that primary care providers should be paid an equivalent rate to specialty care providers, those who train the next generation of scientists should be compensated and recognized at a rate comparable to those doing the science.

4. Collaboration: Collaboration requires robust infrastructure that needs to be built, maintained and sustained. In the 2000s, Several NIH agencies supported research infrastructures for cancer, mental health, and cardiovascular health for years, but eventually paused these and in some cases, restarted similar endeavors in the 2020s. What if we just acquiesced to the need for ongoing, publicly funded research infrastructures so that we don't need to build new roads every time the car needs to go somewhere?

The peer review process offers an opportunity to identify overlapping/similar initiatives and could actually be a source for brokering collaboration rather than competition

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: I once asked an NIH program officer what it would take for NIH to start looking at research impact vs. length of CV or prominence of publications as a yardstick for research success. If we have a successful intervention to help bolster participation in cancer clinical trials (a longstanding deficit of biomedical research), the intervention should be promulgated and the researchers who built the intervention and fostered its implementation would deserve merit (tenure credits internally). We have an R01 mindset with less attention to the ROI. Particularly for embedded researchers (i.e., in health systems), there should be a mechanism to support dissemination and implementation efforts within the health system for a successful intervention. PCORI does something similar to this with its D&I and HSII mechanisms and could serve as a blueprint.

8. Other Areas: Impact is hastened when study populations are sufficiently large and representative. Research recruitment remains a chokepoint for many studies. What could be done via a public-private campaign to reinforce the value of research to society and encourage people to participate? Altruism, but also financial incentives, could go a long way to accelerate the impact of taxpayer funded research.

152. Chaitanya Jain

I am responding: On behalf of myself

Name: Chaitanya Jain

Name of Organization: University of Miami

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/12/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

8. Other Areas: The following addresses how to ensure that funds spent on competitive renewals are best distributed.

I have long felt that there has not been any good way to measure the effectiveness of NIH funding when grants come up for competitive renewal. Many application reviews tend to be biased towards an investigator's reputation or a long list of publications in which the primary contribution was mostly by others. As a result, investigators who are not as well established or have fewer publications, albeit with with greater effort, are disproportionately left out. To provide a quantitative metric for evaluating applications, I would measure the impact of funding of an investigator or laboratory using the following equation:

Impact = Sum(publications x lab contribution percentage x Impact score)/Dollars awarded.

In this model, I am evaluating the funding impact by measuring the number of research publications generated by a laboratory over the funding duration, each multiplied by the percentage contribution of the laboratory and the impact of the publication (e.g., impact factor). The numerator should then be divided by the total funds received by the laboratory. The final number will help to rank the impact of each grant, and hopefully, create a more equitable basis to determine how NIH could distribute its funds to deliver the most impact.

A few notes on the % contribution metric. For any manuscript, the contribution of all authors in any

paper should add up to 100%. Then, in the equation above, the total contribution of all members of the laboratory who were funded by a grant should be used. Only research publications that generate new findings should be considered, with reviews excluded.

To illustrate this point, I would like to use some hypothetical examples. Let's say that a publication has five authors, of which only the first and the fifth have been funded by an application that is being considered for re-funding. In this example, it would be appropriate to assume that project was initiated by the lab whose PI has submitted a renewal application and that the sum of the contributions of the first and fifth authors might be 60-80%. In a second example, let’s assume there are eight authors, and the persons from the lab that is being considered for re-funding are the third and sixth authors. In that example, I will assume that the work was initiated by a different lab and the bulk of the work was done by the other authors, so the contribution of the third and the sixth authors might only be 5-10%.

I acknowledge that determining the contribution of each author will not be simple and it might need other opinions to decide on the best way to do this. Moreover, basing a grant's impact on publications alone may not be appropriate for all applications. Nonetheless, I hope that whatever I have written, however, imperfect, will help to stimulate a discussion on the best way to distribute NIH funds in a manner that quantifies research impact normalized by the amount of funds received.

153. Institute for Progress

I am responding: On behalf of an organization

Name: Daniel Turner-Evans

Name of Organization: Institute for Progress

Type of Organization: Non-Profit Research Organization

Role: Investigator/Researcher

Date Submitted: 8/13/2026

1. Rigor and Reproducibility: Replicating research findings to confirm their legitimacy is an important part of the scientific process. When determining how much to spend on replication, NIH should carefully consider the return on investment from each dollar spent. Under realistic assumptions, NIH could productively spend about 1.4% of its annual budget on targeted replication studies before hitting negative returns relative to funding new science.

2. Data, Software, and Model Sharing: NIH recently concluded a competition to develop a metric to quantify data sharing, the S-Index, and should now encourage the scientific community to adopt it. As a first step to make PIs aware of the S-Index and to build their comfort with the metric, NIH should pick one of the S-Index metrics from the competition and require that PIs list it in the Data, Management, and Sharing plan for any of their grants.

NIH should also offer incentives for PIs to improve the quality and accessibility of the data, software, and models that they share. PIs can already request funds for Data Management and Sharing, and additional funding opportunities should be made available for personnel or services, including AI tools, to perform these functions

3. Training and Mentorship: Academic graduate programs rarely focus on preparing students for careers in the biomedical industry. NIH should incentivize programs that fill this gap by, for example, incentivizing Ph.D. programs that offer industry internships, similar to the University-Industry Demonstration Partnership Industry-Integrated Ph.D. Scholars Program just launched at NSF.

NIH should also incentivize students to learn how to use state-of-the-art tools, including LLMs and field-specific AI models. The agency should expand support for summer schools and courses that teach students these methods, like the Marine Biological Labs Courses. These courses also offer an excellent opportunity for students to develop budding collaborations and inspire interdisciplinary work.

NIH should quantify how well students learn how to pursue independent research. Many Ph.D. programs already ask students to write an NIH-style grant proposal for their qualifying exam, and NIH should develop guiding rubrics for these exams and dissertation committee assessments and then collect evaluations from faculty who serve on those committees.

NIH should also determine if students are being given sufficient opportunities to collaborate. The number of co-PI publications could serve as a starting point for this evaluation.

4. Collaboration: To incentivize collaboration, NIH could offer additional funding opportunities for multiple PIs, such as the U19 mechanism. The agency could also work to develop a new citation metric that more heavily weights publications with multiple PIs than those with a single PI.

5. Entrepreneurship and Translation: NA

6. Foundational Scientific Exploration: NIH should support a portfolio of mechanisms that can promote both more novel / higher-risk research and more incremental research. Some funding mechanisms are more appropriate for funding conventional research (such as the R01), whereas others are designed to allow for flexibility. For example, person-based grants like the NIH R35 grant provide longer-term funding and flexibility that can allow for innovative research. NIH could also pilot smaller, fast-timeline grants for nascent ideas, as the National Science Foundation does through its EArly-Concept Grants for Exploratory Research (EAGER) program. NIH institutes and centers can also experiment with integrating "golden tickets" into conventional award processes, which increases the novelty of awards by giving reviewers a "golden ticket" to select a project even when the other reviewers disagree.

7. Public Impact: NA

8. Other Areas: Clear metrics are essential for evaluating the success of NIH funding mechanisms and the impact of federally funded science, and carefully structured incentives are necessary for aligning research efforts with national goals. However, when considering how to develop and apply new metrics, NIH should be aware that applying new metrics can add administrative burden on staff or grantees and should therefore perform careful cost-benefit analysis for each new metric before implementing it. We therefore primarily recommend incentives that NIH can use to stimulate more novel, open, and collaborative work and suggest a balance of options that NIH can pursue to shape the research enterprise.

File Upload: https://osp.od.nih.gov/wp-content/uploads/ninja-forms/77/IFP-Response-to-Metrics-and-Incentives-RFI.pdf

About IFP

The Institute for Progress (IFP) is a non-partisan think tank focused on innovation policy. Our organization works to accelerate and shape the direction of scientific, technological, and industrial progress. Headquartered in Washington D.C., IFP works with policymakers across the political spectrum to make it easier to build the future in the United States.

Introduction

The National Institutes of Health requested input on metrics and incentives that reflect the collaborative and interdisciplinary nature of the modern biomedical research enterprise. Clear metrics are essential for evaluating the success of NIH funding mechanisms and the impact of federally funded science, and carefully structured incentives are necessary for aligning research efforts with national goals. However, when considering how to develop and apply new metrics, NIH should be aware that applying new metrics can add administrative burden on staff or grantees and should therefore perform careful cost-benefit analysis for each new metric before implementing it. We therefore primarily recommend incentives that NIH can use to stimulate more novel, open, and collaborative work and suggest a balance of options that NIH can pursue to shape the research enterprise.

Rigor and Reproducibility

Replicating research findings to confirm their legitimacy is an important part of the scientific process. When determining how much to spend on replication, NIH should carefully consider the return on investment from each dollar spent. Under realistic assumptions, NIH could productively spend about 1.4% of its annual budget on targeted replication studies before hitting negative returns relative to funding new science.

Data, Software, and Model Sharing

NIH recently concluded a competition to develop a metric to quantify data sharing, the S-Index, and should now encourage the scientific community to adopt it. As a first step to make PIs aware of the S-Index and to build their comfort with the metric, NIH should pick one of the S-Index metrics from the competition and require that PIs list it in the Data, Management, and Sharing plan for any of their grants.

NIH should also offer incentives for PIs to improve the quality and accessibility of the data, software, and models that they share. PIs can already request funds for Data Management and Sharing, and additional funding opportunities should be made available for personnel or services, including AI tools, to perform these functions

Training and mentorship

Academic graduate programs rarely focus on preparing students for careers in the biomedical industry. NIH should incentivize programs that fill this gap by, for example, incentivizing Ph.D.

programs that offer industry internships, similar to the University-Industry Demonstration Partnership Industry-Integrated Ph.D. Scholars Program just launched at NSF.

NIH should also incentivize students to learn how to use state-of-the-art tools, including LLMs and field-specific AI models. The agency should expand support for summer schools and courses that teach students these methods, like the Marine Biological Labs Courses. These courses also offer an excellent opportunity for students to develop budding collaborations and inspire interdisciplinary work.

NIH should quantify how well students learn how to pursue independent research. Many Ph.D. programs already ask students to write an NIH-style grant proposal for their qualifying exam, and NIH should develop guiding rubrics for these exams and dissertation committee assessments and then collect evaluations from faculty who serve on those committees.

NIH should also determine if students are being given sufficient opportunities to collaborate. The number of co-PI publications could serve as a starting point for this evaluation.

Collaboration

To incentivize collaboration, NIH could offer additional funding opportunities for multiple PIs, such as the U19 mechanism. The agency could also work to develop a new citation metric that more heavily weights publications with multiple PIs than those with a single PI.

Foundational Scientific Exploration

NIH should support a portfolio of mechanisms that can promote both more novel / higher-risk research and more incremental research. Some funding mechanisms are more appropriate for funding conventional research (such as the R01), whereas others are designed to allow for flexibility. For example, person-based grants like the NIH R35 grant provide longer-term funding and flexibility that can allow for innovative research. NIH could also pilot smaller, fast-timeline grants for nascent ideas, as the National Science Foundation does through its EArly-Concept Grants for Exploratory Research (EAGER) program. NIH institutes and centers can also experiment with integrating “golden tickets” into conventional award processes, which increases the novelty of awards by giving reviewers a “golden ticket” to select a project even when the other reviewers disagree.

154. David Piston

I am responding: On behalf of myself

Name: David Piston

Name of Organization:

Type of Organization: Not Applicable

Role: Investigator/Researcher

Date Submitted: 8/13/2026

1. Rigor and Reproducibility: To improve reproducibility, replication studies should be reviewed and funded on their own terms and not compete against novel-science R01s for the same reviewers' attention. We would also need to count replication studies legitimate scientific outputs, with dedicated paths to publication in the same place that the original study was published. If replication studies are underfunded and siloed, they will become a career backwater where labs will do more when they do not have novel science grants – leading to weaker replication studies.

2. Data, Software, and Model Sharing: Data/software sharing is one place where simple metrics, such as was it deposited, does the code run, is it used by others? This check-box stuff can be verified by an NIH program officer, but trying to rank sharing "quality" would invite gaming.

3. Training and Mentorship: Mentorship is of utmost importance, yet it resists quantification almost entirely. Output measures such as job placement mainly reflect trainee talent, not mentoring effort, and metrics for this area can punish people who take on harder cases. A structured and qualitative approach would be confidential trainee letters read by people who've actually mentored. This could be informed by the approach used by HHMI, where lab staff are surveyed extensively and the data are taken seriously. Mentorship evaluation is a category where people should be punished for coming up short but not rewarded for pumping out more PhDs.

4. Collaboration: Given the current interdisciplinary requirements for biomedical research, collaboration and team science should be a top priority. We have not found a clean fix for individual attribution in team science, and perhaps it would be better for NIH to accept this rather than pretend a formula can solve it. CRediT-style contribution statements are a useful input, but turning this into a “point system” could be a real deterrent from collaboration. Instead, it takes careful evaluation by experts to assess whether scientists are embracing collaborative science by reading the papers and evaluating the data from the collaborative teams.

5. Entrepreneurship and Translation: For basic biomedical research, entrepreneurship and translation should sit adjacent to the core reward system, not inside it. If these areas become necessary for judging the impact of basic science research, folks are likely to start chasing patentable results rather than focusing on rigorous and reproducible biological results.

6. Foundational Scientific Exploration: We should place substantially greater emphasis on the quality of science rather than the quantity or perceived prestige of publications. This should include evaluating the

rigor of the work, reproducibility, methodological innovation, the quality and independence of peer review, and the significance of the questions being addressed. Of course, the biggest issue with evaluating impact is that any given quality is a judgment call and figuring out if something/someone is actually good takes experts spending real time, which is at a premium. Any efforts to produce simple indicators to replace publications and citations as measures used to evaluate funding research will ultimately come up somewhat short. No qualitative-judgment-over-metrics system can work unless reviewers actually have time to read things carefully and think about it deeply. An effective system would need to account for limited reviewer bandwidth and not just add new review categories to already overloaded study sections. Similarly, the scientific community should also rethink the peer-review system itself. High-quality reviewing is an essential scholarly contribution, yet it is largely invisible in current academic evaluation systems. Recognizing meaningful reviewing, and particularly sustained, thoughtful, and expert reviewing, could help create incentives for scientists to invest the time necessary to maintain the quality of scientific literature.

7. Public Impact: I am skeptical about any attempt to simplify measurement of scientific impact of NIH-funded research. Public impact is almost impossible to assign to any one set of work. Building scientific progress is like building a pyramid – adding one block at the base doesn't change the height of the pyramid, but the bigger the base, the higher the pyramid can rise. Is the one block at the bottom less impactful than the one at the top, even though the impact on human health will come from the top block? Health impacts play out on wildly different timescales, and evaluating everything by a single metric ends up favoring flashy short-horizon work that will end up killing future advances. Because it builds the base of our research to health impact pyramid, foundational and high-risk science is poorly suited to qualitative evaluation over traditional metrics here. Basic biomedical science would benefit from longer award periods, real freedom to change direction, and renewal evaluation that asks, "was this a good question, and was it pursued rigorously" instead of "did you hit your milestones." The NIH R35/MIRA model is successful proof of this concept.

8. Other Areas: There are significant problems exist in the current publication landscape and find a strong consensus in our department that publications have become a dubious measure of impact. There has been an astronomical ever-growing number of journals, driven by an expansion of low-quality publications, coupled with unreliable citation-based metrics and a review system in which scientists are asked to evaluate an enormous number of manuscripts without compensation. Inevitably, this compromises the depth and quality of peer review, and inevitably, the quality of science in general. The expansion of OA publishing model, coupled in many cases with very high OA charges, has created incentives for publishers to maximize the number of papers processed rather than necessarily the number of papers that represent truly important advances. This proliferation of journals and the focus of these journals to "game" citation metrics makes it difficult to distinguish scientific impact from sheer publication volume. We agree that to improve the quality of science, we need to move away from asking "how much has this person published, and where?" towards asking "what is the quality of their scientific contribution, how rigorously has it been evaluated, and how much has it advanced the field?"

Re: Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Submitted via: https://osp.od.nih.gov/comment-form-measuring-and-rewarding-scientific-impact/

Cleveland Clinic is a not-for-profit, integrated healthcare system dedicated to patient-centered care, teaching, and research. With a footprint in Northeast Ohio, Florida, and Nevada, Cleveland Clinic Health System operates 23 hospitals, including a main campus near downtown Cleveland, with more than 6,690 beds, and 276 outpatient locations. Cleveland Clinic employs over 5,700 physicians and researchers, and 16,500 nurses. Last year, our system cared for 3.3 million patients, including 13.7 million outpatient visits and 323,000 hospital admissions and observations. Below are our comments on the draft guidance.

Cleveland Clinic is home for laboratory-based, translational, computational, clinical and implementation science across Cleveland Clinic's global health system. Cleveland Clinic's research footprint, which includes facilities in Cleveland and Florida, spans nearly one million square feet. Our research enterprise includes over 2,400 researchers and support personnel, and in 2025 our annual research funding exceeded $479 million.

Cleveland Clinic Research encompasses ten scientific departments of Biomedical Engineering; Cancer Sciences; Computational Life Sciences; Heart, Blood and Kidney Research; Genomic Sciences and Systems Biology; Inflammation and Immunity; Microbial Sciences in Health; Neurosciences; Ophthalmic Research; and Quantitative Health Sciences. Cleveland Clinic Research is also committed to the training and career development of young research scientists and physician-scientists. In 2017, the Cleveland Clinic BioRepository was established with a vision to fuel translational research and innovation that leads to improved clinical outcomes and the betterment of patients' lives. The mission of the BioRepository is to safely maximize the value of human samples by supplying high-quality, well-annotated specimens to researchers whose discoveries will be essential for the evolution of personalized medicine.

We appreciate the opportunity to provide comments in response to the National Institutes of Health (NIH) Request for Information (RFI) on Measuring and Rewarding Scientific Impact (NOT-OD-26-087). We commend NIH's efforts through its Replication and Reproducibility Initiative and Plan to Drive Gold Standard Science to identify approaches that more accurately recognize the diverse activities that contribute to scientific advancement and public benefit. NIH has specifically requested feedback regarding measurable indicators, implementation approaches, potential benefits, and unintended consequences related to modern biomedical research. We offer the following

recommendations based on perspectives from active investigators engaged in basic, translational, and clinical research.

Rigor and Reproducibility

Scientific rigor and reproducibility are foundational elements of impactful biomedical research. While investigators currently address rigor and reproducibility requirements in grant applications, we encourage NIH to focus on approaches that influence research culture and daily scientific practices rather than solely emphasizing application requirements.

Strong training environments remain among the most effective mechanisms for promoting rigorous and reproducible research. NIH should consider indicators that evaluate the quality and extent of training in experimental design, statistical rigor, transparency, and reproducibility practices. Additionally, NIH should explore mechanisms to support and reward replication studies, which often provide substantial scientific value but receive limited recognition in traditional research assessment frameworks.

Importantly, NIH should recognize that uncertainty regarding funding availability may create pressure that unintentionally discourages careful, deliberate scientific investigation. Clear and consistent communication regarding research priorities and funding expectations can help reduce these pressures and reinforce rigorous scientific practices.

Data, Software, and Model Sharing

Cleveland Clinic strongly supports data sharing as a critical component of scientific advancement. Shared datasets, software tools, and analytical models enable validation of results, promote transparency, facilitate collaboration, and accelerate discovery.

To encourage meaningful participation, NIH should recognize that data sharing requires substantial investments of investigator time and institutional resources. Measurable indicators could include the number of datasets deposited, dataset utilization rates, adoption of common data elements, and documented reuse of shared resources. However, these expectations should be accompanied by appropriate support.

We recommend that NIH permit dedicated budget allocations for data-sharing activities, including personnel effort required to curate, prepare, and submit data. NIH should also continue efforts to simplify repository submission processes and support development of common data elements across clinical and basic research disciplines. Without these improvements, administrative complexity may become a significant unintended barrier to compliance and meaningful participation.

Training and Mentorship

The future of biomedical research depends upon a stable and confident workforce. We are increasingly hearing concerns from trainees and early-career investigators regarding the long-term stability of federal research support. This uncertainty may discourage talented individuals from pursuing research careers at a time when biomedical innovation depends on attracting and retaining highly qualified investigators.

NIH should consider indicators such as trainee retention, career progression, fellowship participation, and application rates for career development and training awards. Such measures would provide meaningful insight into the workforce and the effectiveness of NIH training investments.

In addition, NIH should recognize high-quality mentorship as a significant scientific contribution. Effective mentors help ensure rigor, foster collaboration, develop future scientific leaders, and sustain the biomedical research enterprise. Institutions and investigators who demonstrate excellence in mentorship should receive appropriate recognition within NIH evaluation frameworks.

Collaboration

Modern biomedical research increasingly depends upon collaborative, interdisciplinary, and multi-institutional teams. Traditional measures of scientific productivity often fail to capture the value of these contributions.

NIH should develop assessment approaches that recognize meaningful participation in team science. Potential indicators could include participation in multi-principal investigator grants, leadership or coordination roles within collaborative initiatives, contributions to shared scientific resources, and evidence of successful multi-institutional partnerships.

We also encourage NIH to consider potential unintended consequences of policies that may inadvertently discourage collaborative applications, including domestic and international collaborations. For example, policies that limit grant submission opportunities, create uncertainty around eligibility or administrative requirements, or increase the complexity of cross-border partnerships could reduce participation in multi-principal investigator proposals and ultimately diminish incentives for team science. NIH should consider addressing challenges specific to international collaborations, including differences in regulatory requirements, data-sharing expectations, institutional approvals, and timelines that may affect investigators' ability to participate fully in collaborative research. Monitoring trends in collaborative grant submissions, including applications involving international partners, may help NIH identify such impacts and ensure that policies continue to support productive scientific collaboration.

Entrepreneurship and Translation

Translation of scientific discoveries into therapies, diagnostics, technologies, and clinical applications represents a critical component of NIH's mission to improve human health.

Artificial intelligence and advanced computational approaches are increasingly creating opportunities to accelerate the movement of discoveries from laboratory investigations to real-world clinical implementation. NIH should consider indicators that measure successful translation, including development of clinical decision-support tools, commercialization activities, implementation of research findings into clinical practice, and responsible application of emerging technologies.

Future NIH assessment frameworks should reward investigators who successfully bridge basic science and clinical application while maintaining rigorous standards for scientific validity, safety, and ethical implementation.

Foundational Scientific Exploration

Many transformative discoveries arise from basic science investigations and high-risk, high-reward research that may not produce immediate outcomes. However, these efforts remain essential to long-term scientific progress.

NIH should continue to support and recognize foundational scientific exploration by valuing scientific creativity, innovation, and willingness to pursue challenging research questions. Stable funding environments and transparent expectations will encourage investigators to undertake ambitious projects that may ultimately yield paradigm-shifting advances.

Assessment frameworks should avoid overemphasizing short-term productivity metrics that may inadvertently discourage innovative or exploratory research.

Public Impact

Biomedical research generates value extending far beyond publications and citations. NIH should continue exploring approaches to assess public impact, including contributions to health outcomes, patient education, community engagement, public trust, accessibility of scientific knowledge, and societal benefit.

Effective communication strategies increasingly rely on both traditional community engagement and modern communication platforms, including digital content, webinars, public education resources, and social media. Meaningful indicators could include dissemination activities, public engagement efforts, adoption of evidence-based health information, and demonstrated influence on health behaviors or clinical practice.

Evaluation systems should recognize investigators and institutions that successfully translate scientific knowledge into tangible public benefit.

Conclusion

As NIH continues to develop approaches for measuring and rewarding scientific impact, it is important that future frameworks reflect the collaborative, rigorous, and mission-driven nature of modern biomedical research. The most meaningful indicators will be those that encourage behaviors that strengthen the biomedical research enterprise, including mentorship, transparency, collaboration, data sharing, innovation, and public engagement.

We appreciate NIH's commitment to ensuring that scientific incentives align with activities that ultimately improve human health and advance discovery. Thank you for your consideration of our feedback. Should you need any further information, please contact me.

Sincerely,

Serpil C. Erzurum, MD
Alfred Lerner Memorial Chair in Innovative Biomedical Research
Cleveland Clinic Chief Research & Academic Officer

8. Other Areas: The NIH's decision to collapse qualities of the Investigator - prior productivity, accomplishments, ability to deliver etc. - into a simple binary of acceptable or unacceptable undermines the mission to support impactful science. I cannot think of other endeavors - in business, the arts, or anything else - where the abilities of the grantee are not evaluated along with the proposed work. (Not to mention the double standard of having the investigator track record rank highly for new investigators in mechanisms such as the DP2. If the qualities of an early career investigator be a matter worth considering in funding decisions, why should it be different for a mid-career or senior investigator?) I understand the fairness argument - that it is unacceptable to simply give a researcher the "benefit of the doubt" - but the pendulum has swung too far in terms of the restrictions placed on what grant reviewers are "allowed" to consider. I think this results in a different kind of unfairness.

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: I am concerned about the erosive effect of AI on data and result integrity. There could be counterintuitive adverse effects of data sharing. If a lab has expensively acquired data, it will have a better understanding of its limitations. I'm concerned that AI chatbots will make it possible to repeatedly reuse public data, exposing the public to the risks of false discovery due to repeated hypothesis testing. I see this in peer review requests that I get, where unknown research groups are grinding against public data (typically TCGA or UKBB). Even if there is internal correction for multiple hypothesis testing, the reduplicative use of the data will eventually lead to type I errors. AI overall makes it possible to iteratively create grants, models, papers and presentations. This can be both good and bad but is currently completely uncontrolled. People use AI to write their papers, then reviewers use AI to read them, then hiring committees use AI to evaluate these scientists' CVs... what if the AI is just wrong about any of this? How will we know?

3. Training and Mentorship: Realistically an assistant professor needs to secure at least two R01 equivalents. As it starts to become unrealistic to maintain this cadence, talented individuals will drop out of the tenure track pool. The training and recruitment pipeline into the tenure track is at risk currently due to low paylines and uncertain funding environment/priorities.

With regard to paylines, when 5% or less of grants are funded, the probability of successfully securing enough funding to keep a lab running becomes impossibly low. At such low paylines, even meritorious grants can fail by chance. NIH scientific review is effective and improves the quality of science but it definitely has a component of noise. There is subjectivity in NIH scoring (intra/inter-observer variability) and so a grant that might have been funded in one round, or with a given set of reviewers, can fail, not because it needed to be improved, but simply by chance. Or grants that meet all standards of scientific review ("fundable" on scientific merit) may be denied repeatedly simply because there is not enough money. What are these investigators supposed to do? Keep trying in case they get lucky a different time? Reduplicatively submit more and more grants in order to get more darts to throw? It is not efficient to expect applicants to invest resources not only in their best ideas, but also in their 2nd, 3rd, 4th, 5th best ideas.

With regard to funding priorities, the vast majority of scientists are not ideologically driven and are pursuing a combination of pure truth, societal benefit and personal career stability. They rely on the

principle that their field will not experience major shifts in fundability over their career (or only on a timeframe where they can reasonably pivot). In the current environment it seems entire areas of research are at risk of being de-emphasized on short notice. Regardless of the societal merit or legal defensibility of this approach, there will be a chilling effect on recruitment of talented scientists into the tenure-track pipeline, if there is a risk that the rug will be pulled out from under their research area at a moment's notice.

158. Suresh Palaniyandi

I am responding: On behalf of myself

Name: Suresh Palaniyandi

Name of Organization: Henry Ford Health System/Wayne State University

Type of Organization: Non-Profit Research Organization

Role: Investigator/Researcher

Date Submitted: 8/13/2026

1. Rigor and Reproducibility: NIH should reward researchers who demonstrate that their findings are reproducible, not simply those who publish the greatest number of papers. Practical indicators could include successful replication by independent laboratories, publication of negative or confirmatory results, use of validated methods, and transparent reporting of experimental conditions. NIH could provide small supplemental awards for independent replication studies and allow investigators to identify their most reproducible or independently validated findings in biosketches and progress reports. Importantly, these measures should recognize rigorous work without creating additional paperwork for investigators.

2. Data, Software, and Model Sharing: NIH should recognize and reward the act of making scientific data, software, models, and protocols openly available, since sharing itself requires time, effort, documentation, and resources and is the essential first step toward reproducibility and reuse. Additional indicators could then capture the broader value of these resources, such as downloads, reuse of datasets, requests for animal models or reagents, adoption of protocols or software, and publications generated using shared resources. Investigators who create and maintain useful shared resources should be able to list these as major scientific contributions comparable to publications. NIH could also provide small supplements or dedicated support for preparing, documenting, and maintaining high-value resources so that data sharing does not become an unfunded administrative burden.

3. Training and Mentorship: NIH should recognize mentorship across the entire biomedical research pipeline, including high school, undergraduate, master's, PhD and MD students, postdoctoral fellows, and other degree holders entering or advancing in research. The number of individuals trained is an important indicator of a researcher's commitment to developing the workforce, but it should be considered together with the quality, duration, and depth of mentorship. Useful outcomes could include trainee publications and presentations, research skills gained, fellowship or grant applications, continued education, transition to independent positions, and career advancement in biomedical research or related fields. Importantly, dedicated mentorship of a smaller number of trainees can have substantial impact and should not be undervalued simply because another investigator has trained a larger number. NIH should recognize both the reach of training and the quality and sustained commitment of mentorship, without creating substantial additional reporting burden.

4. Collaboration: Modern biomedical research increasingly depends on collaboration, yet current measures often give disproportionate credit to the PI, corresponding author, or senior author. NIH

should recognize building productive collaborations as a scientific achievement itself, particularly when those collaborations lead to joint grant applications, funded projects, publications, abstracts, presentations, shared resources, new methods, or multidisciplinary research directions. Contributions such as providing specialized expertise, developing methods, generating unique models or datasets, and performing critical experiments should also receive meaningful recognition regardless of authorship position.

Investigators should be able to document important collaborative accomplishments in their biosketches and progress reports, including collaborative grant submissions and scientific outputs. NIH could further incentivize collaboration through supplemental funding, recognition of sustained productive partnerships, or consideration of collaborative accomplishments during grant review. This would encourage investigators to share expertise and build strong research teams rather than compete primarily for individual credit, while still recognizing leadership by PIs and senior investigators.

5. Entrepreneurship and Translation: Patents, licensing, startup companies, and commercialization are important and measurable indicators of successful translation and should continue to be recognized and rewarded. NIH should also recognize additional steps that move discoveries toward practical application, including development of biomarkers, diagnostics, therapeutic targets, assays, research tools, clinical protocols, and technologies; industry partnerships; progression to preclinical or clinical testing; and adoption by other researchers or healthcare systems. Importantly, translation often requires years and contributions from multiple investigators. Researchers should therefore receive credit for meaningful milestones along the translational pathway, not only for the final commercial product. NIH could also provide targeted supplemental funding to help promising discoveries cross the difficult gap between an academic finding and the proof-of-concept work needed for commercialization or clinical development.

6. Foundational Scientific Exploration: NIH should recognize that positive, negative, nonsignificant, and unexpected results can all contribute to scientific knowledge when the research is rigorous and well designed. Negative or nonsignificant findings can prevent unnecessary duplication, challenge existing assumptions, and guide future research, yet these results are often difficult to publish and therefore receive little recognition. This strong emphasis on positive and novel findings may also unintentionally contribute to publication bias and create pressure that can undermine research rigor and integrity. NIH should encourage and give credit for communicating rigorous negative and nonsignificant findings through publications, brief reports, data repositories, or other appropriate scientific forums.

Publications should remain an important measure of scientific productivity, but they should not be treated as the sole measure of scientific achievement. Building collaborations, training and mentoring researchers, developing methods and models, sharing data and resources, presenting findings, contributing reviews or scientific perspectives, and other scholarly activities all contribute to knowledge building. NIH evaluation should recognize this broader range of contributions so that investigators are rewarded for advancing science, not simply for producing a larger number of positive-result publications.

7. Public Impact: Public impact should be measured broadly and over an appropriate time frame. Useful indicators could include changes in clinical practice, incorporation into guidelines, development of diagnostics or treatments, use of research findings by healthcare systems, public-health applications, patents or licensing, and educational or community outreach. NIH should recognize that basic

discoveries may require many years before producing measurable health outcomes; therefore, investigators should not be penalized when immediate clinical impact is unrealistic.

8. Other Areas: NIH should consider measuring scientific value created per research dollar, rather than relying heavily on publication quantity. Investigators at smaller institutions or with limited resources may produce highly rigorous and impactful science without generating large numbers of publications. Indicators could include discoveries produced, resources shared, collaborations enabled, trainees developed, subsequent research stimulated, and progress toward clinical or public-health applications relative to the resources available.

NIH should also recognize research that saves the scientific community time and money. Demonstrating that a widely assumed mechanism does not reproduce, validating an inexpensive alternative method, sharing a model that prevents other laboratories from recreating it, or identifying why an experimental approach fails can have substantial value even if these contributions generate fewer citations. Preventing unnecessary research expenditure is itself an important return on NIH investment.

Finally, any new system should remain simple. NIH should avoid replacing publication counts with dozens of new metrics that increase investigators' administrative workload. A practical approach could allow researchers to select three to five major contributions from the previous funding period and briefly document their measurable impact—such as independent validation, data or model reuse, collaboration, trainee development, translation, or public benefit. Reviewers could then evaluate the quality and impact of those contributions rather than relying primarily on publication and citation counts.

I especially recommend including that last paragraph. It addresses a major risk in this initiative: NIH could create 20 new metrics and inadvertently make life harder for the very "average researcher" it is trying to recognize. Your proposal—“show me your 3–5 most valuable contributions and evidence of their impact”—is simple, feasible, and gives researchers multiple ways to demonstrate success.

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

8. Other Areas: The American Society of Human Genetics (ASHG) appreciates the opportunity to respond to NIH's Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087). We offer these comments in our capacity as the world's largest professional organization for human genetics research. Our membership includes researchers, academics, physicians, technicians, genetic counselors, students, and others with an interest in human genetics and genomics.

Human genetics and genomics provide a strong example of how rigorous research and team science work together to produce impactful discoveries. Advances in our field often result from contributions by large multi-institutional teams, longitudinal data generation and stewardship, engagement with research participants and patient communities, and translation of discoveries into clinical care. ASHG welcomes NIH's efforts to develop scientific assessment frameworks that better recognize and incentivize the collaborative, rigorous, and mission-driven nature of modern biomedical research.

At the same time, ASHG encourages NIH to consider changes to indicators and incentives through a coordinated framework that benefits from the expertise of NIH's advisory councils and advisory committees. Because research evaluation policies influence funding decisions, workforce development, institutional investments, and scientific culture, they should be developed holistically rather than through a series of discrete policy changes that may create unintended or conflicting incentives. Engagement with NIH peer advisory groups can help ensure that proposed updates are evaluated in the broader context of the agency's mission and the long-term health of the biomedical research enterprise.

We also emphasize the importance of transparent peer review and peer advice in assessing scientific quality and impact. While alternative indicators can complement traditional evaluation methods, they should not replace expert scientific judgment. Maintaining the integrity, independence, and credibility of peer review is essential to ensuring public trust in federally funded research and to maximizing the value and impact of research investments.

ASHG appreciates NIH's consideration of these comments and looks forward to ongoing dialogue as NIH continues this work. For additional information, please contact Karina Miller, PhD, at kmiller@ashg.org.

7. Public Impact: Response to NIH Request for Information NOT-OD-26-087: Measuring and Rewarding Scientific Impact

Respondent: Kirsten K. Davison, PhD, Associate Dean for Research, Boston College School of Social Work. I respond as an individual investigator and research administrator; the views are my own.

Sub-topic addressed: Public Impact.

CONTEXT

Research impact, the benefit science delivers to health, the economy, public policy, the environment, and quality of life, is an established field of practice [1] and, more recently, of research [2,3]. Our counterparts in Canada, the Netherlands and, especially, the United Kingdom (UK) have prioritized and measured research impact at a national scale for more than a decade. Because the US does not utilize a national impact framework, many US academics and institutions lack an impact vocabulary and culture [1].

NIH has requested input on a number of areas of modern-day science including "approaches for assessing and recognizing the broader public impact of biomedical research," with a premium placed on "specific and measurable indicators." In the case of societal research impact, which emerges through many hands, over long and uneven timeframes, and in forms that are hard to attribute to any single study or summarize with a specific metric, this framing invites a long and unwinnable debate [3,4].

Bodies from the UK's Research Excellence Framework (REF) to the San Francisco Declaration on Research Assessment have long recognized that research impact resists simple quantitative metrics.

NIH can distinguish between measuring impact, the downstream outcomes that are slow to appear and hard to attribute, and rewarding the practices that reliably produce impact, which we can see today. It can expect and reward knowledge translation, community engagement, open science, and technology transfer. The currency should not be a new citation-focused metric; rather, it should be evidence that a researcher planned and implemented the translational work alongside their high-quality science: the policy brief, the community report, or the licensed technology.

Not all science should be judged this way. Discovery research, curiosity-driven research that is often decades ahead of its application, is the foundation of scientific progress, and forcing it into near-term translation would be a mistake. Such research should be explicitly exempt, not scored as weak.

Recognizing these challenges, and drawing on my personal experiences (as an NIH-funded researcher and associate dean of research) along with the empirical literature, I provide four recommendations to shift researcher behavior toward prioritizing the societal impact of research. Alongside these recommendations, I provide specifics of their implementation, candidate indicators, and the conditions under which they would work across career stages, disciplines and institutions with varying impact capacity.

RECOMMENDATIONS

1. BUILD ON NSF'S "BROADER IMPACTS" CRITERION

In my experience, NSF's emphasis on societal impact (i.e., broader impacts criterion), and the way reviewers weigh it, pushes research markedly closer to impact than the process adopted by NIH [5]. Adapting a proven, domestic model rather than inventing one from scratch is the most immediately achievable step.

1.1 Implementation. Integrate a scored translation and public benefit element into the existing review criteria for applicable activity codes, with an exemption for discovery research. It is critical to provide reviewer guidance and worked examples before the first receipt date; inconsistent reviewer interpretation, not the criterion itself, has been the main failure of impact criteria elsewhere [6].

1.2 Indicators. At the application stage, indicators could include specificity of the named intended users, evidence that the resulting outputs are valuable to said users, and personnel time and funds budgeted for translation.

2. LEARN FROM INTERNATIONAL FRAMEWORKS AND FROM THEIR FAILURES

The UK's REF, Horizon Europe, and Canada's knowledge-translation framework offer hard-won lessons in implementing impact frameworks, including the administrative burden and gaming of the exercise [4,7,8] and the risk of rewarding polished storytelling over real change [9,10]. Australia is a case in point:

its national Engagement and Impact Assessment ran once, in 2018, and was discontinued in 2023 with no replacement as yet identified. NIH should study the implementation of existing and retired impact frameworks, and talk directly with their sponsors, before importing them.

3. BUILD IMPACT LITERACY AND CAPACITY ACROSS RESEARCHERS, INSTITUTIONS AND THE WIDER RESEARCH SECTOR

Impact does not happen by chance. It requires the knowledge, skills, systems and culture to anticipate, design for, support and document change from the outset [11]. Established frameworks and practical resources already exist to strengthen individual and institutional impact literacy [12,13]. Requiring translational planning without building this capacity would undermine the objective.

3.1 Implementation. Incorporate activities to build impact literacy into institutional and career development training awards, fund administrative supplements for translational planning and implementation, and provide shared or regional expertise for institutions with limited translation infrastructure.

3.2 Indicators. Trainee completion of translation or engagement training, presence of institutional support structures, and translational output of trained cohorts relative to comparison groups.

4. REQUIRE INVESTIGATORS TO REPORT TRANSLATIONAL ACTIVITIES ANNUALLY, AND MAKE THOSE REPORTS PUBLIC

Today there are few expectations for what to include in progress reports, so meaningful work goes unrecorded. NIH should instruct researchers to document the knowledge- and technology-transfer practices (open science, co-creation) and products (op-eds, policy briefs) that move science beyond academia. These are not achievements to save for the final progress report; they are real outcomes along the pathway to impact. When shared openly, the research community can study them and build the science of impact alongside its practice.

4.1 Implementation. NIH should collect this information through a structured module in the Research Performance Progress Report using a controlled vocabulary rather than narrative, with persistent identifiers where they exist and a brief free-text field. The resulting data should be released as a public, machine-readable resource linked to RePORTER, as NIH already does for publication linkages.

4.2 Indicators of activity. The module should capture non-journal outputs with persistent identifiers, including policy briefs, community reports, curricula, decision aids, protocols, datasets, software, invention disclosures, and licenses. It should also record engagement roles, such as practice or policy advisory bodies, co-authorship with non-academic partners, and formal comment or testimony to public bodies.

4.3 Indicators of early uptake. Early uptake can be tracked using existing data sources. These include citation of award-linked publications in policy documents and clinical practice guidelines, documented reuse of deposited data and software, and downstream licensing.

4.4 Portfolio-level indicators. NIH can compute a set of indicators from its own records including the share of awards reporting at least one translational output, time from award to first non-journal output, share of award-linked publications cited in guidelines or policy documents, and data reuse rates by repository.

These are indicators of practice and early uptake, not of health, economic, or social outcomes. They should be reported as a profile rather than combined into a composite score, and NIH should state that they are unsuitable for ranking individual investigators.

CLOSING

Changes like these would ripple well beyond NIH, reshaping how universities evaluate and promote their faculty and, over time, helping to build an impact culture. Two strategies could improve NIH's impact strategy. First, treat the initial indicator set as provisional, evaluate the protocol and its outcomes, and disseminate the findings. Second, release the structured reporting data publicly.

Response to NIH Request for Information NOT-OD-26-087: Measuring and Rewarding Scientific Impact

Respondent: Kirsten K. Davison, PhD, Associate Dean for Research, Boston College School of Social Work. I respond as an individual investigator and research administrator; the views are my own.
Sub-topic addressed: Public Impact.

The Context
Research impact, the benefit science delivers to health, the economy, public policy, the environment, and quality of life, is an established field of practice [1] and, more recently, of research [2,3]. Our counterparts in Canada, the Netherlands and, especially, the United Kingdom (UK) have prioritized and measured research impact at a national scale for more than a decade. Because the US does not utilize a national impact framework, many US academics and institutions lack an impact vocabulary and culture [1].

NIH has requested input on a number of areas of modern-day science including “approaches for assessing and recognizing the broader public impact of biomedical research,” with a premium placed on “specific and measurable indicators.” In the case of societal research impact, which emerges through many hands, over long and uneven timeframes, and in forms that are hard to attribute to any single study or summarize with a specific metric, this framing invites a long and unwinnable debate [3,4]. Bodies from the UK's Research Excellence Framework (REF) to the San Francisco Declaration on Research Assessment have long recognized that research impact resists simple quantitative metrics.

NIH can distinguish between measuring impact, the downstream outcomes that are slow to appear and hard to attribute, and rewarding the practices that reliably produce impact, which we can see today. It can expect and reward knowledge translation, community engagement, open science, and technology transfer. The currency should not be a new citation-focused metric; rather, it should be evidence that a researcher planned and implemented the translational work alongside their high-quality science: the policy brief, the community report, or the licensed technology.

Not all science should be judged this way. Discovery research, curiosity-driven research that is often decades ahead of its application, is the foundation of scientific progress, and forcing it into near-term translation would be a mistake. Such research should be explicitly exempt, not scored as weak.

Recognizing these challenges, and drawing on my personal experiences (as an NIH-funded researcher and associate dean of research) along with the empirical literature, I provide four recommendations to shift researcher behavior toward prioritizing the societal impact of research. Alongside these recommendations, I provide specifics of their implementation, candidate indicators, and the conditions under which they would work across career stages, disciplines and institutions with varying impact capacity.

Recommendations

1. Build on NSF’s "broader impacts" criterion

In my experience, NSF's emphasis on societal impact (i.e., broader impacts criterion), and the way reviewers weigh it, pushes research markedly closer to impact than the process adopted by

NIH [5]. Adapting a proven, domestic model rather than inventing one from scratch is the most immediately achievable step.

1.1 *Implementation.* Integrate a scored translation and public benefit element into the existing review criteria for applicable activity codes, with an exemption for discovery research. It is critical to provide reviewer guidance and worked examples before the first receipt date; inconsistent reviewer interpretation, not the criterion itself, has been the main failure of impact criteria elsewhere [6].

1.2 *Indicators.* At the application stage, indicators could include specificity of the named intended users, evidence that the resulting outputs are valuable to said users, and personnel time and funds budgeted for translation.

2. Learn from international frameworks and from their failures

The UK's REF, Horizon Europe, and Canada's knowledge-translation framework offer hard-won lessons in implementing impact frameworks, including the administrative burden and gaming of the exercise [4,7,8] and the risk of rewarding polished storytelling over real change [9,10]. Australia is a case in point: its national Engagement and Impact Assessment ran once, in 2018, and was discontinued in 2023 with no replacement as yet identified. NIH should study the implementation of existing and retired impact frameworks, and talk directly with their sponsors, before importing them.

3. Build impact literacy and capacity across researchers, institutions and the wider research sector

Impact does not happen by chance. It requires the knowledge, skills, systems and culture to anticipate, design for, support and document change from the outset [11]. Established frameworks and practical resources already exist to strengthen individual and institutional impact literacy [12,13]. Requiring translational planning without building this capacity would undermine the objective.

3.1 *Implementation.* Incorporate activities to build impact literacy into institutional and career development training awards, fund administrative supplements for translational planning and implementation, and provide shared or regional expertise for institutions with limited translation infrastructure.

3.2 *Indicators.* Trainee completion of translation or engagement training, presence of institutional support structures, and translational output of trained cohorts relative to comparison groups.

4. Require investigators to report translational activities annually, and make those reports public

Today there are few expectations for what to include in progress reports, so meaningful work goes unrecorded. NIH should instruct researchers to document the knowledge- and technology-transfer practices (open science, co-creation) and products (op-eds, policy briefs) that move science beyond academia. These are not achievements to save for the final progress report; they are real outcomes along the pathway to impact. When shared openly, the research community can study them and build the science of impact alongside its practice.

4.1 *Implementation.* NIH should collect this information through a structured module in the Research Performance Progress Report using a controlled vocabulary rather than narrative, with persistent identifiers where they exist and a brief free-text field. The

resulting data should be released as a public, machine-readable resource linked to RePORTER, as NIH already does for publication linkages.

4.2 *Indicators of activity.* The module should capture non-journal outputs with persistent identifiers, including policy briefs, community reports, curricula, decision aids, protocols, datasets, software, invention disclosures, and licenses. It should also record engagement roles, such as practice or policy advisory bodies, co-authorship with non-academic partners, and formal comment or testimony to public bodies.

4.3 *Indicators of early uptake*. Early uptake can be tracked using existing data sources. These include citation of award-linked publications in policy documents and clinical practice guidelines, documented reuse of deposited data and software, and downstream licensing.

4.4 *Portfolio-level indicators.* NIH can compute a set of indicators from its own records including the share of awards reporting at least one translational output, time from award to first non-journal output, share of award-linked publications cited in guidelines or policy documents, and data reuse rates by repository.

These are indicators of practice and early uptake, not of health, economic, or social outcomes. They should be reported as a profile rather than combined into a composite score, and NIH should state that they are unsuitable for ranking individual investigators.

Closing

Changes like these would ripple well beyond NIH, reshaping how universities evaluate and promote their faculty and, over time, helping to build an impact culture. Two strategies could improve NIH's impact strategy. First, treat the initial indicator set as provisional, evaluate the protocol and its outcomes, and disseminate the findings. Second, release the structured reporting data publicly.

Name of Organization:

Type of Organization: Not Applicable

Role: Other

Role - Other: Retired head of the Google Accelerated Science lab (Corporate AI/bio research)

Date Submitted: 8/13/2026

1. Rigor and Reproducibility: Instead of asking people to create datasets we need to ask them to create reference implementations of the experimental systems that can produce such data. We need incentives for people to build, run, and help create instances of these systems. With AI we need to exit the era of "datasets" and usher in the era of "reference experimental implementations" that can create multiple related but different datasets repeatedly and reproducibly. In building AI models you need experimental infrastructure to both provide training data, but even more importantly, to provide ground truth verification data. In most cases you need to train and differentiate the performance of dozens if not hundreds of models with different parameters to figure out what works best. Even with data holdouts, doing this with a single data set becomes extremely limiting.

We need to create incentives for people to create systems that generate data, not standalone datasets. These systems need to be fully open, replicable, and made widely available.

2. Data, Software, and Model Sharing: This is similar and tied in to the reproducibility and rigor problem. Again, we need to incentivize the production of systems that produce experimental data, not datasets. In the age of AI models the key to success is an iterative process between building and testing a model, and producing new experimental data specifically to eliminate noise in the model (as opposed to illuminate a specific hypothesis). By doing this repeatedly the model becomes truly predictive. This cannot be accomplished with a dataset because it is impossible to predict ahead of time exactly what data will be needed for the model to converge. By incentivizing the creation of datasets we are actually holding back the effectiveness of AI in biology and chemistry. We need to incentivize the production of reference implementations of experimental infrastructure that produce datasets, not a particular dataset.

3. Training and Mentorship: N/A

4. Collaboration: Collaboration is crucial for making progress. Especially with AI techniques revolutionizing scientific capabilities. For the first time ever, something other than a human brain can make sense of complex patterns in scientific data, and do it in ways that are different and frequently complimentary to human abilities. I spent 15 years creating and running such collaborations. The main problem is that it takes significant time for very smart people from different disciplines to truly

understand each other. Collaborations without a long term commitment are fundamentally limited. Biologists naturally gravitate to having AI solve one of their current problems. Computer Scientists naturally gravitate to the biology problem that best matches the abilities of their current model or algorithm. In almost all cases both of these approaches are suboptimal. The right thing to do is to ask "what scientific question could we answer together that was previously not approachable". This is a difficult thought exercise, but crucial. Otherwise a lot of effort is spent on the wrong (or at least suboptimal) problems. This is an extreme case of only looking for your keys under the streetlight. I would argue that this is currently the worst problem we have in interdisciplinary collaborations. The main way to fix this is to tailor incentives for longer collaborations and bigger impact. This will both allow both side to understand each other to ask the right big questions, and discourage short term but lower impact work.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: The right approach it to create longer term incentives with a higher bar. Often PIs answer the biggest question they can fit into the timeline of a grant and not the question they truly think is important. Incentivizing PIs to answer questions that are not actually very important is a waste. It makes more sense to create bigger and longer term grants but hold PIs to a higher standard for productivity. Publication should be encouraged but should not be used as a real measure of impact. We need to incentivize the building of reusable experimental systems and the production of reusable models. This is harder than publishing a paper, but much more valuable. If other scientists actually use the actual models or experimental systems, that is a much much higher accomplishment than referencing a paper and should be rewarded as such.

7. Public Impact: N/A

8. Other Areas: N/A

Date Submitted: 8/13/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: I will only comment on this category, which I believe is the single most important and yet the single most ignored issue in grant evaluation. And in this category I single out, to use your terminology "contributions to health outcomes". Useful as they are, none of the considerations in the six categories listed above have any long-lasting significance for NIH unless they lead to measurable improvement in the health of the population. Health is the purpose of the NIH, just as science is the purpose of the NSF.
So how do we assess this impact? Simply by asking of studies, how was the health of the population affected by the findings?
I am a pediatrician and it is sobering to consider that some of the most important recent advances in child health did not emerge from NIH research. The finding that neural tube defects can be prevented by periconceptional folic acid is owed to trials conducted in the UK and in Hungary. Notably, the NIH hesitated to undertake a trial of folic acid supplementation in the 1980s preferring to continue with observational research on the hypothesis. Supine sleeping in infants, which saves some 4,000 US lives annually, emerged from studies done in Holland , New Zealand and Australia.
The development of components of newborn intensive care and the demonstration of their impact on child health, one the other hand, did emerge from NIH research. What I think we are missing is a systematic inventory of major advances in health and an attempt to trace back their origins in research. If we did that, we might better understand how research eventuates in measurable improvements in population health parameters. And, in parallel with the above, we need to ask of studies what impact they had on population health after enough time has passed to make a judgment, The lack of immediacy in the result should not preclude examining outcomes a decade after a study has been completed. It might be interesting and useful to ask investigators to provide an assessment of the improvements in

health that have resulted from their work - a question that could be asked 2, 5 and ten years after study completion. I would be happy to provide such an assessment of the several NIH studies I have undertaken as a PI since my first R01 that began in 1978.

Name:

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/14/2026

1. Rigor and Reproducibility: Incentives: failures to replicate need to be publishable. Built-in replications need to be rewarded in both the publishing and granting process. For example, it many cases it is trivial to build a replication into a new study and find (or not find) the prior results along with generating new results. Such a process should be rewarded; however, often it is penalized. Journals reject manuscripts that include such replications along with new results, citing lack of novelty, which actively de-incentivizes researchers from taking this approach. This approach should be easy and low cost. Infrastructure: researchers need training in null hypothesis testing, Bayesian inference, and overall replication best-practices. Changing every variable in a study and failing to replicate prevents interpretation of what factor may have driven the original effect. Combining both: registered-reports for replication studies is a good idea on paper; however, in practice it is insanely cumbersome. The months that it can take a basic replication to pass through multiple rounds of peer review is unacceptable and untenable.

2. Data, Software, and Model Sharing: Then why won't the NIH fund the Center for Open Science (COS)? This open-access platform was used for a decade by many researchers and due to lack of funding, will no longer host data in 2027. This is a major loss to the research community. To incentivize sharing, it must be made easy and free. The level of burden placed on researchers is incredible: researchers do not have the time or money to share their data, even if they are amenable to the practice. It is also not just the time it takes to organize the data to comply with policies. It is also the time it takes to format the "data/code availability" sections and tables of manuscripts since the rules and expectations are different for nearly every academic journal.

3. Training and Mentorship: Indicators - how many F31 recipients proceed to a post-doc position, other academic position, industry position, or leave science relative to those who do not? Same for F32, but transition to faculty positions. If the goals of the training is career potential and preparedness, measure the careers obtained as the outcome measure.

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: Fund more basic research. Do not evaluate basic science proposals on their translational/clinical potential, but instead on the knowledge to be gained from the work itself. No one, both basic and applied science researchers, can operate to their maximum potential

in this climate of uncertainty. Ensure support for basic science by removing threats to cancel grants at will, without cause, and without recourse to appeal.

7. Public Impact: N/A

8. Other Areas: N/A

164. American Psychological Association

I am responding: On behalf of an organization

Name: Angela Sharpe for Adrienne Stith, PhD

Name of Organization: American Psychological Association

Type of Organization: Non-Profit Research Organization

Role: Organizational Official

Date Submitted: 8/14/2026

1. Rigor and Reproducibility: APA supports NIH's efforts to recognize rigor, reproducibility, replicability, robustness, and credibility as important dimensions of scientific impact. Psychological science has contributed significantly to the study of research credibility and has demonstrated that confidence in findings can be strengthened through complementary approaches such as transparent reporting, independent replication, reproducibility checks, robustness analyses, preregistration, and structured expert assessment.

Drawing on the literature, APA recommends that NIH distinguish between reproducibility, robustness, replicability, and trustworthiness when developing assessment frameworks. This distinction is important for implementation. Treating these concepts as interchangeable may create confusion and unintended incentives. In addition, different research questions may require different forms of assessment. Assessment systems should encourage investigators and reviewers to identify the most appropriate methods for evaluating confidence in findings and reward contributions that make research more transparent, interpretable, and verifiable.

Nosek, B. A., et al., propose a concise glossary to improve precision and communication about research quality and evidence assessment. The glossary is directly relevant because assessment systems can create unclear incentives when key concepts are treated as interchangeable. Accordingly, APA recommends that NIH use precise terminology in application instructions, review criteria, reviewer guidance, progress reports, and renewal decisions so that investigators and reviewers understand whether they are assessing reproducibility of analyses, robustness of conclusions across defensible analytic choices, replicability with independent data, or broader credibility and trustworthiness.

APA recommends that NIH invest in the science of credibility assessment itself. Nosek and colleagues' work on replicability, robustness, and reproducibility demonstrates that scientific impact depends not only on producing new findings, but also determining whether findings are reliable, interpretable, reusable, and capable of informing cumulative knowledge. SCORE shows that scalable indicators of replicability, robustness, reproducibility, transparency, and other credibility dimensions must be validated before they are used as incentives. NIH should support research, infrastructure, and pilot programs that test whether proposed indicators are reliable, explainable, field-sensitive, and useful to reviewers and decision-makers. Vazire's work reinforces this point by showing that quality uncertainty erodes trust when consumers of science lack the information needed to evaluate claims, and that the

credibility revolution may reduce apparent individual productivity while increasing genuine scientific progress. Policies for measuring and rewarding impact should be evaluated empirically, implemented flexibly, and designed to encourage ongoing scrutiny of whether new metrics actually improve science.

APA recommends that NIH incentivize practices that increase confidence in findings, including well-powered designs, transparent analytic decisions, preregistration where appropriate, clear reporting of methods and limitations, independent replication, and evaluation of whether findings hold across analytic choices, populations, measures, and contexts. These practices are especially important in fields that inform clinical care, public health, education, and policy, where premature or overstated claims have significant downstream consequences, despite the frequent need for rapid decision-making and response.

At the same time, APA encourages NIH to implement rigor and reproducibility indicators in ways that are appropriate. Not all research questions are suited to the same forms of replication or preregistration, and exploratory, qualitative, community-engaged, longitudinal, and observational research may require different standards of transparency and robustness. NIH should support discipline-specific guidance and avoid rigid requirements that could unintentionally discourage innovation, exploratory discovery, and more research with hard-to-reach populations.

APA recommends that NIH incorporate these indicators into grant review, progress reporting, and career advancement mechanisms through narrative contribution statements and portfolio-based assessments that allow investigators to show the significance of their most meaningful work. In psychology and behavioral science, especially valuable contributions include demonstrating that findings replicate across diverse populations and settings, developing culturally valid measures, creating reusable research resources, advancing methods for studying behavior and mental health, and generating evidence that informs clinical practice, prevention, education, workplace well-being, and public policy.

The association further recommends that NIH also recognize contributions that strengthen the research enterprise itself, such as leadership in multi-site collaborations, training the next generation of scientists, and advancing open and transparent research practices. Rewarding the practices that produce trustworthy, reproducible, and actionable knowledge would strengthen stewardship of public research investments, accelerate scientific progress, and enhance public trust in biomedical and behavioral research.

Psychology-specific research indicators include:

- Independent replications of influential findings and interventions.
- Evidence that findings are robust across populations, contexts, measures, and analytic approaches.
- Preregistration and registered reports, when appropriate to research design.
- Transparent reporting of methods, limitations, analytic decisions, and effect sizes.
- Development and use of rigorous standards for causal inference in behavioral and social science research.
- Clear differentiation among reproducibility of analyses, replicability of findings, and robustness across analytic choices, samples, measures, and contexts.
- Use of repeatability as an umbrella term while separately assessing reproducibility, robustness, and

replicability.
- Validated, explainable credibility indicators that assess research features directly rather than relying only on journal prestige, citation counts, or publication status.

2. Data, Software, and Model Sharing: APA recommends that NIH recognize open science practices as meaningful contributions to scientific impact. Sharing data, code, software, research materials, protocols, measures, models, and analytic plans can accelerate discovery, enable independent verification, reduce duplication, and increase the public return on federal research investments.

The Score initiative is one of the largest efforts ever to evaluate the credibility of research findings in social and behavioral science. The project was developed through a DARPA-funded collaboration involving the Center for Open Science, academic researchers, and technology partners. The SCORE program underscores that scientific trustworthiness does not require certainty. It depends on the research enterprise's capacity to reduce uncertainty through credible evidence, transparent critique, and ongoing assessment. Common proxies for credibility, such as peer-reviewed publication, journal prestige, and citation counts are easy to measure but weak indicators of research quality because they do not examine the research itself. According to Nosek, B. A. et al, credibility assessment should instead ask whether the findings deserve serious consideration and whether the evidence is strong enough to guide future research, resource allocation, policy, practice, or translation.

SCORE tested whether human judgements and automated methods could predict replication outcomes and provide explainable assessments. The results show modes of progress but also indicate that neither human nor machine predictions are yet accurate enough to replace replication studies. For NIH, this shows that credibility indicators require sustained investment, validation, transparency, and caution before they are used to guide incentives or decision-making.

According to Nosek, B. A., et al., replicability is only part of a broader credibility landscape that includes transparent peer evaluation, engagement with prior knowledge, bias control, measurement precision and reliability, accountability, and whether research claims are proportionate to the evidence. Emerging modes such as Lifecycle Journal, an open-science scholarly publishing platform designed to evaluate research across the entire research lifecyle, allow multiple independent review services to assess discrete features of credibility, such as code execution, data sharing quality, consistency between research plans and outcomes, reporting standards, and statistical errors. A more diversified assessment system could complement peer review and help researchers, reviewers, policymakers, journalists, and the public evaluate research quality more effectively.

3. Training and Mentorship: APA strongly supports NIH's inclusion of mentorship, training, and team science as dimensions of scientific impact. These activities contribute directly to the integrity, sustainability, and the effectiveness of the biomedical and behavioral research enterprise but are often undervalued in publication-based assessments.

NIH should recognize evidence of effective mentorship, trainee development, inclusive research environments, methodological and ethical training, collaborative leadership, shared infrastructure development, and contributions to large interdisciplinary projects. Evaluation criteria should remain flexible enough to accommodate differences in career stage, institutional context, and research settings.

Psychology-specific research indicators include:
- Development of rigorous methodological and ethical training programs.
- Contributions to building and sustaining the behavioral and social science workforce.
- Successful mentorship of trainees and early-career investigators.

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: Public Impact Should Include Health, Trust, Accessibility, and Community Benefit
APA strongly agrees that scientific impact should ultimately be connected to NIH's mission to generate knowledge that enhances health, lengthens life, and reduces illness and disability. Public impact should be understood broadly to improvements in health outcomes, clinical practice, prevention, education, public policy, community well-being, accessibility of scientific knowledge, and public trust in science.

For psychological and behavioral science, public impact may include validated interventions, improved mental and behavioral health services, better measurement tools, evidence-based prevention strategies, reduced stigma, improved adherence to care, enhanced learning and development, strong community resilience, and more effective health communication. NIH should recognize that translation may occur through clinical guidelines, public health programs, community partnerships, education, workforce training, policy implementation, and dissemination of accessible evidence—not only through commercialization or patents. It often requires sustained engagement, adaptation, partnership, and communication beyond publication.

8. Other Areas: N/A

Description: The complete APA response to RFI.

AMERICAN PSYCHOLOGICAL ASSOCIATION

August 14, 2026

Lyric Jorgenson, PhD
NIH Associate Director for Science Policy
NIH Office of Science Policy
6705 Rockledge Drive
Suite 630, MSC-7985
Bethesda, MD 20892-7985

Re: Request for Information on Measuring and Rewarding Scientific Impact (Notice Number: NOT-OD-26-087)

Via email: SciencePolicy@od.nih.gov

Dear Dr. Jorgenson:

The American Psychological Association (APA) appreciates the opportunity to provide input to the National Institutes of Health (NIH) regarding how scientific impact should be measured, recognized, and incentivized in modern biomedical and behavioral research via the Request for Information (RFI): Measuring and Rewarding Scientific Impact, Notice Number: NOT-OD-26-087. The APA is the nation's largest scientific and professional nonprofit organization representing the discipline and profession of psychology, as well as 190,000 members and affiliates who are clinicians, researchers, educators, consultants, and students in psychological science.

APA welcomes NIH's efforts to update how scientific impact is measured and rewarded. Research assessment should reflect the practices that support credible science, including rigorous methods, transparency, collaboration, mentorship, and public benefit. As behavioral, cognitive, developmental, mental health, and social sciences research continue to inform health and well-being, NIH has an opportunity to reward not only productivity, but quality, credibility, openness, mentorship, collaboration, and real-world value.

Academia's reliance on quantitative indicators, including publication counts, journal impact factors, and citation metrics, creates incentives that can work against research quality. Assessment systems should move from asking how much research is produced to asking how well research is conducted. APA supports NIH's interests in responsible research assessment that prioritizes research quality, rigor, transparency, credibility, and societal value over simple measures of productivity. Psychology has been a leader in developing methods that support this shift. Assessment and incentive systems should recognize contributions that strengthen the credibility and usefulness of science, including transparent reporting, data and code sharing, preregistration where appropriate, replication efforts, methodological

750 First Street, NE
Washington, DC 20002-4242
202.336.5800
202.336.6123 TDD

innovation, team science, and shared research resources. Several initiatives currently exist that aim to address this challenge.

For behavioral and social science research, quality indicators should recognize contributions that improve credibility, reproducibility, and cumulative nature of scientific knowledge, including the development of validated measures, replication studies, open research resources, methodological advances, and efforts that improve research transparency and accessibility. Psychological science has been at the forefront of developing and evaluating approaches to replication, reproducibility, research transparency, and credibility assessment, and these advances demonstrate that scientific quality can be measured in ways that are more closely aligned with NIH's mission than traditional publication-based metrics alone.[1]

Accordingly, APA recommends that NIH take a multidimensional approach to scientific impact that balances traditional indicators, such as publications and citations, with evidence of rigor, reproducibility, responsible data and software sharing, effective training and mentorship, meaningful collaboration, translation, and contributions to public trust. No single metric can capture the full value of scientific work. NIH should therefore avoid replacing one narrow set of incentives with another and instead develop flexible, field sensitive approaches that recognize diverse forms of contributions across career stages, institution types, research methods, and communities served.

Systematizing Confidence in Open Research and Evidence (SCORE) Credibility Assessment

APA recommends that NIH recognize open science practices as meaningful contributions to scientific impact. Sharing data, code, software, research materials, protocols, measures, models, and analytic plans can accelerate discovery, enable independent verification, reduce duplication, and increase the public return on federal research investments.[2]

The Score initiative is one of the largest efforts ever to evaluate the credibility of research findings in social and behavioral science. The project was developed through a DARPA-funded collaboration involving the Center for Open Science, academic researchers, and technology partners. The SCORE program underscores that scientific trustworthiness does not require certainty. It depends on the research enterprise's capacity to reduce uncertainty through credible evidence, transparent critique, and ongoing assessment. Common proxies for credibility, such as peer-reviewed publication, journal prestige, and citation counts are easy to measure but weak indicators of research quality because they do not examine the research itself. According to Nosek, B. A. et al, credibility assessment should instead ask whether the findings deserve serious consideration and whether the evidence is strong enough to guide future research, resource allocation, policy, practice, or translation.[3]

guidance, progress reports, and renewal decisions so that investigators and reviewers understand whether they are assessing reproducibility of analyses, robustness of conclusions across defensible analytic choices, replicability with independent data, or broader credibility and trustworthiness.

APA recommends that NIH invest in the science of credibility assessment itself. Nosek and colleagues' work on replicability, robustness, and reproducibility demonstrates that scientific impact depends not only on producing new findings, but also determining whether findings are reliable, interpretable, reusable, and capable of informing cumulative knowledge. SCORE shows that scalable indicators of replicability, robustness, reproducibility, transparency, and other credibility dimensions must be validated before they are used as incentives. NIH should support research, infrastructure, and pilot programs that test whether proposed indicators are reliable, explainable, field-sensitive, and useful to reviewers and decision-makers. Vazire's work reinforces this point by showing that quality uncertainty erodes trust when consumers of science lack the information needed to evaluate claims, and that the credibility revolution may reduce apparent individual productivity while increasing genuine scientific progress.[8] [9] Policies for measuring and rewarding impact should be evaluated empirically, implemented flexibly, and designed to encourage ongoing scrutiny of whether new metrics actually improve science.

APA recommends that NIH incentivize practices that increase confidence in findings, including well-powered designs, transparent analytic decisions, preregistration where appropriate, clear reporting of methods and limitations, independent replication, and evaluation of whether findings hold across analytic choices, populations, measures, and contexts. These practices are especially important in fields that inform clinical care, public health, education, and policy, where premature or overstated claims have significant downstream consequences, despite the frequent need for rapid decision-making and response.

At the same time, APA encourages NIH to implement rigor and reproducibility indicators in ways that are appropriate. Not all research questions are suited to the same forms of replication or preregistration, and exploratory, qualitative, community-engaged, longitudinal, and observational research may require different standards of transparency and robustness. NIH should support discipline-specific guidance and avoid rigid requirements that could unintentionally discourage innovation, exploratory discovery, and more research with hard-to-reach populations.

APA recommends that NIH incorporate these indicators into grant review, progress reporting, and career advancement mechanisms through narrative contribution statements and portfolio-based assessments that allow investigators to show the significance of their most meaningful work. In psychology and behavioral science, especially valuable contributions include demonstrating that findings replicate across diverse populations and settings, developing culturally valid measures, creating reusable research resources, advancing methods for studying behavior and mental health, and generating evidence that informs clinical practice, prevention, education, workplace well-being, and public policy.

202.336.6123 TDD

The association further recommends that NIH also recognize contributions that strengthen the research enterprise itself, such as leadership in multi-site collaborations, training the next generation of scientists, and advancing open and transparent research practices. Rewarding the practices that produce trustworthy, reproducible, and actionable knowledge would strengthen stewardship of public research investments, accelerate scientific progress, and enhance public trust in biomedical and behavioral research.

Psychology-specific research indicators include:

- Independent replications of influential findings and interventions.
- Evidence that findings are robust across populations, contexts, measures, and analytic approaches.
- Preregistration and registered reports, when appropriate to research design.
- Transparent reporting of methods, limitations, analytic decisions, and effect sizes.
- Development and use of rigorous standards for causal inference in behavioral and social science research.
- Clear differentiation among reproducibility of analyses, replicability of findings, and robustness across analytic choices, samples, measures, and contexts.
- Use of repeatability as an umbrella term while separately assessing reproducibility, robustness, and replicability.
- Validated, explainable credibility indicators that assess research features directly rather than relying only on journal prestige, citation counts, or publication status.

Reward Open, Transparent, and Reusable Research Outputs

APA supports NIH's interest in recognizing open and reusable research outputs as meaningful scientific contributions. Sharing data, code, software, measures, protocols, materials, and analytic workflows increase the value of public research investments by enabling verification, reuse, collaboration, and cumulative knowledge building.

NIH should evaluate both the availability and usability of these resources, including documentation quality, accessibility, responsible governance, and evidence of reuse by others. At the same time, sharing requirements should remain flexible enough to accommodate privacy concerns, Tribal sovereignty, community governance, consent limitations, and other ethical obligations.

Consistent with the Transparency and Openness Promotion (TOP) framework, a set of guidelines developed by the Center for Open Science and a coalition of journal editors, researchers, funders, and scientific organizations to improve transparency, credibility, and reproducibility of research, NIH should adopted a tiered approach that encourages transparency while recognizing the differences across research designs and disciplines. Tiered standards would allow NIH to recognize meaningful progress toward transparency across diverse research designs, including experimental, observational, qualitative, longitudinal, clinical, and community-engaged research. This approach would also help ensure that data, code materials, protocols, and analysis plans are shared when appropriate, while preserving necessary protections for privacy, consent, Tribal sovereignty, community governance, and sensitive human subjects data.

NIH should also treat open research outputs as substantive scholarly contributions. Investigators should be able to document the quality, accessibility, reuse, and scientific value of shared datasets, measures,

APA.ORG

750 First Street, NE
Washington, DC 20002-4242

202.336.5500
202.336.6123 TDD

protocols, software, code, analytic workflows, and other research materials in bio-sketches, progress reports, grant renewals, and career-stage assessments. Recognizing these outputs would align individual incentives with the public value of research that is verifiable, reusable, and cumulative.

Psychology-specific research indicators include:

- Public sharing of validated measures, intervention manuals, study protocols, code, and datasets where appropriate.
- Development of research infrastructure, repositories, and community resources that benefit the field.
- Demonstrated reuse of shared resources by other investigators.
- Use of tiered transparency standards that recognize appropriate sharing of data, code, materials, protocols, analysis plans, and documentation across different research designs.

Value Quality Over Quantity

As noted above, APA recommends that NIH reduce reliance on publication counts, journal prestige, and citation-based indicators when evaluating scientific impact. Although such measures can provide useful contextual information, they should not serve as the only proxy for scientific value.

Assessment systems should instead emphasize the quality, credibility, transparency, rigor, and cumulative contribution of scientific work. Activities such as replication, correction of errors, development of methods and measures, open science practices, development of community resources, and meaningful translation often create substantial scientific value when they do not generate large numbers of publications.

Narrative contributions statements and portfolio-based assessment approaches may provide a more accurate picture of scientific impact by allowing investigators to describe their most significant contributions rather than simply listing outputs.[10]

APA recommends that NIH also protect creativity and foundational exploration while strengthening rigor. Assessment frameworks should recognize exploratory and high-risk research when investigators are transparent about uncertainty, clearly distinguish exploratory from confirmatory analysis, and describe how early-stage findings will be tested, replicated, or refined. This would help avoid a narrow compliance culture in which researchers pursue only low-risk, easily preregistered questions, while still advancing NIH's goals of rigor, reproducibility, and public trust.[11]

NIH should reward research practices that make scientific claims easier to evaluate. Impact indicators should recognize transparent disclosure of study design, measures, sampling decisions, exclusions, analytic flexibility, limitations, and departures from preregistered plans when applicable. These practices would help reviewers, other scientists, policymakers, and the public distinguish well-supported claims from more tentative findings and would strengthen trust in NIH-supported science.[12]

Recognize Mentorship, Training, and Team Science as Scientific Contributions
APA strongly supports NIH's inclusion of mentorship, training, and team science as dimensions of scientific impact. These activities contribute directly to the integrity, sustainability, and the effectiveness of the biomedical and behavioral research enterprise but are often undervalued in publication-based assessments.

NIH should recognize evidence of effective mentorship, trainee development, inclusive research environments, methodological and ethical training, collaborative leadership, shared infrastructure development, and contributions to large interdisciplinary projects. Evaluation criteria should remain flexible enough to accommodate differences in career stage, institutional context, and research settings.[13]

Psychology-specific research indicators include:

- Development of rigorous methodological and ethical training programs.
- Contributions to building and sustaining the behavioral and social science workforce.
- Successful mentorship of trainees and early-career investigators.

Public Impact Should Include Health, Trust, Accessibility, and Community Benefit
APA strongly agrees that scientific impact should ultimately be connected to NIH's mission to generate knowledge that enhances health, lengthens life, and reduces illness and disability. Public impact should be understood broadly to improvements in health outcomes, clinical practice, prevention, education, public policy, community well-being, accessibility of scientific knowledge, and public trust in science.

For psychological and behavioral science, public impact may include validated interventions, improved mental and behavioral health services, better measurement tools, evidence-based prevention strategies, reduced stigma, improved adherence to care, enhanced learning and development, strong community resilience, and more effective health communication. NIH should recognize that translation may occur through clinical guidelines, public health programs, community partnerships, education, workforce training, policy implementation, and dissemination of accessible evidence—not only through commercialization or patents. It often requires sustained engagement, adaptation, partnership, and communication beyond publication.

Implementation Should Minimize Unintended Consequences
APA encourages NIH to implement new impact measures cautiously and evaluate them regularly for unintended consequences. Indicators should be piloted across disciplines, institution types, and career stages before broad adoption. NIH should monitor whether proposed measures improve the assessment of rigor, transparency, and scientific value without creating excessive administrative burden, discouraging innovation, or disadvantaging researchers working in resource-constrained settings or with sensitive data.

[13] Gärtner, A., Leising, D., & Schönbrodt, F. D. (2024). Towards responsible research assessment: How to reward research quality. *PLoS Biology, 22*(2), e3002553. https://doi.org/10.1371/journal.pbio.3002553

APA.ORG
750 First Street, NE
Washington, DC 20002-4242
202.336.5500
202.336.6123 TDD

Successful implementation will require reviewer guidance, stakeholder feedback, and investments in the infrastructure needed to support replication, data stewardship, software maintenance, training, and methodological support.[14]

Recommended Indicators and Incentives
APA urges NIH to elevate rigor, transparency, collaboration, and public impact by operationalizing new incentives through application instructions, review criteria, reviewer guidance, progress reports, renewals, bio-sketches, final reports, and career-stage assessments.

Responsible Research Assessment
- Reduce reliance on publication counts and journal-level metrics.
- Use narrative contributions statements and portfolio-based evaluations emphasizing rigor, transparency, and cumulative value.

Rigor and Credibility
- Reward reproducibility, robustness analyses, replication, transparent reporting, appropriate preregistration, adequate methods and analyses,
- and evidence of generalizability.

Open and Reusable Research
- Recognize sharing of data, code, measures, software, protocols, and research materials, with appropriate privacy and governance protections.

Mentorship and Team Science
- Recognize mentorship quality, trainee and workforce development, methodological and ethical training, inclusive research environments, collaborative leadership, shared infrastructure, and interdisciplinary teamwork.

Innovation and Translation
- Support credible high-risk research and recognize contributions to policy, practice, implementation, and public health impact.

Evaluation and Continuous Improvement
- Pilot, validate, and periodically reassess indicators to ensure they are reliable, fair, field sensitive, and resistant to unintended consequences.

APA commends NIH for seeking input on how to better measure and reward scientific impact. The biomedical and behavioral research enterprise depends on incentives that support credible, transparent, collaborative, and socially beneficial science. By broadening assessment beyond narrow productivity measures and recognizing rigor, reproducibility, openness, mentorship, collaboration, and public benefit, NIH can strengthen the reliability of scientific findings, improve stewardship of public research investments, and reinforce public trust in science. Should you have any questions, please contact Angela L. Sharpe, MG, Senior Director, Congressional & Federal Relations at asharpe@apa.org.

165. American Dental Association

I am responding: On behalf of an organization

Name: David Linn

Name of Organization: American Dental Association

Type of Organization: Professional Organization/Association

Role: Other

Role - Other: Director, Federal Affairs

Date Submitted: 8/14/2026

1. Rigor and Reproducibility: NIH should establish dedicated incentives and funding opportunities for replication and reproducibility, including access to small-grant mechanisms such as R03 awards, supplements, or other limited-duration mechanisms where appropriate, while preserving robust support for R01-scale projects that feature rigorous replication and reproducibility.
Replication studies, pre-registration, transparent reporting of methods and analyses, and publication of well-designed negative or null findings should be recognized as meaningful scientific contributions. NIH could incorporate these activities into appropriate application and progress-report materials and provide reviewers and program staff with guidance for assessing them separately from the production of novel findings.
Recognition should be based on the quality and informativeness of the work rather than the simple presence of a replication label. Funding such rigorous replication projects through a range of award sizes would allow early-career investigators, clinician-scientists, and researchers at dental schools and smaller institutions to participate without requiring the resources or preliminary development associated with a large research project.
A diversified funding structure would increase the efficiency of NIH investments and broaden participation without creating unnecessary competition between replication and discovery. NIH should also ensure that replication incentives do not unintentionally reduce support for exploratory or hypothesis-generating research. Review criteria should distinguish causal conclusions from associational findings based on study design, methodology, and analytic limitations, while recognizing the value of research that appropriately identifies associations warranting further study.

2. Data, Software, and Model Sharing: NIH should recognize persistent identifiers, including dataset and software digital object identifiers and Research Resource Identifiers, as verifiable evidence of contributions to data, software, model, and research-resource sharing, while assessing scientific impact based on the quality, stewardship, adoption, and reuse of those resources rather than on identifiers or usage counts alone.
Investigators should be able to document these contributions in appropriate application, review and progress-report materials alongside publications and other research outputs. NIH should assess not only whether a dataset, model, software tool, or research resource has been shared, but also whether it is adequately documented, accessible, reusable, appropriately curated, and capable of supporting validation, replication, or additional research. Relevant indicators of impact could include independent

scientific reuse, citations or other documented attribution, incorporation into external analyses or resources, adoption by the research community, and evidence that a shared resource has enabled subsequent scientific discoveries.

The Human Oral Microbiome Database (HOMD), developed and sustained at the ADA Forsyth Institute with NIDCR support, provides an example of the long-term scientific value that can result from investing in openly accessible and expertly curated research resources. Since its public launch, HOMD has provided the scientific community with curated taxonomic, genomic, phylogenetic, and bibliographic information and associated bioinformatics resources for microorganisms of the human oral and aerodigestive tract. Its continuing expansion and use across the scientific community illustrate how an NIH-supported research program can produce both new scientific knowledge and a durable shared resource that enables research well beyond the originating institution. NIH should therefore recognize not only the initial act of sharing but also the scientific stewardship required to sustain high-value community resources over time, including expert curation, quality control, annotation, updating, interoperability, documentation, and development of tools that make shared information scientifically useful.

Consistent recognition of these contributions could expand the value of oral health datasets, practice-based research network data, software and other resources beyond the institutions that initially developed them. NIH should, however, account for the technical and administrative burden associated with preparing materials for responsible sharing, particularly for smaller laboratories, clinical practices and community-based research networks. Phased requirements, technical assistance and funding for data management and documentation could improve feasibility and reduce disparities in institutional capacity.

3. Training and Mentorship: NIH should incorporate measurable indicators of mentorship quality and trainee development into the assessment of institutional and individual awards.

Relevant indicators could include trainee retention, scholarly contributions, completion of research or career-development milestones, placement across a range of professional settings, and continued participation in research, teaching, clinical investigation, public health or related scientific activities. These measures should recognize that successful trainees may pursue varied career paths and should not presume that placement in a traditional academic research position is the only evidence of effective mentorship.

NIH should also support cohort-based and cross-disciplinary mentorship programs that develop research, teaching, leadership, and other professional competencies. HRSA's Primary Care Dental Faculty Development Center Program provides one model for supporting the development of junior dental faculty through structured training and institutional collaboration. Similar NIH approaches could help dental schools and academic health centers that may not have enough research-active faculty in a single discipline to sustain a traditional mentorship pipeline.

Implementation should remain flexible. Cross-disciplinary programs should complement, rather than replace, discipline-specific scientific mentorship and should not impose substantial new coordination burdens on faculty or institutions with limited administrative resources.

4. Collaboration: NIH should use standardized contributor-role frameworks, such as the Contributor Roles Taxonomy, to recognize the full range of contributions to interdisciplinary and team-based science. Authorship position alone may not adequately capture the work of biostatisticians, data scientists, clinicians, community partners, research coordinators, software developers and other contributors. NIH

should allow these roles to be documented consistently in appropriate application and reporting materials and should provide clear guidance so their recognition does not depend on the practices of individual reviewers or institutions.
NIH should also ensure that community-based research partners are appropriately involved and resourced. Funding structures should account for the direct and indirect costs attributable to community partners' roles, including staffing, data collection, patient engagement, and administrative responsibilities. Direct funding, subawards or other arrangements may be appropriate when they allow community organizations to participate meaningfully in study design, implementation, interpretation and dissemination rather than serving solely as recruitment or data-collection sites.
To improve feasibility for smaller institutions and early-career investigators, NIH should provide model language, templates and technical assistance for contributor-role documentation and community-partnership agreements.

5. Entrepreneurship and Translation: NIH should recognize a broad range of translational outputs, including patents, licensing agreements, technology-transfer milestones, clinical tools, guidelines, validated measures, implementation models and public-health interventions, while recognizing that commercialization is one of several pathways through which research may achieve translational impact. Patents and licensing activity may provide useful evidence that a discovery is progressing toward application, particularly in fields such as dental devices, diagnostics, and biomaterials. These indicators should not, however, be treated as the sole or preferred measure of translation. Many important research outputs advance clinical care or public health without resulting in a commercial product, while other discoveries may require appropriate intellectual-property protection to support further development and enable convergence to eventual translation.
NIH should allow investigators to document commercial and noncommercial translational milestones using appropriate, verifiable materials. Review guidance should also account for differences in institutional scale, infrastructure, and access to technology-transfer and commercialization resources, so that investigators are evaluated on the significance and progress of their translational work rather than on the size of the institutional support structure available to them. Small, independent research institutes such as the ADA Forsyth Institute demonstrate that relatively small institutions without an affiliated medical center can nevertheless achieve excellence across the continuum from foundational discovery to translational research and should not be disadvantaged by impact measures that implicitly favor the infrastructure of large academic health centers.
NIH should further guard against incentives that could encourage unnecessary proprietary restrictions on data, methods, or research materials. Measures of entrepreneurial impact should be balanced with NIH's goals for transparency, validation, and responsible sharing. Evaluation should recognize that intellectual property protection and research sharing can serve complementary purposes and should avoid creating incentives either to restrict research resources unnecessarily or to discourage appropriate protection of discoveries needed for successful development and translation.

6. Foundational Scientific Exploration: NIH should protect support for foundational, high-risk, and high-reward research and assess its impact using criteria appropriate to the scientific question, stage of discovery, and time required for important advances to emerge.
Foundational research should not be disadvantaged because it lacks an immediate clinical, commercial or economic application. NIH should recognize rigorous methods, the development of new scientific concepts or tools, as well as the generation of important negative findings that are derived from well-

designed, appropriately controlled, carefully executed, and adequately powered studies. Rigorous investigation that lead to the resolution of significant scientific uncertainties, and the opening of productive new lines of inquiry are meaningful forms of progress that should be supported.
These questions should be investigated using study designs and analytical approaches appropriate to the claims being tested, without presuming causation or effects that have not been firmly established. Their scientific value may include determining the strength and consistency of observed associations, identifying plausible mechanisms, defining populations in which effects may differ, and generating the evidence needed to inform larger prospective, mechanistic, or interventional studies where appropriate.
NIH should also encourage cross-institute and multidisciplinary research examining potential relationships among oral health interventions, oral disease burden, systemic health outcomes, health care utilization, and quality of life. Such research could include studies evaluating oral hygiene interventions and respiratory outcomes or examining how visual, motor, or other functional limitations affect oral disease burden and access to care.
Their value lies in determining whether relationships exist, identifying relevant mechanisms and establishing the evidence needed to guide clinical care and health-system decision-making. Clear, field-appropriate evaluation standards would help preserve accountability without imposing conventional short-term productivity expectations on research whose impact may take years to emerge.

7. Public Impact: NIH should develop standardized field-appropriate measures of public impact that recognize contributions to clinical practice, health outcomes, public policy, accessibility, public trust and community benefit, where such outcomes are relevant to the scientific aims and stage of research. Potential indicators could include citations in clinical guidelines or public policy, adoption of validated clinical or public-health tools, incorporation of findings into care-delivery models, meaningful community engagement and measurable effects on patient or population outcomes. These indicators should supplement, rather than replace, rigorous scientific assessment and should not be applied in ways that disadvantage foundational, mechanistic, exploratory, or early-stage research for which downstream public impact may not yet be measurable by current methods within the timeframe of the research.
For oral health research, NIH should consider validated patient-reported and health-outcome measures, including the Oral Health Impact Profile where appropriate, as potential secondary endpoints in studies that are not primarily dental. Procedure-based measures remain important, but may not independently capture quality of life, functional status, prevention, access or the effects of interventions that are not themselves dental procedures.
Because nonbibliometric measures may be more difficult to standardize and verify, NIH should develop clear definitions, documentation requirements, and review rubrics. These safeguards would reduce inconsistent application across institutes and discourage superficial activities undertaken solely to satisfy an impact metric.

Re: Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Dear NIH Office of Science Policy:

As the leading authority on oral health in the United States, the American Dental Association (ADA) appreciates the opportunity to comment on NIH Notice NOT-OD-26-087, "Request for Information on Measuring and Rewarding Scientific Impact."

Dental, oral and craniofacial research is an integral part of the biomedical research enterprise. It encompasses foundational, clinical, behavioral, translational and population-based research and contributes to the development of evidence-based prevention and treatment, improved health outcomes and a better understanding of the relationship between oral health and overall health. NIH policies governing how scientific impact is measured and rewarded directly affect dental schools, academic health centers, community-based research partners, clinician-scientists and interdisciplinary research teams.

The ADA supports broadening the assessment of scientific impact beyond publication counts and citation metrics. At the same time, NIH should avoid replacing one overly narrow set of measures with another. New indicators should be transparent, verifiable, appropriate to the relevant field and research stage, and feasible for investigators and institutions with differing missions and resources. They should also recognize that scientific impact may emerge over different timelines and through different outputs, including replication, data and resource sharing, mentorship, collaboration, clinical translation and public benefit.

Rigor and Reproducibility

NIH should establish dedicated incentives and funding opportunities for replication and reproducibility, including access to small-grant mechanisms such as R03 awards, supplements, or other limited-duration mechanisms where appropriate, while preserving robust support for R01-scale projects that feature rigorous replication and reproducibility.

Replication studies, pre-registration, transparent reporting of methods and analyses, and publication of well-designed negative or null findings should be recognized as meaningful scientific contributions. NIH could incorporate these activities into appropriate application and

progress-report materials and provide reviewers and program staff with guidance for assessing them separately from the production of novel findings.

Recognition should be based on the quality and informativeness of the work rather than the simple presence of a replication label. Funding such rigorous replication projects through a range of award sizes would allow early-career investigators, clinician-scientists, and researchers at dental schools and smaller institutions to participate without requiring the resources or preliminary development associated with a large research project.

A diversified funding structure would increase the efficiency of NIH investments and broaden participation without creating unnecessary competition between replication and discovery. NIH should also ensure that replication incentives do not unintentionally reduce support for exploratory or hypothesis-generating research. Review criteria should distinguish causal conclusions from associational findings based on study design, methodology, and analytic limitations, while recognizing the value of research that appropriately identifies associations warranting further study.

Sharing Data, Software, and Models

NIH should recognize persistent identifiers, including dataset and software digital object identifiers and Research Resource Identifiers, as verifiable evidence of contributions to data, software, model, and research-resource sharing, while assessing scientific impact based on the quality, stewardship, adoption, and reuse of those resources rather than on identifiers or usage counts alone.

Investigators should be able to document these contributions in appropriate application, review and progress-report materials alongside publications and other research outputs. NIH should assess not only whether a dataset, model, software tool, or research resource has been shared, but also whether it is adequately documented, accessible, reusable, appropriately curated, and capable of supporting validation, replication, or additional research. Relevant indicators of impact could include independent scientific reuse, citations or other documented attribution, incorporation into external analyses or resources, adoption by the research community, and evidence that a shared resource has enabled subsequent scientific discoveries.

The Human Oral Microbiome Database (HOMD), developed and sustained at the ADA Forsyth Institute with NIDCR support, provides an example of the long-term scientific value that can result from investing in openly accessible and expertly curated research resources. Since its public launch, HOMD has provided the scientific community with curated taxonomic, genomic, phylogenetic, and bibliographic information and associated bioinformatics resources for microorganisms of the human oral and aerodigestive tract. Its continuing expansion and use across the scientific community illustrate how an NIH-supported research program can produce both new scientific knowledge and a durable shared resource that enables research well beyond the originating institution. NIH should therefore recognize not only the initial act of sharing but also the scientific stewardship required to sustain high-value community resources over time, including expert curation, quality control, annotation, updating, interoperability, documentation, and development of tools that make shared information scientifically useful.

Consistent recognition of these contributions could expand the value of oral health datasets, practice-based research network data, software and other resources beyond the institutions that initially developed them. NIH should, however, account for the technical and administrative burden associated with preparing materials for responsible sharing, particularly for smaller laboratories, clinical practices and community-based research networks. Phased requirements, technical assistance and funding for data management and documentation could improve feasibility and reduce disparities in institutional capacity.

Training and Mentorship

NIH should incorporate measurable indicators of mentorship quality and trainee development into the assessment of institutional and individual awards.

Relevant indicators could include trainee retention, scholarly contributions, completion of research or career-development milestones, placement across a range of professional settings, and continued participation in research, teaching, clinical investigation, public health or related scientific activities. These measures should recognize that successful trainees may pursue varied career paths and should not presume that placement in a traditional academic research position is the only evidence of effective mentorship.

NIH should also support cohort-based and cross-disciplinary mentorship programs that develop research, teaching, leadership, and other professional competencies. HRSA's Primary Care Dental Faculty Development Center Program provides one model for supporting the development of junior dental faculty through structured training and institutional collaboration. Similar NIH approaches could help dental schools and academic health centers that may not have enough research-active faculty in a single discipline to sustain a traditional mentorship pipeline.

Implementation should remain flexible. Cross-disciplinary programs should complement, rather than replace, discipline-specific scientific mentorship and should not impose substantial new coordination burdens on faculty or institutions with limited administrative resources.

Collaboration

NIH should use standardized contributor-role frameworks, such as the Contributor Roles Taxonomy, to recognize the full range of contributions to interdisciplinary and team-based science.

Authorship position alone may not adequately capture the work of biostatisticians, data scientists, clinicians, community partners, research coordinators, software developers and other contributors. NIH should allow these roles to be documented consistently in appropriate application and reporting materials and should provide clear guidance so their recognition does not depend on the practices of individual reviewers or institutions.

NIH should also ensure that community-based research partners are appropriately involved and resourced. Funding structures should account for the direct and indirect costs attributable to community partners' roles, including staffing, data collection, patient engagement, and

administrative responsibilities. Direct funding, subawards or other arrangements may be appropriate when they allow community organizations to participate meaningfully in study design, implementation, interpretation and dissemination rather than serving solely as recruitment or data-collection sites.

To improve feasibility for smaller institutions and early-career investigators, NIH should provide model language, templates and technical assistance for contributor-role documentation and community-partnership agreements.

Entrepreneurship and Translation

NIH should recognize a broad range of translational outputs, including patents, licensing agreements, technology-transfer milestones, clinical tools, guidelines, validated measures, implementation models and public-health interventions, while recognizing that commercialization is one of several pathways through which research may achieve translational impact.

Patents and licensing activity may provide useful evidence that a discovery is progressing toward application, particularly in fields such as dental devices, diagnostics, and biomaterials. These indicators should not, however, be treated as the sole or preferred measure of translation. Many important research outputs advance clinical care or public health without resulting in a commercial product, while other discoveries may require appropriate intellectual-property protection to support further development and enable convergence to eventual translation.

NIH should allow investigators to document commercial and noncommercial translational milestones using appropriate, verifiable materials. Review guidance should also account for differences in institutional scale, infrastructure, and access to technology-transfer and commercialization resources, so that investigators are evaluated on the significance and progress of their translational work rather than on the size of the institutional support structure available to them. Small, independent research institutes such as the ADA Forsyth Institute demonstrate that relatively small institutions without an affiliated medical center can nevertheless achieve excellence across the continuum from foundational discovery to translational research and should not be disadvantaged by impact measures that implicitly favor the infrastructure of large academic health centers.

NIH should further guard against incentives that could encourage unnecessary proprietary restrictions on data, methods, or research materials. Measures of entrepreneurial impact should be balanced with NIH's goals for transparency, validation, and responsible sharing. Evaluation should recognize that intellectual property protection and research sharing can serve complementary purposes and should avoid creating incentives either to restrict research resources unnecessarily or to discourage appropriate protection of discoveries needed for successful development and translation.

Foundational Scientific Exploration

NIH should protect support for foundational, high-risk, and high-reward research and assess its impact using criteria appropriate to the scientific question, stage of discovery, and time required for important advances to emerge.

Foundational research should not be disadvantaged because it lacks an immediate clinical, commercial or economic application. NIH should recognize rigorous methods, the development of new scientific concepts or tools, as well as the generation of important negative findings that are derived from well-designed, appropriately controlled, carefully executed, and adequately powered studies. Rigorous investigation that lead to the resolution of significant scientific uncertainties, and the opening of productive new lines of inquiry are meaningful forms of progress that should be supported.

These questions should be investigated using study designs and analytical approaches appropriate to the claims being tested, without presuming causation or effects that have not been firmly established. Their scientific value may include determining the strength and consistency of observed associations, identifying plausible mechanisms, defining populations in which effects may differ, and generating the evidence needed to inform larger prospective, mechanistic, or interventional studies where appropriate.

NIH should also encourage cross-institute and multidisciplinary research examining potential relationships among oral health interventions, oral disease burden, systemic health outcomes, health care utilization, and quality of life. Such research could include studies evaluating oral hygiene interventions and respiratory outcomes or examining how visual, motor, or other functional limitations affect oral disease burden and access to care.

Their value lies in determining whether relationships exist, identifying relevant mechanisms and establishing the evidence needed to guide clinical care and health-system decision-making. Clear, field-appropriate evaluation standards would help preserve accountability without imposing conventional short-term productivity expectations on research whose impact may take years to emerge.

Public Impact

NIH should develop standardized field-appropriate measures of public impact that recognize contributions to clinical practice, health outcomes, public policy, accessibility, public trust and community benefit, where such outcomes are relevant to the scientific aims and stage of research.

Potential indicators could include citations in clinical guidelines or public policy, adoption of validated clinical or public-health tools, incorporation of findings into care-delivery models, meaningful community engagement and measurable effects on patient or population outcomes. These indicators should supplement, rather than replace, rigorous scientific assessment and should not be applied in ways that disadvantage foundational, mechanistic, exploratory, or early-stage research for which downstream public impact may not yet be measurable by current methods within the timeframe of the research.

For oral health research, NIH should consider validated patient-reported and health-outcome measures, including the Oral Health Impact Profile where appropriate, as potential secondary endpoints in studies that are not primarily dental. Procedure-based measures remain important,

but may not independently capture quality of life, functional status, prevention, access or the effects of interventions that are not themselves dental procedures.

Because no bibliometric measures may be more difficult to standardize and verify, NIH should develop clear definitions, documentation requirements, and review rubrics. These safeguards would reduce inconsistent application across institutes and discourage superficial activities undertaken solely to satisfy an impact metric.

****

The ADA appreciates NIH's efforts to develop measures that better reflect the collaborative, rigorous, and mission-driven nature of modern biomedical science. A balanced framework should recognize varied forms of scientific contribution while remaining feasible across career stages, disciplines, and institution types. The ADA welcomes continued engagement with NIH as it develops and implements these measures.

For questions regarding these comments, please contact Jorge E. Rojas, DDS, MDS, Director of Scientific Affairs, at rojasj@ada.org.

Sincerely,

/s/

Richard J. Rosato, D.M.D.
President

3. Training and Mentorship: I encourage NIH to think expansively about "training and mentorship" to include undergraduate research mentorship specifically, not just formally funded trainees (T32s, F-mechanisms, postdocs). My lab runs on a substantial undergraduate research assistant program — students commit meaningful weekly hours across a full academic term, and take on real scientific responsibilities: stimulus design, data collection, data analysis, and increasingly, contributions to manuscript preparation and shared code repositories. This work is currently almost entirely invisible to NIH's own measures of a PI's impact, despite representing a substantial and sustained investment in workforce development.

A useful model to consider may be NSF's Broader Impacts criterion, which formally evaluates a "how does this advance training" component alongside intellectual merit. NIH has no close equivalent — training impact shows up informally in biosketches at best, and isn't a scored review criterion. Concrete possibilities:

- A dedicated, actually-scored training narrative in RPPRs and renewal applications, rather than a largely pro forma section
- Counting undergraduate-authored outputs (posters, papers, code contributions) as legitimate PI-level training impact, distinct from — but connected to — the PI's own publication record

4. Collaboration: Pure quantitative counts — publication counts, citation rates, author position — miss important nuance about how contributions to collaborative science actually happen. As the junior half of a co-PI lab, I've experienced firsthand how my contributions can be undervalued when credit is assumed to be due to the senior person. Substantial intellectual and technical work often doesn't map cleanly onto first-authorship or grant-PI-count.

Some recent changes have helped. Preprints now counting toward productivity, and the cultural shift toward citing open datasets as first-class scholarly contributions, both better reflect where real effort goes. Building on that momentum, I'd encourage NIH to consider:

- Formalizing contribution statements (e.g., CRediT taxonomy) as a recognized, review-relevant part of the biosketch or progress report, rather than leaving them buried in journal front-matter where they aren't weighted in funding decisions. This would let a junior collaborator document "I led the analysis pipeline" or "I co-designed the shared paradigm" as a citable, evaluable contribution distinct from authorship order.
- Recognizing MPI/Co-PI leadership explicitly, not just PI-count, in career-stage criteria (e.g., Early Stage Investigator status, K-award eligibility) — the current framing can implicitly penalize junior faculty who choose collaborative, multi-PI structures over solo R01s early in their careers.

1. Rigor and Reproducibility: As a regular and diligent reviewer for NIH, I have seen large discrepancies in how the rigor of grants is assessed and graded by reviewers. Merit measured by publishing in high impact journals does not reward rigorous and well controlled research as splash and reputation is prioritized over rigor and controls and a balanced presentation of ALL of the results. Of course, publishing in lower impact journals does not ensure rigor either! Clear and specific standards are needed for how reviewers (and grant writers) should apply standards for replication, statistical analysis, and critical controls to preliminary data and proposed studies. There need to be very specific standards regarding expectations for specific kinds of experiments, not just broad and general statements about rigor and reproducibility that are interpreted very differently by different people. This is also a problem for publications, work that is not rigorous is published even in the "best" journals. From personal experience I can attest that critical controls are often missing, and statistical practices can be suspect, but if the author has sufficient prestige, the work gets published in science, nature, and cell even when these things are pointed out to the editors during review. No wonder there is a replication problem! On the other hand, reviewers for these journals can make dogmatic but factually incorrect statements without editorial pushback at these journals. Who better than NIH to take the lead in providing clear standards for rigor and replication when performing specific kinds of experiments, incorporating feedback from and fostering open discussions within the scientific community? This kind of guidance would also help shape grant budgets to allow rigor and replication and pilot studies to be appropriately planned for and funded.

2. Data, Software, and Model Sharing: current rules for data sharing (e.g. providing ALL primary data in public repositories) is very burdensome without sufficient benefit to justify the effort. Sharing of large datasets in ways that allow reanalysis by others make sense, but putting all pieces of every kind of data in a repository does not make sense and is not likely to be accurately or sufficiently annotated anyway. Sharing large datasets, software, animal models, cell models, and plasmids (or similar reagents) is CRITICAL and should be REQUIRED (many people do not share models and reagents at present and there is no cost to them for not sharing). Asking researchers to place ALL data in a repository is a waste of resources. Make them deposit plasmids and models and cell lines so people can reproduce their work and evaluate these reagents independently makes more sense. This would need a mechanism for enforcement, or at least an incentive mechanism, or people will continue to fail to make these reagents widely available to others. There is no mechanism to report an ignored request to share reagents from NIH funded research or consequence for doing so.

3. Training and Mentorship: The incentive system currently does not fairly reward those who invest time and effort in mentoring and training. How good mentoring is assessed and rewarded definitely needs discussion. There is not an easy answer for how to do this. it is also a problem that people at undergraduate institutions who have significant teaching commitments have their research productivity directly compared to people at medical schools or institutes where significant teaching is not required. This is not a fair comparison for impact on the scientific enterprise. Good teachers make good researchers, but good teaching also takes a lot of time and effort.

4. Collaboration: The policy considering capping the number of grants an investigator can participate in is BAD for collaborations and misses the point. Any restriction should be based on funding $$. Furthermore, NIH should take into account the increased cost of paying personnel and buying supplies over the last 10 years when setting limits on funding. Team science should not just be a bunch of "famous" scientists at "prestige" universities - teams of people from diverse backgrounds who work together, particularly at the same university, can bring humility and collegiality to a collaboration that allows truly new ideas to incubate and develop. Some products of these collaborations will be publications, but it can take a very long time for these collaborations to advance health - publications (number of impact factor) should not be the only metric as they do not reflect the decades it can take to make an idea benefit health (see comments under Entrepreneurship and Translation) and the many years it takes to accumulate citations.

5. Entrepreneurship and Translation: The paper about modified RNA bases that provided a foundation for the development of the COVID vaccine was rejected from Nature. Dr. Kariko (Nobel laureate!) never had an NIH grant of her own! Something is wrong here. The grant system needs a separate track for innovative grants beyond the DP1 - innovation can take a long slog and really SHOULD require preliminary data and the "outstanding track record" part is not rational. It takes years of dedication and diligent work to go bench to bedside - the COVID vaccine science story should shape how you think about funding innovative work and innovative scientists who are not already famous. Moreover, keeping work patentable/developable is not always compatible with publication and this is not recognized. Entrepreneurship is tremendous work, and often fails at first - so what is strong track record really? A commitment to innovation and entrepreneurship is not appropriately recognized and rewarded with the present review structure. Translational research that could benefit patients is reviewed by people who simply do not understand this process - SBIR review is a mess (I have been on both ends), and the entrepreneurial process is too difficult to participate in while maintaining an academic appointment.

6. Foundational Scientific Exploration: you need to change the peer review system if you want to fund innovative research. The reviewers often lack entrepreneurial experience and/or are not diligent in their assessment of grants - there is little reward for participating in peer review and no cost for failing to participate or serving but failing to provide diligent, accurate, EVIDENCE BASED reviews. Funding famous people to do innovative work with no preliminary data and very large budgets is not a good strategy (DP1). Neither is funding people with many publications in journals that do not require rigor. R21 awards are too small and too short to do the work that is needed to open new areas of investigation. The target researchers and key features of the DP1 (giving large amount of money to researchers that publish in science, nature, and cell without preliminary data needed) is not a foundation that supports the reality of new therapeutic advances with truly new ideas at their root. I think you need a realistic entrepreneurial track award path focused on translational science from everyone and everywhere, not just the prestige crowd, that is founded on preliminary data and that assesses the risk reward balance

more accurately and with more weight on REWARD. Innovation to market takes DECADES in biology, and funding people based on a "track record of success" simply does not make sense.

7. Public Impact: You need stakeholders - the public - to have a say in NIH's broad goals and priorities. The American Cancer Society and CDMRP involves stakeholders in review, the NIH should too. This could potentially help the public understand and appreciate science more as well. Science that addresses the most important unmet needs to be prioritized for the limited funding available while scientists clearly need to assess if the approach is sound. A 2-3 sentence narrative statement is not an effective way to make researchers accountable for taxpayer priorities being considered in research.

1. Rigor and Reproducibility: Create an NIH non-profit electronic journal explicitly to publish reproducibility findings. Include short format micropublications and longer formats as well. This could be an excellent venue to support rigor and reproducibility while also supporting training and publications from faculty at resource limited institutions. For example, an undergraduate or junior graduate student could do a reproducibility study on an important experiment as part of their training/foundational work on their thesis. If this was a small publishable unit at the NIH Journal for RIGOR and Reproducibility, they could learn about the data standards for publication, and how to author a small publication, and they and their mentor would generate citable, valuable (but likely not high impact) work. This kind of work is important for the community and could be valuable to these participants but is likely not going to be taken on by large labs at the edge of their fields; but it could also provide a check on those labs that are leading their fields.

2. Data, Software, and Model Sharing: Provide federally funding, secure, open-access databases for these data, and work with ORCID to provide a way of tracking dataset deposition to facilitate it becoming a productivity and impact metric since the goal it to reward the creation and sharing of these datasets.

3. Training and Mentorship: I am the PI of a lab in a department that awards MS and BS degrees. I do not have access to PhD students or Postdocs. The bulk of my research effort is in training individuals that can only conduct research for 10-20 hours per week. Many of these people join my group having read less than 10 scientific papers in their career to date. I have placed 6 into biomedical/technical manufacturing, 8 into health related doctoral programs, 10 into biomedical MS degrees, and 7 into R1 PhD programs since I joined the faculty in 2018. An additional 8 are still working on applications to graduate or professional programs. I would like to believe that this is valuable work at the base of the biomedical workforce pipeline. I am able to report these outcomes at my institutional level, and I do report in my RPPR each year about trainee outcomes and contributions, but to my knowledge, that is it. This is considerable, and I would argue valuable, work. Maybe there could be a "trainee tracker" program and PI's could get a mentor score component based on the outcomes of their trainees. This could be algorithmically integrated with ORCID with users needing to add a field for the name of their undergraduate, MS, PhD and PostDoc mentors, for example. Maybe?

4. Collaboration: Make more awards that are specifically for research teams with multiple Co-Is

5. Entrepreneurship and Translation: I think the bottleneck between IP ownership by academic institutions and private companies is most of the bottleneck, and so focusing efforts to smooth that out, as well as increased trainings on how to navigate it, might make it more accessible. Many people don't want to bother because it is typically very time consuming, difficult, and prone to failure at late stages.

6. Foundational Scientific Exploration: Make more funding available for basic and lower model organism research; potentially consider specific categories earmarked for that. Stop creating narratives that only translational and clinical work is fundable. Promote basic findings more and have a stronger media presence valorizing and contextualizing basic work to increase public trust. Make social media shorts reflecting on how, for example, basic work in understanding how a fruit fly eye forms was critical to understanding EGFR signaling, which empowers our breakthroughs in cancer research today. Often times the value of basic work takes time to fully be clear, so retrospective "connections" type videos could be really great on social media: How can studying a fruit fly eye help cure cancer? How does watching a worm develop unlock the secrets of cell death? How does studying bacterial immune systems lead to a personalized genome editing cure for sickle cell anemia?
There are so many options and I think if it was well done it could be a great way to increase public trust in science.

7. Public Impact: Promote basic findings more and have a stronger media presence valorizing and contextualizing basic work to increase public trust. Make social media shorts reflecting on how, for example, basic work in understanding how a fruit fly eye forms was critical to understanding EGFR signaling, which empowers our breakthroughs in cancer research today. Often times the value of basic work takes time to fully be clear, so retrospective "connections" type videos could be really great on social media: How can studying a fruit fly eye help cure cancer? How does watching a worm develop unlock the secrets of cell death? How does studying bacterial immune systems lead to a personalized genome editing cure for sickle cell anemia?
There are so many options and I think if it was well done it could be a great way to increase public trust in science.

169. Good Science Project

I am responding: On behalf of an organization

Name: Stuart Buck

Name of Organization: Good Science Project

Type of Organization: Non-Profit Research Organization

Role: Investigator/Researcher

Date Submitted: 8/14/2026

1. Rigor and Reproducibility: The NIH Director's Office should put serious resources from the Common Fund (e.g., at least $100m a year) into large-scale replication efforts. These can take a number of forms:

1) Randomly sampling across some field, domain, or IC, so as to provide systematic and representative evidence on the rate of replicability in that area.

2) Sampling from the most highly-funded and/or highly-cited scientists, so as to see the rate of replicability as to labs that are getting the most money and attention.

3) Sampling from some high-impact disease area that has stalled (e.g., Alzheimer's), so as to help us tell whether the replication problem is part of the reason for the lack of progress.

All three forms of sampling make sense, and should be pursued in parallel.

As well, due to the length of time it takes to perform the normal peer review process at NIH, plus the length of time it takes to set up replication experiments, we highly recommend that NIH use OTA contracts to engage with outside organizations, such as the Center for Open Science (COS). COS led a huge DARPA contract that performed the most extensive replication effort in the world to date, involving 865 researchers and resulting in 9 papers as a collection in Nature: https://www.cos.io/score They could spin up an NIH replication project quickly and could start showing impact soon.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: High-risk, high-reward science is something of a misnomer. Many scientific breakthroughs come not from doing anything that was identified as "high risk" ahead of time, but from exploring areas thought to be irrelevant--such as mRNA research in the 1990s, or the early CRISPR research on archaebacteria, or the early research on taq polymerase by Thomas Brock, or Hamilton Smith's early research on restriction enzymes.

If we want to encourage more breakthroughs, we need a system that tolerates a little more curiosity-driven research in obscure bacteria, non-model organisms, botanical specimens, and more.
Moreover, we need to systematically reward scientists who are honest about failures and null results. Specifically, NIH should either require scientists to publish failures and null results on a regular basis, or should give an extra "thumb on the scale" in reviewing future grant applications if the scientist has published failures and null results.
Nobel winner Robert Lefkowitz has said, "Science is 99 percent failure, and that's an optimistic view." https://today.duke.edu/2012/11/lefkowitzdukeidea Any scientist who is actually pushing the frontier of human knowledge cannot truthfully claim a record of 100% success as to every experiment, every idea, etc. When scientists are discouraged from talking openly about failure, that leads to many systematic inefficiencies: 1) the rest of the field doesn't have a chance to learn about dead ends, mistakes, etc.; 2) scientists are incentivized to study marginal questions where they already have a high chance of getting positive results; and 3) scientists are incentivized to exaggerate or p-hack their results to avoid failures.

7. Public Impact: N/A

8. Other Areas: N/A

Date Submitted: 8/14/2026

1. Rigor and Reproducibility: N/A

2. Data, Software, and Model Sharing: In considering approaches to incentivize and reward data, software, and model sharing, NIH could recognize contributions across the research product lifecycle, including responsible and timely sharing; fitness for reuse; discoverability, accessibility, and interoperability; independent reuse; and downstream scientific impact. Indicators and incentives could reflect contributions across this continuum while accounting for differences in disciplines, data types, research products, and research communities.

Potential indicators

Examples of measurable indicators that could be considered include:

Responsible and timely sharing: Whether data, software, and models are shared through appropriate repositories or other mechanisms and within timeframes appropriate to the research context. Observable indicators could include use of appropriate repositories, assignment of persistent identifiers, timing of release, and documentation of access conditions. Measures should recognize legitimate restrictions related to participant privacy and consent, security, and other applicable ethical, legal, or governance considerations. Controlled access or other appropriate sharing mechanisms should not be interpreted as a lack of sharing when open access is not appropriate.

Fitness for reuse: Whether shared research products contain sufficient information and documentation for others to understand, evaluate, and appropriately reuse them. Observable indicators could include the presence and completeness of metadata, data dictionaries, provenance and processing documentation, quality-control information, software or model version information, and clear terms of reuse. For software, models, and computational workflows, relevant evidence could also include documentation sufficient for use or implementation and information necessary to reproduce or extend the resource. Where appropriate, alignment with relevant community standards and FAIR principles could provide additional evidence of fitness for reuse.

Discoverability, accessibility, and interoperability: Whether research products can be found,

appropriately accessed, and integrated by the intended research community. Observable indicators could include indexing in relevant catalogs or search systems, availability through appropriate access mechanisms, and use of community standards, formats, terminologies, common data elements, or computational interfaces that facilitate integration with other research products.

Independent reuse: Evidence that data, software, or models are used beyond the originating project or team, regardless of whether that use has yet resulted in a subsequent scientific output. Observable indicators could include documented use in independent research studies, application to new research questions, integration with other datasets, use in secondary or validation analyses, or incorporation into new analytic workflows, software, or models.

Downstream scientific impact: Evidence that sharing and reuse contribute to subsequent scientific outputs, findings, methods, or applications. Indicators could include citations or other attribution in publications and research products; derived datasets; new software, models, methods, or workflows; subsequent research building on the shared resource; or documented instances in which reuse contributed to new findings or applications.

NIH's ongoing Data Sharing Index (S-index) initiative offers an opportunity to test and evaluate several of these concepts in practice. The S-index Challenge considers factors including FAIR practices, timeliness, completeness of annotation, subsequent data use, and related scientific outputs, which align with several of the indicators described above. Lessons from this initiative could inform how indicators are applied across research contexts and how they might be used to recognize and incentivize high-quality data sharing.

These indicators capture related but distinct dimensions of scientific contribution. Investigators can control the quality and timeliness of their sharing practices but have less control over whether or when others reuse their work. Independent reuse and downstream impact, in turn, may provide additional evidence of scientific value. Considering these dimensions together could provide a more complete picture of the scientific contribution of sharing.

It may also be useful to distinguish compliance with applicable sharing requirements from indicators of scientific contribution or impact. While compliance is essential, incentives could additionally recognize practices that increase the usability, interoperability, and scientific value of shared research products.

Potential approaches to incentivize and recognize contributions

Recognize shared research products as scientific contributions. NIH could consider mechanisms that allow investigators and teams to identify significant datasets, software, models, workflows, and other shared research products in applications and relevant reporting mechanisms. Information about an individual's or team's role in developing, curating, documenting, maintaining, or sharing these products, together with available evidence of their use or impact, could complement traditional publication-based measures of scientific contribution.

Strengthen attribution of shared research products and their reuse. Consistent citation practices,

persistent identifiers, and standardized attribution mechanisms could make it easier to connect research products to their creators and contributors and to subsequent research that uses them. Where feasible, automated capture of attribution and reuse information from repositories and other research systems could improve recognition while minimizing additional reporting burden.

Incentivize reuse as well as sharing. Recognition of rigorous reuse of existing research products could complement incentives for original investigators to make their work reusable. Relevant activities could include secondary analysis, data integration, validation and replication studies, development or evaluation of models, or enhancement of existing resources through curation, annotation, or harmonization.

Recognize stewardship and sustainability. High-value data resources, software, models, and computational tools may require ongoing curation, maintenance, documentation, harmonization, security updates, or user support to remain scientifically useful. NIH could consider ways to recognize these activities as substantive scientific contributions and, where appropriate, support the personnel and infrastructure necessary to sustain valuable shared resources.

Potential benefits and considerations for implementation

A multidimensional approach could provide a more complete picture of the scientific value of sharing by recognizing both the quality and usability of shared research products and evidence that they enable subsequent research, collaboration, and discovery. It could also provide greater recognition for scientific and technical contributions that may not be fully reflected in publication- and citation-based measures.

Care should be taken to avoid over-reliance on easily quantified measures such as numbers of datasets deposited, downloads, users, API calls, citations, or software activity. These measures may provide useful contextual information but do not necessarily indicate meaningful scientific use or impact. For example, a highly specialized resource may have relatively few users but enable an important scientific advance, while a widely accessed resource may not necessarily result in substantive reuse.

Measures should also account for differences across disciplines, research products, career stages, institutions, and the sensitivity or maturity of the resource. Appropriate controlled-access sharing should be recognized alongside open sharing, and investigators should not be disadvantaged when ethical, legal, privacy, security, consent, or governance considerations appropriately limit access.

Where possible, multiple indicators could be considered alongside qualitative information about the nature and significance of a contribution. A context-sensitive approach could help incentivize and recognize the quality, reuse, sustainability, and scientific impact of shared research products without reducing these contributions to a single metric or score or creating unnecessary administrative burden.

171. University of New Mexico Health Sciences

I am responding: On behalf of an organization

Name: Stacy Catanach

Name of Organization: University of New Mexico Health Sciences

Type of Organization: Not Applicable

Role: Organizational Official

Date Submitted: 8/14/2026

1. Rigor and Reproducibility: UNM HSC Research Administration supports NIH's continued emphasis on rigor, reproducibility, transparency, and replication as essential components of high-quality biomedical research. Recognition of researchers who undertake replication studies, develop reproducible methodologies, transparently report results, and contribute to validation of scientific findings could strengthen the research enterprise and encourage activities that may not be adequately recognized through traditional publication and citation metrics.

Potential indicators could include completion and dissemination of replication or validation studies; use of transparent and well-documented research methods; preregistration when appropriate to the discipline; availability of protocols, analytic methods, and supporting documentation; and demonstrated adoption or reuse of reproducible methods by other researchers.

However, measures of rigor and reproducibility should remain primarily within the scientific evaluation process. Institutions should not be required to independently certify scientific rigor, validate reproducibility, or establish new administrative monitoring systems to verify scientific practices. NIH should also recognize that reproducibility may be demonstrated differently across basic, clinical, translational, behavioral, population health, and other research disciplines.

We believe implementation should build upon existing NIH requirements and scientific peer review rather than create duplicative proposal, progress-reporting, or institutional certification requirements. Where additional information is needed, NIH should use standardized investigator-reported information and existing federal systems whenever possible.

NIH should also consider providing dedicated funding for replication and reproducibility activities. Expectations for additional validation, replication, documentation, data management, or quality-control activities may require additional personnel, infrastructure, statistical support, and institutional resources. Expectations should therefore be accompanied by appropriate financial support rather than becoming unfunded institutional responsibilities.

2. Data, Software, and Model Sharing: UNM HSC Research Administration supports appropriate sharing of scientific data, software, models, protocols, and other research resources. Responsible sharing can increase the value of federal research investments, facilitate validation and secondary research, reduce

unnecessary duplication, and promote collaboration.

Potential measures of impact could include deposition of data or research resources in recognized repositories; assignment of persistent identifiers; documented reuse or citation of datasets, software, models, or protocols; development of broadly utilized research tools; and adherence to FAIR principles where appropriate.

NIH should recognize, however, that the ability to share and the cost of sharing vary significantly by research type. Human participant data, protected health information, proprietary information, Tribal data, sensitive datasets, intellectual property, controlled-access data, and large or technically complex datasets may require substantial institutional infrastructure and oversight.

Institutions may incur significant costs associated with data curation, storage, cybersecurity, repository fees, privacy review, access controls, software maintenance, licensing, and long-term preservation. If NIH expands expectations in this area, adequate funding should be available to support these activities.

Measures should recognize responsible sharing rather than simply the volume of information made public. A dataset that is appropriately restricted to protect participants should not be considered less valuable than an openly accessible dataset when restrictions are scientifically, ethically, legally, or culturally appropriate.

NIH should also rely upon existing repositories, persistent identifiers, and machine-readable information to measure sharing and reuse whenever possible rather than requiring institutions to manually track downstream use of research products.

3. Training and Mentorship: UNM HSC Research Administration strongly supports recognition of training and mentorship as important contributions to the biomedical research enterprise. Effective mentorship contributes to workforce development, research integrity, scientific independence, retention, and the development of future generations of researchers.

Potential indicators could include completion of structured mentoring activities; trainee progression and achievement of educational or career milestones; successful transition to independent research roles; development of mentoring plans; participation in mentor training; and demonstrated contributions to the professional development of students, trainees, junior investigators, and research staff.

We believe NIH should avoid relying solely on traditional outcomes such as the number of trainees who subsequently obtain NIH funding or tenure-track academic positions. Successful biomedical research careers include clinical research, industry, government, research administration, public health, technology transfer, data science, and other sectors that contribute to the research ecosystem.

Long-term career tracking also presents a substantial feasibility concern. Institutions may not have access to reliable information about individuals years after they complete training or leave the institution. NIH should use federal data sources, ORCID, researcher profiles, and voluntary trainee reporting where possible rather than placing responsibility on institutions to maintain indefinite longitudinal tracking systems.

Measures should also recognize the quality and depth of mentorship rather than simply the number of individuals mentored. Incentives that emphasize volume could unintentionally encourage superficial mentoring relationships.

4. Collaboration: UNM HSC Research Administration supports increased recognition of collaborative and team-based science. Modern biomedical research frequently requires multidisciplinary teams, shared infrastructure, specialized expertise, community partnerships, clinical collaborations, and contributions from individuals whose scientific impact may not be reflected through first- or senior-author publications.

Potential indicators could include documented investigator contribution statements; participation in multidisciplinary or multi-institutional research; development or leadership of collaborative research infrastructure; contributions to shared datasets, cores, methods, or research resources; and successful integration of expertise across disciplines.

NIH should recognize the full range of meaningful scientific contributions without requiring institutions to independently quantify or validate the relative contribution of every member of a research team. Standardized contribution frameworks, such as structured investigator contribution statements, may provide a more practical approach.

We believe NIH should also avoid measures that unintentionally favor large research teams or highly resourced institutions simply because they generate larger numbers of collaborations. Quality, scientific necessity, and meaningful contribution should be considered alongside quantity.

Recognition should extend beyond investigators to the research professionals and infrastructure that make collaborative science possible, including biostatisticians, data scientists, research coordinators, core facilities, research administrators, and other specialized contributors where appropriate.

5. Entrepreneurship and Translation: UNM HSC Research Administration supports recognizing activities that successfully translate scientific discoveries into products, technologies, diagnostics, therapeutics, clinical practices, and other applications that benefit patients and the public.

Potential indicators could include invention disclosures, patents, licensing activity, startup formation, industry partnerships, advancement of technologies toward clinical use, implementation of evidence-based interventions, regulatory milestones, and adoption of research findings into healthcare practice.

We believe NIH should exercise caution, however, in relying heavily on commercialization-based measures such as patents, licensing revenue, startup formation, or private investment. Such measures may favor institutions with substantial commercialization infrastructure or research portfolios concentrated in areas that readily produce patentable technologies.

Scientific translation also occurs without commercialization. Research may change clinical guidelines, improve healthcare delivery, inform public health practices, develop noncommercial tools, improve diagnostic approaches, or result in interventions adopted by communities or healthcare systems.

NIH should therefore define translation broadly enough to recognize multiple pathways from discovery to impact.

In addition, commercialization outcomes can occur many years after the underlying NIH-supported research. Institutions and investigators should not be expected to establish direct causal attribution between an individual NIH award and a downstream commercial product when numerous researchers, organizations, funding sources, and subsequent discoveries contributed to the outcome.

6. Foundational Scientific Exploration: UNM HSC Research Administration strongly supports NIH's recognition of foundational research and high-risk, high-reward scientific exploration. Fundamental discoveries frequently precede clinical or commercial applications by many years, and their ultimate impact may not be foreseeable during the period of an NIH award.

NIH should therefore avoid evaluating foundational research primarily through short-term measures such as commercialization, immediate clinical impact, citation counts, or measurable public-health outcomes.

Potential indicators could instead recognize generation of new hypotheses; development of novel methodologies; creation of foundational datasets or research resources; opening of new areas of scientific inquiry; replication or refutation of established assumptions; and contributions that subsequently enable other scientific discoveries.

NIH should also recognize that scientifically valuable research does not always produce the anticipated result. Well-designed studies that generate negative, null, or unexpected findings can contribute substantially to scientific knowledge and prevent unnecessary duplication of research.

Measures intended to reward impact should not create incentives for investigators or institutions to avoid scientifically important but uncertain research in favor of projects more likely to generate immediately measurable outcomes.

UNM HSC support's NIH preserving peer review and scientific judgment as central components of evaluating foundational research and should ensure that quantitative impact metrics supplement rather than replace expert assessment.

7. Public Impact: UNM HSC Research Administration supports NIH's goal of recognizing the broader public impact of biomedical research, including improvements in health outcomes, clinical practice, accessibility, public trust, economic activity, and societal benefit.

This category presents significant opportunities but also substantial measurement challenges.

Potential indicators could include incorporation of research findings into clinical guidelines or healthcare practice; implementation of evidence-based interventions; improvements in healthcare access or delivery; adoption of research findings by public agencies or community organizations; contributions to workforce development; public-facing research resources; community engagement; and demonstrated

improvements in health outcomes where attribution is reasonably possible.

We would hope that NIH recognize that public impact may look substantially different depending upon an institution's mission and the populations it serves. Measures should appropriately recognize research conducted in rural, underserved, and geographically dispersed communities, as well as research focused on improving healthcare delivery and access.

Public impact should not be measured primarily through economic return, commercialization, media attention, or other measures that may disproportionately favor certain research areas or highly resourced institutions.

Attribution also requires caution. Changes in health outcomes or clinical practice frequently result from decades of research involving numerous investigators, institutions, funding agencies, healthcare systems, and community partners. Requiring an investigator or institution to demonstrate that a specific NIH award directly produced a particular societal outcome could create substantial administrative burden while producing unreliable measures.

8. Other Areas: UNM HSC Research Administration supports NIH's effort to develop a broader and more meaningful understanding of scientific impact. Moving beyond publication counts, citation metrics, and grant funding has the potential to more appropriately recognize the many activities necessary to advance biomedical research.

However, implementation will be critical. UNM HSC suggests that NIH:

Use existing information whenever possible. NIH should leverage federal systems, repositories, persistent identifiers, ORCID, PubMed, and other machine-readable sources rather than requiring institutions and investigators to repeatedly enter the same information.

Avoid new institutional certifications. Measures intended to recognize scientific contributions should not evolve into institutional compliance certifications requiring central administrative offices to validate scientific impact.

Provide funding for new expectations. Expanded requirements for data sharing, reproducibility, long-term preservation, tracking, reporting, or research infrastructure should be accompanied by appropriate funding.

Maintain proportionality. Reporting expectations should be proportional to the size, complexity, duration, and risk of the funded activity.

Recognize institutional and disciplinary differences. Metrics should not unintentionally disadvantage institutions because of geography, institutional resources, research portfolio, patient population, commercialization infrastructure, or discipline.

Avoid excessive longitudinal tracking requirements. Institutions should not be expected to indefinitely track trainees, downstream data reuse, commercialization, clinical implementation, or societal outcomes

after an award has ended.

Separate scientific evaluation from administrative compliance. Indicators designed to recognize scientific contributions should primarily inform scientific evaluation rather than create additional administrative review and monitoring responsibilities.

Pilot new measures before broad implementation. NIH should test proposed indicators across different institution types, disciplines, career stages, and award mechanisms before establishing agency-wide requirements and assess both scientific value and administrative burden.

Avoid overreliance on quantitative metrics. Measures should supplement, rather than replace, expert scientific judgment. Metrics that become targets may unintentionally influence researcher behavior in ways that prioritize measurable activity over meaningful scientific contribution.

Provide clear definitions and standardized guidance. Any new measures should be consistently defined across NIH Institutes and Centers to minimize inconsistent interpretation and institutional implementation.

Overall, UNM HSC Research Administration supports NIH's objective of recognizing the broader range of activities that contribute to rigorous, collaborative, innovative, and publicly beneficial biomedical research. We encourage NIH to develop approaches that reward these contributions while ensuring that the mechanisms used to measure scientific impact do not themselves divert significant investigator and institutional resources away from conducting research.

172. Association of Biomolecular Resource Facilities

I am responding: On behalf of an organization

Name: Joe Dragavon

Name of Organization: Association of Biomolecular Resource Facilities

Type of Organization: Professional Organization/Association

Role: Organizational Official

Date Submitted: 8/15/2026

1. Rigor and Reproducibility: The Association of Biomolecular Resource Facilities (ABRF) Committee for Core Rigor and Reproducibility (CCoRRe) commends the NIH for examining how scientific impact is measured and rewarded. CCoRRe is a standing committee within ABRF dedicated to advancing the rigor, reproducibility, and transparency of scientific research.

Core facilities, also referred to as Shared Research Resources (SRRs) and Shared Resource Laboratories (SRLs), are essential components of the biomedical research ecosystem. These entities provide not only advanced instrumentation, but also deep technical expertise, training, quality management, technology development, data stewardship, and community leadership. Together, these contributions directly support scientific excellence and reinforce public trust in research.

We are submitting these comments because core facilities generate a substantial proportion of research data at many institutions and serve as institutional anchors for rigorous, reproducible science. Strengthening standards within these environments has meaningful downstream impact on research quality and reliability; as such, strengthening standards within these environments has a broad and meaningful downstream impact on the quality and reliability of science overall.

Current assessment systems tend to emphasize publications, citation counts, journal metrics, and funding success, while underrecognizing critical contributions that enhance the rigor, reproducibility, transparency, accessibility, and long-term value of biomedical research.

NIH has a valuable opportunity to broaden its definition of scientific impact to more fully recognize and incentivize contributions that advance rigor, reproducibility, and transparency, and that enable high-quality, reliable science. We support NIH's efforts to align measures of scientific success with outcomes that strengthen scientific integrity and maximize public health impact.

Reproducibility and replicability are foundational to rigorous biomedical research. Core facilities and SRLs are uniquely positioned to enhance research quality through systemic implementation of technology expertise, quality assurance, protocol standardization, assay validation, experimental design consultation, and workforce training.

ABRF Recommendations

NIH should incentivize, measure, and recognize:

• Adoption and reporting rates of Research Resource Identifiers (RRIDs) across publications, datasets, and protocols
• Development and dissemination of validated protocols, standard operating procedures (SOPs), and reference materials (e.g., downloads, citations, reuse)
• Participation in benchmarking studies, proficiency testing programs, and interlaboratory comparisons, including performance relative to established standards
• Implementation of quality management systems, including metrics such as instrument uptime, calibration frequency, assay validation rates, and error reduction trends
• Publication and dissemination of replication studies, validation studies, and negative findings
• Documented contributions by core facilities and SRLs to study design, methodology selection, quality control, and data integrity (e.g., inclusion in grant applications, protocols, or contributor roles)

These indicators should be incorporated into grant review criteria, progress reports, and renewal evaluations to reward demonstrated commitment to rigor and reproducibility.
Scientific impact assessments should also include evidence that research outputs are reproducible, transparent, reusable, and supported by appropriate methodological documentation.

2. Data, Software, and Model Sharing: The value of scientific research extends beyond publications to include datasets, software, analytical workflows, protocols, and models that enable future discovery and validation.

ABRF CCoRRe Recommendations

NIH should recognize, measure, and incentivize:
• Adoption of FAIR (Findable, Accessible, Interoperable, and Reusable) data principles, including compliance rates in data management plans and demonstrated accessibility of datasets within 12 months of study completion.
• Sharing of datasets, metadata, software tools, analytical workflows, protocols, and computational pipelines, measured by:
o Number of publicly available datasets/tools
o Dataset downloads and reuse frequency
o Citations of datasets and software
• Development and adoption of standards for data formatting, annotation, interoperability, and provenance tracking.
• Use of persistent identifiers (RRIDs, ORCID iDs, DOIs), measured by rates of inclusion in publications and datasets.
• Long-term stewardship metrics, including duration of data availability, dataset updates, and maintenance activities.
• Contributions by core facilities and SRLs to shared data infrastructure, including number of supported users, datasets managed, and pipelines maintained.

NIH could integrate these metrics into funding decisions, data sharing compliance evaluations, and

supplemental funding incentives for high-impact data resources.
Measures of impact should include data reuse, software adoption, protocol utilization, resource citations, and community uptake rather than relying solely on publication-based metrics.

3. Training and Mentorship: Core facilities and SRLs are major contributors to workforce development and provide training that is often not captured by traditional academic metrics.

ABRF CCoRRe Recommendations

NIH should recognize, measure, and reward:
• Training activities conducted by core facility scientists and staff, including:
o Number of trainees per year
o Training hours delivered
o Types of skills taught (technology, data analysis, rigor practices)
• Development and dissemination of educational programs, measured by adoption rates, downloads, and use across institutions.
• Mentorship outcomes, including trainee career progression, publications, and continued use of rigorous practices.
• Contributions to workforce development that improve scientific competency and research quality.
• Training efficacy metrics, including pre- and post-training assessments, trainee feedback, and demonstrated adoption of rigorous practices by trainees in their own research.

NIH could incorporate these metrics into grant progress reports and core facility funding mechanisms and provide supplemental funding or recognition for high-impact training programs. Potential indicators of impact include numbers of individuals trained, adoption of training materials, trainee outcomes, development of educational resources, and demonstrated improvements in research quality attributable to training activities.

4. Collaboration: Modern biomedical research increasingly relies on interdisciplinary teams that include investigators, clinicians, engineers, statisticians, data scientists, and core facility experts.
ABRF CCoRRe Recommendations

NIH should expand recognition of team science by:
• Developing mechanisms to document and quantify contributions using contributor role taxonomies (e.g., CRediT), including counts of technical, methodological, and advisory contributions.
• Encouraging use of ORCID identifiers to track contributions across projects and publications.
• Measuring participation in multidisciplinary, multi-investigator, and multi-institutional projects.
• Recognizing contributions that enable scientific success even when they are not reflected through traditional authorship positions (e.g., acknowledgments, documented consultation hours, technical impact statements).
These contributions should be considered in grant scoring, promotion of collaborative funding mechanisms, and evaluation of investigator impact.
Core facility scientists frequently contribute specialized expertise that directly influences study design, technology implementation, data interpretation, and research outcomes. These contributions should be recognized as meaningful indicators of scientific impact.

We recommend NIH develop guidance on appropriate roles for core facility scientists in authorship vs. acknowledgment to ensure transparent credit attribution while respecting disciplinary norms.

5. Entrepreneurship and Translation: Core facilities frequently serve as innovation hubs where new technologies are developed, optimized, validated, and disseminated.

ABRF CCoRRe Recommendations

NIH should recognize, measure, and incentivize:
• Development of novel methodologies, workflows, instrumentation, software tools, and analytical approaches, measured by adoption across projects and institutions.
• Technology validation and implementation metrics, including number of validated assays and deployment across user groups.
• Public-private partnerships and collaborations, including number of partnerships and resulting outputs.
• Technology transfer outcomes, including patents filed, licenses executed, and commercial products developed.
• Dissemination activities, measured by training workshops, protocol sharing, and cross-institutional adoption.
NIH could incorporate these indicators into translational funding mechanisms and reward successful implementation and dissemination through supplemental funding or programmatic recognition.
Measures of impact should include technology adoption, implementation across institutions, commercialization activities, and demonstrated improvements in research capabilities. Core facility-led innovation often addresses unmet methodological needs identified through direct engagement with end-user researchers, positioning these facilities as natural innovation hubs."

6. Foundational Scientific Exploration: Many transformative discoveries arise from exploratory research, technology development, and high-risk investigations whose value may not be immediately apparent.

ABRF CCoRRe Recommendations

NIH should encourage and measure:
• Investment in novel technologies and proof-of-concept studies, including number and outcomes of pilot projects.
• Utilization of shared research resources for exploratory work, including pilot usage rates and downstream funding success.
• Technical innovation outputs, such as newly developed methods or workflows and their later adoption.
• Long-term impact indicators, including downstream publications, grant funding, and technology diffusion over time.
NIH should align funding review criteria to value long-term influence and provide dedicated funding mechanisms that support early-stage, high-risk innovation.
Core facilities often provide environments where investigators can test innovative ideas, generate preliminary data, and evaluate new technologies.

7. Public Impact: Scientific impact should extend beyond academic metrics and include broader societal benefit.

ABRF CCoRRe Recommendations

NIH should recognize and measure:
• Improvements in reproducibility and research quality, including reductions in irreproducible findings and retraction rates.
• Contributions to clinical translation, public health outcomes, and evidence-based practices.
• Accessibility of scientific outputs, including availability of open datasets, protocols, and educational materials.
• Community engagement activities, including outreach events, training programs, and public-facing resources.
• Economic efficiencies, such as cost savings achieved through shared infrastructure and resource utilization.
• Return on investment metrics, including reuse of federally funded resources and downstream impact of funded work.

These measures could inform program evaluations and demonstrate public value, strengthening accountability for federal investments.
Investments in rigor, reproducibility, quality management, and scientific stewardship provide substantial public value by ensuring that scientific discoveries are trustworthy and reusable.

8. Other Areas: ABRF and CCoRRe recommend NIH consider several additional areas:

• Recognition of Technical Professionals – Career advancement metrics, retention rates, and documented contributions to research outputs.
• Shared Research Resource Contributions – Metrics such as number of users served, projects supported, and publications enabled.
• Quality Management and Accreditation – Adoption rates of quality frameworks, benchmarking participation, and performance improvement metrics.
• Research Resource Stewardship – Duration of resource availability, usage rates, and maintenance activities.
• Community Standards Development – Participation in standards initiatives and adoption rates of developed guidelines.
• Scientific Service and Leadership – Roles in professional societies, committees, and consensus-building efforts.

Cross-Cutting Recommendation: Recognition of Shared Research Resources and Core Facility Contributions

ABRF and the CCoRRe Committee encourage NIH to recognize SRRs, core facilities, and SRLs as critical contributors across all areas addressed in this RFI.

NIH should consider developing mechanisms to document, track, and reward these contributions through:

• Standardized acknowledgment and attribution of core facility contributions in publications and grants.

• Integration of ORCID identifiers and contributor role taxonomies into NIH reporting systems.
• Inclusion of core facility impact metrics (e.g., number of supported projects, training outputs, data generated) in grant applications and progress reports.
• Recognition of facilities that demonstrate excellence in rigor, reproducibility, quality management, and FAIR data practices.
• Incorporation of shared resource contributions into funding decisions, renewals, and institutional evaluations, including development of standardized reporting formats to reduce burden on core facility administrators."

Importantly, many activities essential to rigorous science—such as quality assurance, method validation, benchmarking, standards development, data stewardship, and training—are often performed by core facility personnel and are not adequately captured by traditional metrics.
Because shared research resources contribute directly to all NIH priority areas identified in this RFI, NIH should incorporate recognition of SRR and SRL contributions as a cross-cutting element within any future framework.

Conclusion

NIH has an opportunity to reshape scientific incentives by recognizing rigor, reproducibility, transparency, stewardship, training, collaboration, and shared research infrastructure as essential dimensions of scientific impact.

A modern assessment framework should reward not only scientific discoveries but also the measurable practices, contributions, and infrastructure that ensure research is rigorous, reproducible, transparent, reusable, and trustworthy.

Recognizing these contributions will strengthen the biomedical research enterprise, improve public trust, maximize the return on federal investments, and better align scientific incentives with practices that produce reliable and impactful science.
We are prepared to provide data, case studies, and further detail on implementing these recommendations, and welcome collaboration with NIH to pilot assessment frameworks.

NIH Request for Information: Measuring and Rewarding Scientific Impact

Notice Number: NOT-OD-26-087

The Association of Biomolecular Resource Facilities (ABRF) Committee on Core Rigor and Reproducibility (CCoRRe) commends the NIH for examining how scientific impact is measured and rewarded. CCoRRe is a standing committee within ABRF dedicated to advancing the rigor, reproducibility, and transparency of scientific research.

Core facilities, also referred to as Shared Research Resources (SRRs) and Shared Resource Laboratories (SRLs), are essential components of the biomedical research ecosystem. These entities provide not only advanced instrumentation, but also deep technical expertise, training, quality management, technology development, data stewardship, and community leadership. Together, these contributions directly support scientific excellence and reinforce public trust in research.

We are submitting these comments because core facilities generate a substantial proportion of research data at many institutions and serve as institutional anchors for rigorous, reproducible science. Strengthening standards within these environments has meaningful downstream impact on research quality and reliability; as such, strengthening standards within these environments has a broad and meaningful downstream impact on the quality and reliability of science overall.

Current assessment systems tend to emphasize publications, citation counts, journal metrics, and funding success, while underrecognizing critical contributions that enhance the rigor, reproducibility, transparency, accessibility, and long-term value of biomedical research.

NIH has a valuable opportunity to broaden its definition of scientific impact to more fully recognize and incentivize contributions that advance rigor, reproducibility, and transparency, and that enable high-quality, reliable science. We support NIH's efforts to align measures of scientific success with outcomes that strengthen scientific integrity and maximize public health impact.

SECTION 1: RIGOR AND REPRODUCIBILITY

Reproducibility and replicability are foundational to rigorous biomedical research. Core facilities and SRLs are uniquely positioned to enhance research quality through systemic implementation of technology expertise, quality assurance, protocol standardization, assay validation, experimental design consultation, and workforce training.

ABRF CCoRRe Recommendations

NIH should incentivize, measure, and recognize:

- Adoption and reporting rates of Research Resource Identifiers (RRIDs) across publications, datasets, and protocols
- Development and dissemination of validated protocols, standard operating procedures (SOPs), and reference materials (e.g., downloads, citations, reuse)
- Participation in benchmarking studies, proficiency testing programs, and interlaboratory comparisons, including performance relative to established standards
- Implementation of quality management systems, including metrics such as instrument uptime, calibration frequency, assay validation rates, and error reduction trends
- Publication and dissemination of replication studies, validation studies, and negative findings
- Documented contributions by core facilities and SRLs to study design, methodology selection, quality control, and data integrity (e.g., inclusion in grant applications, protocols, or contributor roles)

These indicators should be incorporated into grant review criteria, progress reports, and renewal evaluations to reward demonstrated commitment to rigor and reproducibility.
Scientific impact assessments should also include evidence that research outputs are reproducible, transparent, reusable, and supported by appropriate methodological documentation.

SECTION 2: DATA, SOFTWARE, AND MODEL SHARING

The value of scientific research extends beyond publications to include datasets, software, analytical workflows, protocols, and models that enable future discovery and validation.

ABRF CCoRRe Recommendations

NIH should recognize, measure, and incentivize:

- Adoption of FAIR (Findable, Accessible, Interoperable, and Reusable) data principles, including compliance rates in data management plans and demonstrated accessibility of datasets within 12 months of study completion.
- Sharing of datasets, metadata, software tools, analytical workflows, protocols, and computational pipelines, measured by:
    - Number of publicly available datasets/tools
    - Dataset downloads and reuse frequency
    - Citations of datasets and software

- Development and adoption of standards for data formatting, annotation, interoperability, and provenance tracking.
- Use of persistent identifiers (RRIDs, ORCID iDs, DOIs), measured by rates of inclusion in publications and datasets.
- Long-term stewardship metrics, including duration of data availability, dataset updates, and maintenance activities.
- Contributions by core facilities and SRLs to shared data infrastructure, including number of supported users, datasets managed, and pipelines maintained.

NIH could integrate these metrics into funding decisions, data sharing compliance evaluations, and supplemental funding incentives for high-impact data resources.
Measures of impact should include data reuse, software adoption, protocol utilization, resource citations, and community uptake rather than relying solely on publication-based metrics.

SECTION 3: TRAINING AND MENTORSHIP

Core facilities and SRLs are major contributors to workforce development and provide training that is often not captured by traditional academic metrics.

ABRF CCoRRe Recommendations

NIH should recognize, measure, and reward:

- Training activities conducted by core facility scientists and staff, including:
    - Number of trainees per year
    - Training hours delivered
    - Types of skills taught (technology, data analysis, rigor practices)
- Development and dissemination of educational programs, measured by adoption rates, downloads, and use across institutions.
- Mentorship outcomes, including trainee career progression, publications, and continued use of rigorous practices.
- Contributions to workforce development that improve scientific competency and research quality.
- **Training efficacy metrics**, including pre- and post-training assessments, trainee feedback, and demonstrated adoption of rigorous practices by trainees in their own research.

NIH could incorporate these metrics into grant progress reports and core facility funding mechanisms and provide supplemental funding or recognition for high-impact training programs.

Potential indicators of impact include numbers of individuals trained, adoption of training materials, trainee outcomes, development of educational resources, and demonstrated improvements in research quality attributable to training activities.

SECTION 4: COLLABORATION

Modern biomedical research increasingly relies on interdisciplinary teams that include investigators, clinicians, engineers, statisticians, data scientists, and core facility experts.

ABRF CCoRRe Recommendations

NIH should expand recognition of team science by:

- Developing mechanisms to document and quantify contributions using contributor role taxonomies (e.g., CRediT), including counts of technical, methodological, and advisory contributions.
- Encouraging use of ORCID identifiers to track contributions across projects and publications.
- Measuring participation in multidisciplinary, multi-investigator, and multi-institutional projects.
- Recognizing contributions that enable scientific success even when they are not reflected through traditional authorship positions (e.g., acknowledgments, documented consultation hours, technical impact statements).

These contributions should be considered in grant scoring, promotion of collaborative funding mechanisms, and evaluation of investigator impact.
Core facility scientists frequently contribute specialized expertise that directly influences study design, technology implementation, data interpretation, and research outcomes. These contributions should be recognized as meaningful indicators of scientific impact.
We recommend NIH develop guidance on appropriate roles for core facility scientists in authorship vs. acknowledgment to ensure transparent credit attribution while respecting disciplinary norms.

SECTION 5: ENTREPRENEURSHIP AND TRANSLATION

Core facilities frequently serve as innovation hubs where new technologies are developed, optimized, validated, and disseminated.

ABRF CCoRRe Recommendations

NIH should recognize, measure, and incentivize:

- Development of novel methodologies, workflows, instrumentation, software tools, and analytical approaches, measured by adoption across projects and institutions.

- Technology validation and implementation metrics, including number of validated assays and deployment across user groups.
- Public-private partnerships and collaborations, including number of partnerships and resulting outputs.
- Technology transfer outcomes, including patents filed, licenses executed, and commercial products developed.
- Dissemination activities, measured by training workshops, protocol sharing, and cross-institutional adoption.

NIH could incorporate these indicators into translational funding mechanisms and reward successful implementation and dissemination through supplemental funding or programmatic recognition.
Measures of impact should include technology adoption, implementation across institutions, commercialization activities, and demonstrated improvements in research capabilities. Core facility-led innovation often addresses unmet methodological needs identified through direct engagement with end-user researchers, positioning these facilities as natural innovation hubs."

SECTION 6: FOUNDATIONAL SCIENTIFIC EXPLORATION

Many transformative discoveries arise from exploratory research, technology development, and high-risk investigations whose value may not be immediately apparent.

ABRF CCoRRe Recommendations

NIH should encourage and measure:

- Investment in novel technologies and proof-of-concept studies, including number and outcomes of pilot projects.
- Utilization of shared research resources for exploratory work, including pilot usage rates and downstream funding success.
- Technical innovation outputs, such as newly developed methods or workflows and their later adoption.
- Long-term impact indicators, including downstream publications, grant funding, and technology diffusion over time.

NIH should align funding review criteria to value long-term influence and provide dedicated funding mechanisms that support early-stage, high-risk innovation.
Core facilities often provide environments where investigators can test innovative ideas, generate preliminary data, and evaluate new technologies.

SECTION 7: PUBLIC IMPACT

Scientific impact should extend beyond academic metrics and include broader societal benefit.

ABRF CCoRRe Recommendations

NIH should recognize and measure:

- Improvements in reproducibility and research quality, including reductions in irreproducible findings and retraction rates.
- Contributions to clinical translation, public health outcomes, and evidence-based practices.
- Accessibility of scientific outputs, including availability of open datasets, protocols, and educational materials.
- Community engagement activities, including outreach events, training programs, and public-facing resources.
- Economic efficiencies, such as cost savings achieved through shared infrastructure and resource utilization.
- Return on investment metrics, including reuse of federally funded resources and downstream impact of funded work.

These measures could inform program evaluations and demonstrate public value, strengthening accountability for federal investments.
Investments in rigor, reproducibility, quality management, and scientific stewardship provide substantial public value by ensuring that scientific discoveries are trustworthy and reusable.

SECTION 8: ADDITIONAL AREAS FOR CONSIDERATION

ABRF CCoRRe recommend NIH consider several additional areas:

- **Recognition of Technical Professionals** – Career advancement metrics, retention rates, and documented contributions to research outputs.
- **Shared Research Resource Contributions** – Metrics such as number of users served, projects supported, and publications enabled.
- **Quality Management and Accreditation** – Adoption rates of quality frameworks, benchmarking participation, and performance improvement metrics.
- **Research Resource Stewardship** – Duration of resource availability, usage rates, and maintenance activities.

- **Community Standards Development** – Participation in standards initiatives and adoption rates of developed guidelines.
- **Scientific Service and Leadership** – Roles in professional societies, committees, and consensus-building efforts.

Cross-Cutting Recommendation: Recognition of Shared Research Resources and Core Facility Contributions

ABRF and the CCoRRe Committee encourage NIH to recognize SRRs, core facilities, and SRLs as critical contributors across all areas addressed in this RFI.

NIH should consider developing mechanisms to document, track, and reward these contributions through:

- Standardized acknowledgment and attribution of core facility contributions in publications and grants.
- Integration of ORCID identifiers and contributor role taxonomies into NIH reporting systems.
- Inclusion of core facility impact metrics (e.g., number of supported projects, training outputs, data generated) in grant applications and progress reports.
- Recognition of facilities that demonstrate excellence in rigor, reproducibility, quality management, and FAIR data practices.
- Incorporation of shared resource contributions into funding decisions, renewals, and institutional evaluations, including development of standardized reporting formats to reduce burden on core facility administrators."

Importantly, many activities essential to rigorous science—such as quality assurance, method validation, benchmarking, standards development, data stewardship, and training—are often performed by core facility personnel and are not adequately captured by traditional metrics. Because shared research resources contribute directly to all NIH priority areas identified in this RFI, NIH should incorporate recognition of SRR and SRL contributions as a cross-cutting element within any future framework.

Conclusion

NIH has an opportunity to reshape scientific incentives by recognizing rigor, reproducibility, transparency, stewardship, training, collaboration, and shared research infrastructure as essential dimensions of scientific impact.

A modern assessment framework should reward not only scientific discoveries but also the measurable practices, contributions, and infrastructure that ensure research is rigorous, reproducible, transparent, reusable, and trustworthy.

Recognizing these contributions will strengthen the biomedical research enterprise, improve public trust, maximize the return on federal investments, and better align scientific incentives with practices that produce reliable and impactful science.

We are prepared to provide data, case studies, and further detail on implementing these recommendations, and welcome collaboration with NIH to pilot assessment frameworks.

Committee on Core Rigor and Reproducibility
Association of Biomolecular Resource Facilities

173. N/A

I am responding: On behalf of myself

Name:

Name of Organization:

Type of Organization: Commercial Entity (Biotech/Device/Pharmaceutical Company/Small Business)

Role: Organizational Official

Date Submitted: 8/15/2026

1. Rigor and Reproducibility: I would commend two areas for enhancing rigor and reproducibility:
1)Rigor: encourage registered reports as a form of publishing. Much science is wasted or slowed through poorly thought out controls and designs. Negative results that are useful to the field but not ground breaking also rarely find their way into publications. Registered Reports, with peer-reviewed methods and provisional acceptance regardless of the results, are a way to address these. Perhaps they could be encouraged with some kind of "priority review voucher" for future grant submissions, much the same as the highly successful FDA program.

2) Reproducibility: encourage each new PhD or masters trainee to have a replication project as part of their work portfolio. This allows them to learn the field, learn techniques, and publish on a shorter timescale than their main thesis. Dedicated repository or journals for this would probably help as well.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: N/A

4. Collaboration: N/A

5. Entrepreneurship and Translation: As a leader at a small biotech that has applied to and successfully completed SBIRs, I feel strongly that this program is crucial to the science ecosystem. It's impact can be amplified by accelerating the timelines on which awards are made. The lag time of ~9 months simply is too long for the pace that many innovative biotechs want to work at. Can companies be vetted a single time and then have expedited reviews in the future? Can administrative fluff be removed to condense that time between step?

6. Foundational Scientific Exploration: N/A

7. Public Impact: N/A

8. Other Areas: N/A

174. Licklider, Inc.

I am responding: On behalf of an organization

Name: Tasuku Kobayashi

Name of Organization: Licklider, Inc.

Type of Organization: Commercial Entity (Biotech/Device/Pharmaceutical Company/Small Business)

Role: Organizational Official

Date Submitted: 8/16/2026

1. Rigor and Reproducibility: DISCLOSURE. The respondent is a company developing verification software for statistical analyses in the life sciences. This response does not ask NIH to adopt, evaluate, or endorse any specific product. A current implementation by the respondent is cited only where explicitly identified as feasibility evidence; the policy proposal does not depend on that implementation.

SUMMARY. NIH already requires investigators to describe plans for rigor and for data sharing, and operates extensive disclosure and reporting instruments across the research life cycle. What remains underdeveloped is a standardized, NIH-wide mechanism for independently machine-checking reported quantitative results against their declared evidence, declared methods, and specified computation; NIH's own implementation plan describes composite measures in this area as still under development. We propose one primary candidate measurable indicator — Machine-Verifiable Coverage, reported as a vector rather than a single ratio — and one secondary indicator suitable only for piloting, an Independent Verification Pass Rate, together with the open infrastructure and measurement procedure needed to compute them. Both are indicators of transparency and checkability, not of scientific quality or validity, and we propose the measurement construct itself for pilot validation: we do not ask NIH to treat it as validated. We state the guarantee boundary explicitly and repeatedly, because misreading verification status as evidence of validity is itself the most foreseeable unintended consequence of any indicator in this area. Since this RFI was issued, OSTP has separately called for building verification infrastructure at scale — investment in verification systems and open standards, standards enabling machine-auditable replication packages, and rewards for those who replicate or disprove influential results (Science: A New Golden Age, July 2026). This response addresses a narrower measurement question within that direction: which verification states should be observable, and how they should be aggregated without implying scientific validity.

DEFINITIONS AND SCOPE. We follow the definitions in the OSTP Gold Standard Science guidance (June 2025) and the NIH implementation plan (August 2025), under which replicability denotes performing the same experiment or study using the same methods and conditions to achieve the same result, and reproducibility denotes independent researchers testing a hypothesis through multiple methods. We note explicitly that these assignments are reversed relative to the National Academies consensus report (NASEM 2019), where reproducibility denotes obtaining consistent results using the same input data, computational steps, methods, code, and conditions of analysis. The property our indicators measure corresponds to NASEM's computational reproducibility, a property that has no dedicated name in the

2025 scheme. To avoid ambiguity, this response uses the term machine-verifiable execution consistency: the ability of software, following an open specification, to confirm that reported quantitative results are consistent with the declared data, the declared methods, and the specified computation. Such checking establishes consistency with declarations; it does not establish that the declared analysis was the one historically performed. NASEM (2019) is explicit that "exact reproducibility does not guarantee the correctness of the computation." Nothing proposed below claims otherwise, and the indicator design treats that limit as a design input rather than a caveat.

THE MEASUREMENT GAP. NIH already operates extensive policy instruments across the research life cycle — the rigor and transparency review criteria in effect since FY2016, authentication plans, the Data Management and Sharing Policy in effect since 2023, the Genomic Data Sharing Policy, the 2024 Public Access Policy, and clinical trial registration and results reporting — including post-execution disclosure and reporting. What remains underdeveloped is a standardized, NIH-wide mechanism for independently machine-checking reported quantitative computations against their declared inputs and methods. A decade of empirical work shows why that layer matters and why statements are weak proxies for practice. In a study of 3,556 articles across 333 BMC journals, 123 of 1,792 manuscripts (6.8 percent) whose authors had stated in a data availability statement that they would share data actually provided it when asked (Gabelica et al. 2022). In a large-scale study of more than 2,000 publicly deposited research code-and-data packages, 74 percent of the R files they contained failed to complete on initial execution (Trisovic et al. 2022). Among 25 articles carrying open-data badges in a leading psychology journal, only 36 percent could be fully analytically reproduced from the original data without author assistance — computational reproducibility in the NASEM sense — and the dominant failure cause was analytical procedures too ambiguously reported to re-execute (Hardwicke et al. 2021). At the same time, policy stringency and enforcement are associated with substantial changes in reporting, data reusability, and re-execution outcomes: a mandatory open-data policy at one journal was followed by an increase in data availability statements from 25 to 78 percent of articles, with data judged reusable in principle rising from 22 to 62 percent (Hardwicke et al. 2018), and journal policy strictness correlates with re-execution success (Trisovic et al. 2022). Finally, the most mature machine checks in existence are automated consistency checks of reported statistics: for supported, machine-detected APA-style null-hypothesis test results, statcheck validation studies reported classification accuracy between 96.2 and 99.9 percent — which does not imply equivalent detection coverage of all statistical results in an article — and such checks have found at least one internally inconsistent statistical result in roughly half of checkable psychology articles (Nuijten et al. 2016; Nuijten, van Assen, Hartgerink, Epskamp & Wicherts 2017), with granularity checks finding a similar rate in a separate sample (Brown & Heathers 2017). These findings support testing execution-side indicators — provided their guarantee boundary is designed in from the start.

PROPOSED INDICATOR 1 — MACHINE-VERIFIABLE COVERAGE (MVC): A CANDIDATE INDICATOR PROPOSED FOR PILOT VALIDATION. MVC measures how much of a research output's quantitative claims can be, and has been, independently machine-checked. It is deliberately reported as a vector, not a single ratio, because collapsing it to one number invites both gaming and misreading. For a given article or project, MVC reports:

- N_major: the number of major quantitative claims, drawn from a claim inventory declared by the

authors and confirmed during review;
- N_eligible: the subset of those claims that fall under a published eligibility rule (i.e., a public verification profile exists for the analysis class);
- N_recorded: the subset represented in machine-verifiable structured records — including, where applicable, claims inside a declared closed verification surface, defined below;
- N_verified: the subset whose records have passed independent verification under the applicable public verification profile (record integrity, declared provenance relations, specified computation, numerical consistency);
- N_bound: the subset of verified claims whose reported values in the final research artifact have additionally been machine-matched, within declared numerical tolerances, to the corresponding structured record;
- N_unsupported: claims whose analysis class has no verification profile yet, reported as a distinct state and never counted as a failure.

These states are nested: N_bound ≤ N_verified ≤ N_recorded ≤ N_eligible ≤ N_major, with N_unsupported = N_major − N_eligible. Two coverage ratios are derived and always reported together: coverage over all major claims (N_bound / N_major) and coverage over eligible claims (N_bound / N_eligible); when N_eligible = 0, the eligible-claims ratio is reported as NOT APPLICABLE, never as zero. Reporting both ratios is an anti-gaming measure: if only the eligible-claims ratio were used, there would be an incentive to classify inconvenient claims as ineligible; if only the all-claims ratio were used, fields with many not-yet-supported analysis classes would be structurally penalized. The distinct unsupported state prevents unsupported methods from being mislabeled as verification failures; it does not by itself remove disincentives to methodological novelty, since all-claims coverage still falls when many claims are unsupported. For this reason, all-claims coverage must not be used to rank investigators, fields, or methods.

MVC is itself an unvalidated measurement construct, and this response treats that as a first-order fact rather than a footnote. Its measurement properties are not yet established: whether independent raters construct the same claim inventory (inter-rater agreement on N_major), whether eligibility classification is consistent across raters, whether independently developed verifiers agree (implementation concordance), and how sensitive the vector is to choices of claim granularity, are all open questions. We therefore propose MVC as a candidate indicator whose reliability and validity should be a primary object of the pilot described below — not as an indicator ready for adoption.

A declared closed verification surface, referenced above, is a delimited set of research outputs — for example, the specified quantitative elements of a figure, its legend, and the corresponding Methods and Results statements — that are generated from, or explicitly bound to, a single structured analysis record, such that every declared in-scope value or structured relation covered by the applicable verification profile can be machine-checked against that record. Within such a surface, checking is binary and complete relative to the declared surface and its verification contract; the coverage vector then records how much of the article's claim inventory lies inside declared surfaces. The two mechanisms are complementary: surfaces make the numerator crisp, and the inventory-based denominators make selective declaration visible.

The final-artifact value binding component (N_bound) is essential rather than optional. One practical advantage of text-based checks such as statcheck is that they test values as actually published; a structured record, by itself, is a self-declaration. Binding record values to the values reported in the final artifact preserves the property that verification confronts the published claim, not a parallel account of it. Consistency of content outside a declared surface — including any subsequent edits in word processors or publisher typesetting — is established only by this explicit value binding and is never presumed.

WHAT MVC ESTABLISHES AND WHAT IT DOES NOT. For claims counted in N_bound, the measurement establishes only that the covered quantitative elements are represented in structured records, that the reported computations have been independently re-derived from the declared inputs under an open specification, and that the published values match those computations within declared tolerances. It does not establish that the experimental design was appropriate, that the data are authentic, that the recorded analysis was the one historically performed, that the statistical model was well specified, that causal interpretations are warranted, or that the scientific conclusions are true. An internally consistent fabrication would pass; a retrospectively constructed record that is internally consistent would pass; a correct analysis expressed in a not-yet-supported method would register as unsupported, not as failed. Machine verification of this kind is a lower bound on internal consistency — in NASEM's framing, an indicator of transparency serving indirect assessment — and any deployment should prohibit representing verification status as evidence of scientific validity. We recommend that this prohibition be an explicit design requirement of any NIH adoption, including in how results are displayed: verification output should take the form of a vector of named checks with explicit not-evaluated dimensions (for example: artifact integrity, recorded-input binding, specified computation, numerical consistency, final-artifact value binding — each PASS/FAIL/UNSUPPORTED — alongside experimental design, data authenticity, causal validity, independent replication — each NOT EVALUATED), rather than a single "verified" label.

PROPOSED INDICATOR 2 — INDEPENDENT VERIFICATION PASS RATE (IVPR), PILOT ONLY. Among structured records submitted for a defined scope, IVPR is the share that pass independent verification of record integrity, declared provenance relations, specified computation, and numerical consistency. We propose IVPR only for piloting and program evaluation, not for investigator-level assessment, because it lacks predictive-validity evidence and is the component most exposed to Goodhart dynamics if elevated into a reward. Its pilot value is diagnostic: it measures where and why verification fails (environment capture, ambiguous specification, tooling gaps), which is exactly the information needed to improve infrastructure.

INFRASTRUCTURE REQUIRED. Computing these indicators requires: an open, versioned specification for structured analysis records, such that — given the required record and evidence — any authorized third party can execute verification under the public specification without proprietary issuer logic or dependence on any single service (issuer-independent verification, a property of open specifications and third-party execution rather than of any count of implementations); public conformance fixtures so that implementations can be checked against one another; ideally, more than one independently developed verifier implementation with distinct numerical backends, to reduce shared-implementation error — with cross-implementation concordance itself measured in the pilot rather than assumed; a registry with

trusted timestamps so that selective disclosure among registered records can be detected — unregistered analyses remain outside detection; and reuse of existing standards vocabularies rather than invention — W3C PROV for provenance relations, RO-Crate and CodeMeta for packaging and software metadata, FAIR4RS for research software, and the NISO RP-31-2021 reproducibility badging taxonomy for any user-facing status vocabulary, with terminology explicitly mapped to the definitions used in this response.

Institutional precedents demonstrate that third-party verification is operable in practice: the ACM TOMS Replicated Computational Results initiative (since 2015), the CODECHECK certificate register, the cascad certification agency (including third-party checking of analyses on restricted data inside a secure computing environment), and publisher-side computational verification workflows. This proposal does not claim novelty in third-party computational verification itself; those programs demonstrate that such verification events are operationally feasible. The additional element proposed here is to test whether those events can be represented as a standardized, machine-readable measurement state — combining a public eligibility profile, an independent recomputation outcome, final-artifact value binding, explicit not-evaluated dimensions, and portfolio-level coverage denominators — designed for funder-level aggregation and integration with existing processes. Whether that additional measurement layer is useful to NIH is a question for the proposed pilot, not an assumption of this response.

As evidence that a substrate of this kind is implementable (offered as feasibility evidence, not as evidence of policy merit): an open record schema, an independently runnable open-source verifier, and public conformance fixtures for a deliberately narrow, explicitly experimental verification contract covering one analysis class (Welch two-group comparisons) are publicly available under an Apache-2.0 license, released by the respondent and fixed by the immutable version identifier given in the attached references, so that this evidence does not change after submission. The current demonstration implements only the structured-record and scoped statistical-recomputation portion of this proposal. It does not implement MVC claim inventories, closed verification surfaces, final-artifact value binding, registry-based coverage measurement, multiple independent verifier implementations, or secure-enclave execution; those are proposed pilot components.

IMPLEMENTATION APPROACHES. Integration should reuse existing process surfaces across the award life cycle rather than create new bureaucracy, and should respect the timing of what exists when. Pre-award, applications can state whether, and for which analysis classes, the project intends to produce verification-eligible artifacts — alongside the rigor and transparency sections and Data Management and Sharing plans that applications already contain; the claim inventory itself concerns completed outputs and cannot exist at application time. Post-award, claim inventories, records, and coverage reporting can attach to annual progress reporting, where NIH already tracks data-sharing implementation, and to publication workflows. Evaluation of any pilot can use the implementation-science frameworks NIH has already designated for Gold Standard Science assessment (CFIR and RE-AIM). NIH could pilot two pathways for the same class of eligible computational analyses. In a legacy pathway — which would require no new authoring environment — a machine-readable record is constructed retrospectively from the analysis artifacts and documentation investigators already produce; this measures the practical ceiling of post-hoc reconstruction, because information that was not captured at execution time cannot reliably be reconstructed later and frequently requires author assistance, as the reproducibility literature

documents. In a native pathway, which would separately test participating tools capable of execution-time record capture, tools emit the record at execution time and may generate a declared closed verification surface from the same structured record. Within that declared surface, deterministic generation can structurally preclude drift along the canonical generation path; consistency with content outside the surface is still established only by explicit value binding and is not presumed. Across the two pathways the pilot should compare verification coverage, missing-information rates, author and reviewer burden, final-artifact binding success, observed gaming behavior, and failure modes. Neither pathway should be treated as producing evidence of scientific validity.

PILOT DESIGN. We recommend a voluntary, registration-based pilot in one or two Institutes or Centers with computation-heavy portfolios, with a concurrent comparison group, prospectively sized with prespecified primary outcomes; any inferential comparison should have a justified sample size. The primary question of the pilot should be measurement itself: can MVC be measured reproducibly, at tolerable burden, without unacceptable gaming or field bias? Concretely, the pilot should measure inter-rater agreement on claim inventories and on eligibility classification; concordance between independently developed verifier implementations; false-pass and false-fail rates against a manual expert-audit benchmark; the sensitivity of the coverage vector to claim granularity; burden by career stage and institution type; observed gaming; and discipline differences. The legacy-versus-native comparison described above is the secondary, implementation-level question. The rationale for building evaluation in from the start is empirical: nominally similar incentive interventions have produced divergent results in different contexts — open-data badges were associated with a rise from under 3 percent to roughly 39 percent data sharing in one journal's observational data, while a randomized trial at another journal did not detect an increase, with a highly imprecise estimate that could not rule out meaningful effects in either direction — so context-dependence should be assumed and measured rather than argued.

POTENTIAL BENEFITS. Execution-side indicators of this kind could add a standardized measurement layer to NIH's developing metric framework where composite measures are still under development; could allow journal reviewers, reproducibility auditors, and programmatic reviewers of completed outputs to spend less attention on arithmetic consistency and more on design and interpretation; could reduce the cost of computational re-execution and of evidence review — whether they affect the cost of experimental replication should be tested rather than assumed; may support long-term preservation of analysis evidence through registry and archival integration; and could give existing mandates (data sharing, rigor criteria) an execution-side outcome measure they currently lack.

UNINTENDED CONSEQUENCES AND ANTI-GAMING DESIGN. We enumerate the principal failure modes and their status honestly, because several are structural rather than fixable. Mitigable by design: surface or claim cherry-picking (mitigated, not eliminated, by the dual denominators and the claim inventory); denominator manipulation via narrow "major claim" definitions (claim inventories confirmed at review); eligibility laundering, i.e., classifying inconvenient claims as ineligible (published eligibility rules plus the all-claims ratio); selective disclosure of passing records (registry with timestamps; unregistered analyses remain undetectable); verifier monoculture and self-verification (third-party execution required; cross-implementation concordance measured); template farming and claim salami-slicing (claim inventories subject to independent review and audit; raw claim counts never themselves used as rewards;

judgments of claim granularity and importance remain a human review function); post-publication mutation of reported values (detectable on re-verification of the published artifact, conditional on re-verification actually being run — not structurally prevented). Structurally unavoidable, and therefore boundary rather than bug: semantic overinterpretation in prose outside declared surfaces; analysis-path selection among internally consistent alternatives; analyses that are wrong in design or model specification yet perfectly executed; and internally consistent fabrication, including retrospective record construction. For these, the honest countermeasure is the display and reporting prohibition described above — verification status must never be presented as validity — plus the separate mechanisms science already uses (audit, raw-data requirements, replication). Two further consequences deserve explicit monitoring: discipline and institutional inequity, since computational fields and well-resourced institutions can generate records more cheaply (partially addressed by scope limitation, hosted verification options, and the unsupported state); and checkbox compliance, the documented fate of data availability statements, which argues for pairing any indicator with spot enforcement rather than self-report alone. Consistent with DORA, the Leiden Manifesto, the Metric Tide, and CoARA, these indicators should support qualitative assessment and never substitute for it; the vector reporting format is chosen specifically so that no single number exists to be ranked on.

FEASIBILITY ACROSS CAREER STAGES, DISCIPLINES, AND INSTITUTION TYPES. Scope should begin with narrow computational analysis classes for which a public verification profile can be specified, benchmarked, and independently tested — the setting in which validated automated checks already exist. Restricted and controlled-access data could participate in a pilot through secure-enclave execution: cascad/CASD demonstrates the feasibility of third-party computational checking without public data release, and adapting the machine-verifiable architecture proposed here to such environments would require separate implementation and validation; issuer independence can in principle be preserved even for hosted execution so long as the specification is open and third parties can execute verification. Smaller institutions without local compute could use hosted verification under the same open contract. Petabyte-scale computations and analyses locked to proprietary software environments should be explicitly out of scope for an initial indicator rather than papered over. The pilot should stratify burden and adoption by career stage rather than assume an advantage or disadvantage in advance.

A PDF version of this response, including full references, is attached.

2. Data, Software, and Model Sharing: This response extends the framework proposed under Topic 1 (Rigor and Reproducibility) to sharing incentives; the definitions, guarantee boundary, anti-gaming design, and pilot structure described there apply here and are not repeated.

FROM EXISTENCE METRICS TO VERIFIABILITY METRICS. Many scalable automated indicators of sharing measure reporting or existence — a data-availability statement, a repository deposit, a code link — rather than successful reuse or re-execution. Existence can be measured at scale: automated extraction across 2.75 million open-access articles estimated mentions of data-sharing information in 14.5 percent of articles and of code-sharing information in 2.5 percent (Serghiou et al. 2021). But the evidence shows that existence alone can be a weak proxy for the outcomes sharing policy actually seeks: 6.8 percent actual provision among authors who had stated willingness to share (Gabelica et al. 2022); 74 percent initial execution failure among the R files in publicly deposited code-and-data packages (Trisovic et al. 2022); and full unassisted analytic reproduction from original data in only about a third of badge-carrying

articles (Hardwicke et al. 2021). Rewarding existence therefore invites the documented checkbox outcome. We propose that NIH pilot whether verified-use and binding states — the full Machine-Verifiable Coverage vector restricted to shared artifacts, interpreted qualitatively — can complement availability and deposit evidence in future sharing incentives. Consistent with Topic 1, this proposes the construct for validation before any connection to rewards; raw counts of bound claims or of deposits, both trivially inflatable, should never themselves be reward-relevant.

SOFTWARE SHARING. NIH-wide research-software sharing is addressed primarily through best-practice guidance rather than a uniform mandatory software-sharing policy. Rather than proposing new mandates, we propose a measurable standard that any future incentive could attach to: software shared with sufficient metadata and environment capture to permit independent re-execution — reusing CodeMeta and FAIR4RS for metadata and interoperability, while a separate verification profile specifies the dependency, environment, and execution requirements that metadata alone does not guarantee — with re-execution success measured rather than assumed. This would convert software sharing from a statement into an event that can be counted, and could provide an execution-side outcome measure for future NIH software-sharing incentives or reporting, without assuming that the Data Management and Sharing Policy itself applies to research software. This initial proposal does not attempt to define a separate indicator for computational-model sharing.

EQUITY ACROSS DATA TYPES. Verification-based sharing measures must not be limited to data that can be posted publicly. Controlled-access and restricted data could participate through verification executed inside secure computing environments, for which an operating precedent exists in third-party checking without public data release (cascad/CASD), with only the verification outcome — not the data — leaving the environment; adapting the proposed machine-verifiable architecture to such environments would require separate implementation and validation. This matters for feasibility across fields: human-subjects research would otherwise be structurally excluded from any verification-linked measure, which would be both inequitable and a perverse incentive against sensitive-data research.

Description: PDF version of the responses submitted in the Topic 1 (Rigor and Reproducibility) and Topic 2 (Data, Software, and Model Sharing) fields, with the full reference list. Content is identical to the form fields; the references (33 sources, including the immutable version identifier for the feasibility evidence cited in Topic 1) appear only in this PDF.

Response to NIH Request for Information NOT-OD-26-087

Measuring and Rewarding Scientific Impact

Respondent: Licklider, Inc. (Kabushiki Kaisha Licklider), Tokyo, Japan — responding on behalf of an organization (private company; developer of open verification infrastructure for statistical analyses in the life sciences). Submitted August 2026 via the NIH Office of Science Policy comment form. This document is the PDF version of the form-field responses to Topics 1 and 2, with full references.

Topic 1: Rigor and Reproducibility

DISCLOSURE. The respondent is a company developing verification software for statistical analyses in the life sciences. This response does not ask NIH to adopt, evaluate, or endorse any specific product. A current implementation by the respondent is cited only where explicitly identified as feasibility evidence; the policy proposal does not depend on that implementation.

SUMMARY. NIH already requires investigators to describe plans for rigor and for data sharing, and operates extensive disclosure and reporting instruments across the research life cycle. What remains underdeveloped is a standardized, NIH-wide mechanism for independently machine-checking reported quantitative results against their declared evidence, declared methods, and specified computation; NIH's own implementation plan describes composite measures in this area as still under development. We propose one primary candidate measurable indicator — Machine-Verifiable Coverage, reported as a vector rather than a single ratio — and one secondary indicator suitable only for piloting, an Independent Verification Pass Rate, together with the open infrastructure and measurement procedure needed to compute them. Both are indicators of transparency and checkability, not of scientific quality or validity, and we propose the measurement construct itself for pilot validation: we do not ask NIH to treat it as validated. We state the guarantee boundary explicitly and repeatedly, because misreading verification status as evidence of validity is itself the most foreseeable unintended consequence of any indicator in this area. Since this RFI was issued, OSTP has separately called for building verification infrastructure at scale — investment in verification systems and open standards, standards enabling machine-auditable replication packages, and rewards for those who replicate or disprove influential results (Science: A New Golden Age, July 2026). This response addresses a narrower measurement question within that direction: which verification states should be observable, and how they should be aggregated without implying scientific validity.

DEFINITIONS AND SCOPE. We follow the definitions in the OSTP Gold Standard Science guidance (June 2025) and the NIH implementation plan (August 2025), under which replicability denotes performing the same experiment or study using the same methods and conditions to achieve the same result, and reproducibility denotes independent researchers testing a hypothesis through multiple methods. We note explicitly that these assignments are reversed relative to the National Academies consensus report (NASEM 2019), where reproducibility denotes obtaining consistent results using the same input data, computational steps, methods, code, and conditions of analysis. The property our indicators measure corresponds to NASEM's computational reproducibility, a property that has no dedicated name in the 2025 scheme. To avoid ambiguity, this response uses the term machine-verifiable execution consistency: the ability of software, following an open specification, to confirm that reported quantitative results are consistent with the declared data, the declared methods, and the specified computation. Such checking establishes consistency with declarations; it does not establish that the

declared analysis was the one historically performed. NASEM (2019) is explicit that "exact reproducibility does not guarantee the correctness of the computation." Nothing proposed below claims otherwise, and the indicator design treats that limit as a design input rather than a caveat.

THE MEASUREMENT GAP. NIH already operates extensive policy instruments across the research life cycle — the rigor and transparency review criteria in effect since FY2016, authentication plans, the Data Management and Sharing Policy in effect since 2023, the Genomic Data Sharing Policy, the 2024 Public Access Policy, and clinical trial registration and results reporting — including post-execution disclosure and reporting. What remains underdeveloped is a standardized, NIH-wide mechanism for independently machine-checking reported quantitative computations against their declared inputs and methods. A decade of empirical work shows why that layer matters and why statements are weak proxies for practice. In a study of 3,556 articles across 333 BMC journals, 123 of 1,792 manuscripts (6.8 percent) whose authors had stated in a data availability statement that they would share data actually provided it when asked (Gabelica et al. 2022). In a large-scale study of more than 2,000 publicly deposited research code-and-data packages, 74 percent of the R files they contained failed to complete on initial execution (Trisovic et al. 2022). Among 25 articles carrying open-data badges in a leading psychology journal, only 36 percent could be fully analytically reproduced from the original data without author assistance — computational reproducibility in the NASEM sense — and the dominant failure cause was analytical procedures too ambiguously reported to re-execute (Hardwicke et al. 2021). At the same time, policy stringency and enforcement are associated with substantial changes in reporting, data reusability, and re-execution outcomes: a mandatory open-data policy at one journal was followed by an increase in data availability statements from 25 to 78 percent of articles, with data judged reusable in principle rising from 22 to 62 percent (Hardwicke et al. 2018), and journal policy strictness correlates with re-execution success (Trisovic et al. 2022). Finally, the most mature machine checks in existence are automated consistency checks of reported statistics: for supported, machine-detected APA-style null-hypothesis test results, statcheck validation studies reported classification accuracy between 96.2 and 99.9 percent — which does not imply equivalent detection coverage of all statistical results in an article — and such checks have found at least one internally inconsistent statistical result in roughly half of checkable psychology articles (Nuijten et al. 2016; Nuijten, van Assen, Hartgerink, Epskamp & Wicherts 2017), with granularity checks finding a similar rate in a separate sample (Brown & Heathers 2017). These findings support testing execution-side indicators — provided their guarantee boundary is designed in from the start.

PROPOSED INDICATOR 1 — MACHINE-VERIFIABLE COVERAGE (MVC): A CANDIDATE INDICATOR PROPOSED FOR PILOT VALIDATION. MVC measures how much of a research output's quantitative claims can be, and has been, independently machine-checked. It is deliberately reported as a vector, not a single ratio, because collapsing it to one number invites both gaming and misreading. For a given article or project, MVC reports:

- N_major: the number of major quantitative claims, drawn from a claim inventory declared by the authors and confirmed during review;
- N_eligible: the subset of those claims that fall under a published eligibility rule (i.e., a public verification profile exists for the analysis class);
- N_recorded: the subset represented in machine-verifiable structured records — including, where applicable, claims inside a declared closed verification surface, defined below;
- N_verified: the subset whose records have passed independent verification under the applicable public verification profile (record integrity, declared provenance relations, specified computation, numerical

consistency);

- N_bound: the subset of verified claims whose reported values in the final research artifact have additionally been machine-matched, within declared numerical tolerances, to the corresponding structured record;
- N_unsupported: claims whose analysis class has no verification profile yet, reported as a distinct state and never counted as a failure.

These states are nested: N_bound ≤ N_verified ≤ N_recorded ≤ N_eligible ≤ N_major, with N_unsupported = N_major – N_eligible. Two coverage ratios are derived and always reported together: coverage over all major claims (N_bound / N_major) and coverage over eligible claims (N_bound / N_eligible); when N_eligible = 0, the eligible-claims ratio is reported as NOT APPLICABLE, never as zero. Reporting both ratios is an anti-gaming measure: if only the eligible-claims ratio were used, there would be an incentive to classify inconvenient claims as ineligible; if only the all-claims ratio were used, fields with many not-yet-supported analysis classes would be structurally penalized. The distinct unsupported state prevents unsupported methods from being mislabeled as verification failures; it does not by itself remove disincentives to methodological novelty, since all-claims coverage still falls when many claims are unsupported. For this reason, all-claims coverage must not be used to rank investigators, fields, or methods.

MVC is itself an unvalidated measurement construct, and this response treats that as a first-order fact rather than a footnote. Its measurement properties are not yet established: whether independent raters construct the same claim inventory (inter-rater agreement on N_major), whether eligibility classification is consistent across raters, whether independently developed verifiers agree (implementation concordance), and how sensitive the vector is to choices of claim granularity, are all open questions. We therefore propose MVC as a candidate indicator whose reliability and validity should be a primary object of the pilot described below — not as an indicator ready for adoption.

A declared closed verification surface, referenced above, is a delimited set of research outputs — for example, the specified quantitative elements of a figure, its legend, and the corresponding Methods and Results statements — that are generated from, or explicitly bound to, a single structured analysis record, such that every declared in-scope value or structured relation covered by the applicable verification profile can be machine-checked against that record. Within such a surface, checking is binary and complete relative to the declared surface and its verification contract; the coverage vector then records how much of the article's claim inventory lies inside declared surfaces. The two mechanisms are complementary: surfaces make the numerator crisp, and the inventory-based denominators make selective declaration visible.

The final-artifact value binding component (N_bound) is essential rather than optional. One practical advantage of text-based checks such as statcheck is that they test values as actually published; a structured record, by itself, is a self-declaration. Binding record values to the values reported in the final artifact preserves the property that verification confronts the published claim, not a parallel account of it. Consistency of content outside a declared surface — including any subsequent edits in word processors or publisher typesetting — is established only by this explicit value binding and is never presumed.

WHAT MVC ESTABLISHES AND WHAT IT DOES NOT. For claims counted in N_bound, the measurement establishes only that the covered quantitative elements are represented in structured records, that the reported computations have been independently re-derived from the declared inputs under an open specification, and that the published values match those computations within declared tolerances. It does not establish that the experimental design was appropriate, that the data are authentic, that the recorded analysis was

the one historically performed, that the statistical model was well specified, that causal interpretations are warranted, or that the scientific conclusions are true. An internally consistent fabrication would pass; a retrospectively constructed record that is internally consistent would pass; a correct analysis expressed in a not-yet-supported method would register as unsupported, not as failed. Machine verification of this kind is a lower bound on internal consistency — in NASEM's framing, an indicator of transparency serving indirect assessment — and any deployment should prohibit representing verification status as evidence of scientific validity. We recommend that this prohibition be an explicit design requirement of any NIH adoption, including in how results are displayed: verification output should take the form of a vector of named checks with explicit not-evaluated dimensions (for example: artifact integrity, recorded-input binding, specified computation, numerical consistency, final-artifact value binding — each PASS/FAIL/UNSUPPORTED — alongside experimental design, data authenticity, causal validity, independent replication — each NOT EVALUATED), rather than a single "verified" label.

PROPOSED INDICATOR 2 — INDEPENDENT VERIFICATION PASS RATE (IVPR), PILOT ONLY. Among structured records submitted for a defined scope, IVPR is the share that pass independent verification of record integrity, declared provenance relations, specified computation, and numerical consistency. We propose IVPR only for piloting and program evaluation, not for investigator-level assessment, because it lacks predictive-validity evidence and is the component most exposed to Goodhart dynamics if elevated into a reward. Its pilot value is diagnostic: it measures where and why verification fails (environment capture, ambiguous specification, tooling gaps), which is exactly the information needed to improve infrastructure.

INFRASTRUCTURE REQUIRED. Computing these indicators requires: an open, versioned specification for structured analysis records, such that — given the required record and evidence — any authorized third party can execute verification under the public specification without proprietary issuer logic or dependence on any single service (issuer-independent verification, a property of open specifications and third-party execution rather than of any count of implementations); public conformance fixtures so that implementations can be checked against one another; ideally, more than one independently developed verifier implementation with distinct numerical backends, to reduce shared-implementation error — with cross-implementation concordance itself measured in the pilot rather than assumed; a registry with trusted timestamps so that selective disclosure among registered records can be detected — unregistered analyses remain outside detection; and reuse of existing standards vocabularies rather than invention — W3C PROV for provenance relations, RO-Crate and CodeMeta for packaging and software metadata, FAIR4RS for research software, and the NISO RP-31-2021 reproducibility badging taxonomy for any user-facing status vocabulary, with terminology explicitly mapped to the definitions used in this response.

Institutional precedents demonstrate that third-party verification is operable in practice: the ACM TOMS Replicated Computational Results initiative (since 2015), the CODECHECK certificate register, the cascad certification agency (including third-party checking of analyses on restricted data inside a secure computing environment), and publisher-side computational verification workflows. This proposal does not claim novelty in third-party computational verification itself; those programs demonstrate that such verification events are operationally feasible. The additional element proposed here is to test whether those events can be represented as a standardized, machine-readable measurement state — combining a public eligibility profile, an independent recomputation outcome, final-artifact value binding, explicit not-evaluated dimensions, and portfolio-level coverage denominators — designed for funder-level aggregation and integration with existing processes. Whether that additional measurement layer is useful to NIH is a question for the proposed pilot, not an assumption of this response.

As evidence that a substrate of this kind is implementable (offered as feasibility evidence, not as evidence of policy merit): an open record schema, an independently runnable open-source verifier, and public conformance fixtures for a deliberately narrow, explicitly experimental verification contract covering one analysis class (Welch two-group comparisons) are publicly available under an Apache-2.0 license, released by the respondent and fixed by the immutable version identifier given in the attached references, so that this evidence does not change after submission. The current demonstration implements only the structured-record and scoped statistical-recomputation portion of this proposal. It does not implement MVC claim inventories, closed verification surfaces, final-artifact value binding, registry-based coverage measurement, multiple independent verifier implementations, or secure-enclave execution; those are proposed pilot components.

IMPLEMENTATION APPROACHES. Integration should reuse existing process surfaces across the award life cycle rather than create new bureaucracy, and should respect the timing of what exists when. Pre-award, applications can state whether, and for which analysis classes, the project intends to produce verification-eligible artifacts — alongside the rigor and transparency sections and Data Management and Sharing plans that applications already contain; the claim inventory itself concerns completed outputs and cannot exist at application time. Post-award, claim inventories, records, and coverage reporting can attach to annual progress reporting, where NIH already tracks data-sharing implementation, and to publication workflows. Evaluation of any pilot can use the implementation-science frameworks NIH has already designated for Gold Standard Science assessment (CFIR and RE-AIM). NIH could pilot two pathways for the same class of eligible computational analyses. In a legacy pathway — which would require no new authoring environment — a machine-readable record is constructed retrospectively from the analysis artifacts and documentation investigators already produce; this measures the practical ceiling of post-hoc reconstruction, because information that was not captured at execution time cannot reliably be reconstructed later and frequently requires author assistance, as the reproducibility literature documents. In a native pathway, which would separately test participating tools capable of execution-time record capture, tools emit the record at execution time and may generate a declared closed verification surface from the same structured record. Within that declared surface, deterministic generation can structurally preclude drift along the canonical generation path; consistency with content outside the surface is still established only by explicit value binding and is not presumed. Across the two pathways the pilot should compare verification coverage, missing-information rates, author and reviewer burden, final-artifact binding success, observed gaming behavior, and failure modes. Neither pathway should be treated as producing evidence of scientific validity.

PILOT DESIGN. We recommend a voluntary, registration-based pilot in one or two Institutes or Centers with computation-heavy portfolios, with a concurrent comparison group, prospectively sized with prespecified primary outcomes; any inferential comparison should have a justified sample size. The primary question of the pilot should be measurement itself: can MVC be measured reproducibly, at tolerable burden, without unacceptable gaming or field bias? Concretely, the pilot should measure inter-rater agreement on claim inventories and on eligibility classification; concordance between independently developed verifier implementations; false-pass and false-fail rates against a manual expert-audit benchmark; the sensitivity of the coverage vector to claim granularity; burden by career stage and institution type; observed gaming; and discipline differences. The legacy-versus-native comparison described above is the secondary, implementation-level question. The rationale for building evaluation in from the start is empirical: nominally similar incentive interventions have produced divergent results in different contexts — open-data badges were associated with a rise from under 3 percent to roughly 39 percent data sharing in one journal's observational data, while a randomized trial at another journal did not detect an increase, with a highly imprecise estimate that

could not rule out meaningful effects in either direction — so context-dependence should be assumed and measured rather than argued.

POTENTIAL BENEFITS. Execution-side indicators of this kind could add a standardized measurement layer to NIH's developing metric framework where composite measures are still under development; could allow journal reviewers, reproducibility auditors, and programmatic reviewers of completed outputs to spend less attention on arithmetic consistency and more on design and interpretation; could reduce the cost of computational re-execution and of evidence review — whether they affect the cost of experimental replication should be tested rather than assumed; may support long-term preservation of analysis evidence through registry and archival integration; and could give existing mandates (data sharing, rigor criteria) an execution-side outcome measure they currently lack.

UNINTENDED CONSEQUENCES AND ANTI-GAMING DESIGN. We enumerate the principal failure modes and their status honestly, because several are structural rather than fixable. Mitigable by design: surface or claim cherry-picking (mitigated, not eliminated, by the dual denominators and the claim inventory); denominator manipulation via narrow "major claim" definitions (claim inventories confirmed at review); eligibility laundering, i.e., classifying inconvenient claims as ineligible (published eligibility rules plus the all-claims ratio); selective disclosure of passing records (registry with timestamps; unregistered analyses remain undetectable); verifier monoculture and self-verification (third-party execution required; cross-implementation concordance measured); template farming and claim salami-slicing (claim inventories subject to independent review and audit; raw claim counts never themselves used as rewards; judgments of claim granularity and importance remain a human review function); post-publication mutation of reported values (detectable on re-verification of the published artifact, conditional on re-verification actually being run — not structurally prevented). Structurally unavoidable, and therefore boundary rather than bug: semantic overinterpretation in prose outside declared surfaces; analysis-path selection among internally consistent alternatives; analyses that are wrong in design or model specification yet perfectly executed; and internally consistent fabrication, including retrospective record construction. For these, the honest countermeasure is the display and reporting prohibition described above — verification status must never be presented as validity — plus the separate mechanisms science already uses (audit, raw-data requirements, replication). Two further consequences deserve explicit monitoring: discipline and institutional inequity, since computational fields and well-resourced institutions can generate records more cheaply (partially addressed by scope limitation, hosted verification options, and the unsupported state); and checkbox compliance, the documented fate of data availability statements, which argues for pairing any indicator with spot enforcement rather than self-report alone. Consistent with DORA, the Leiden Manifesto, the Metric Tide, and CoARA, these indicators should support qualitative assessment and never substitute for it; the vector reporting format is chosen specifically so that no single number exists to be ranked on.

FEASIBILITY ACROSS CAREER STAGES, DISCIPLINES, AND INSTITUTION TYPES. Scope should begin with narrow computational analysis classes for which a public verification profile can be specified, benchmarked, and independently tested — the setting in which validated automated checks already exist. Restricted and controlled-access data could participate in a pilot through secure-enclave execution: cascad/CASD demonstrates the feasibility of third-party computational checking without public data release, and adapting the machine-verifiable architecture proposed here to such environments would require separate implementation and validation; issuer independence can in principle be preserved even for hosted execution so long as the specification is open and third parties can execute verification. Smaller institutions without local compute could use hosted verification under the same open contract. Petabyte-scale computations and analyses

locked to proprietary software environments should be explicitly out of scope for an initial indicator rather than papered over. The pilot should stratify burden and adoption by career stage rather than assume an advantage or disadvantage in advance.

A PDF version of this response, including full references, is attached.

Topic 2: Data, Software, and Model Sharing

This response extends the framework proposed under Topic 1 (Rigor and Reproducibility) to sharing incentives; the definitions, guarantee boundary, anti-gaming design, and pilot structure described there apply here and are not repeated.

FROM EXISTENCE METRICS TO VERIFIABILITY METRICS. Many scalable automated indicators of sharing measure reporting or existence — a data-availability statement, a repository deposit, a code link — rather than successful reuse or re-execution. Existence can be measured at scale: automated extraction across 2.75 million open-access articles estimated mentions of data-sharing information in 14.5 percent of articles and of code-sharing information in 2.5 percent (Serghiou et al. 2021). But the evidence shows that existence alone can be a weak proxy for the outcomes sharing policy actually seeks: 6.8 percent actual provision among authors who had stated willingness to share (Gabelica et al. 2022); 74 percent initial execution failure among the R files in publicly deposited code-and-data packages (Trisovic et al. 2022); and full unassisted analytic reproduction from original data in only about a third of badge-carrying articles (Hardwicke et al. 2021). Rewarding existence therefore invites the documented checkbox outcome. We propose that NIH pilot whether verified-use and binding states — the full Machine-Verifiable Coverage vector restricted to shared artifacts, interpreted qualitatively — can complement availability and deposit evidence in future sharing incentives. Consistent with Topic 1, this proposes the construct for validation before any connection to rewards; raw counts of bound claims or of deposits, both trivially inflatable, should never themselves be reward-relevant.

SOFTWARE SHARING. NIH-wide research-software sharing is addressed primarily through best-practice guidance rather than a uniform mandatory software-sharing policy. Rather than proposing new mandates, we propose a measurable standard that any future incentive could attach to: software shared with sufficient metadata and environment capture to permit independent re-execution — reusing CodeMeta and FAIR4RS for metadata and interoperability, while a separate verification profile specifies the dependency, environment, and execution requirements that metadata alone does not guarantee — with re-execution success measured rather than assumed. This would convert software sharing from a statement into an event that can be counted, and could provide an execution-side outcome measure for future NIH software-sharing incentives or reporting, without assuming that the Data Management and Sharing Policy itself applies to research software. This initial proposal does not attempt to define a separate indicator for computational-model sharing.

EQUITY ACROSS DATA TYPES. Verification-based sharing measures must not be limited to data that can be posted publicly. Controlled-access and restricted data could participate through verification executed inside secure computing environments, for which an operating precedent exists in third-party checking without public data release (cascad/CASD), with only the verification outcome — not the data — leaving the environment; adapting the proposed machine-verifiable architecture to such environments would require separate implementation and validation. This matters for feasibility across fields: human-subjects research would otherwise be structurally excluded from any verification-linked measure, which would be both inequitable and a perverse incentive against sensitive-data research.

1. Rigor and Reproducibility: Rigor and reproducibility are essential for advancing research and transforming science into discoveries that benefit public health and build trust in science. The National Institutes of Health (NIH) should revise the NIH Data Management and Sharing Policy to create standard operating procedures for the management and sharing of data, guide the review of data and data analysis, and strengthen data integrity practices.

All NIH intramural and extramural researchers supported by training grants or career development awards are required to take Responsible Conduct of Research (RCR) courses. NIH should consider expanding RCR training to all researchers (graduate students, postdocs, staff, PIs) to develop and enhance their foundational knowledge of experimental design, replication, and reproducibility.

A cultural shift is needed in the academic system to incentivize replication studies. The current tenure system rewards scientific advancements. Novel discoveries and related publications are what help protect a Principal Investigator's (PI's) job security and lead to promotions. The "publish or perish" mentality discourages replication studies as the publication of "negative" or non-innovative data is not seen as something that will help advance their research or their career. Incentives and rewards must be built into the grant application system to consider replication in the context of rigor and reproducibility and shift the culture of the tenure system.

Implementing plans to validate previously published scientific data and to generate novel data are two important but separate goals that require different incentives and rewards. To support ongoing and future research efforts, NIH should consider providing PIs with additional financial support for additional materials and other costs associated with replicating their own scientific findings when needed. While the onus is on the PI for ensuring all lab personnel are adhering to best practices in the lab to maximize rigor and reproducibility efforts and avoid scientific misconduct, the NIH should consider providing workshops and resources to help PIs and their institutions with training to maintain consistency across the U.S. Evaluation of plans for addressing rigor, reproducibility, and transparency should be underscored through the grant review process.

To address the reproducibility of previously published fundings, NIH should create a dedicated funding

stream (such as a new R award) to support the materials and personnel needed for the replication of high-impact findings and should coordinate which research findings are prioritized for replication to avoid duplicative efforts. To incentivize researchers to replicate and publish replication studies of previously published studies, NIH should partner with high-impact journals to provide a pathway for publications of replication efforts that help researchers build prestige. Building upon NIH's desire to support and expand data sharing among researchers, NIH could require that all raw data be uploaded for sharing, except when disclosure of such data would potentially identify human subjects. Supplemental data repositories can be cost limiting for journals. NIH should find a way to partner with journals to support these extra costs. It is important to note that replication of clinical trials may be challenging, particularly for studies involving rare diseases or diseases that affect specific populations. There may not be enough patients in the U.S. or worldwide for a new cohort to yield statistical power for a replication study.

2. Data, Software, and Model Sharing: NIH must develop clearly quantifiable metrics to assess the utility and reuse of shared data, software, and models. Study section review is essential for the evaluation of these shared resources to ensure fairness amongst researchers. NIH could consider creating a "citation index" as a metric to quantify the use and reuse of shared scientific data and tools. A combination of the number of downloads, number of article citations, and number of derivative products that were developed from these resources could be used to develop the citation index.

To incentivize the development and validation of new software and models for the advancement of biomedical research, NIH should consider developing a new grant category for methodology development and in silico modeling development. Through this mechanism, projects that have clear plans for producing new technologies, methods, and tools could be prioritized as a way to incentivize these important activities.

3. Training and Mentorship: Training and mentoring graduate students and postdoctoral researchers (postdocs) is essential for the professional development of the next generation of scientists. Recognizing and rewarding effective training and mentorship will foster healthier and more productive research environments that advance medical research.

While mentorship is an essential skill for lab leaders to have, it is not routinely taught. Instead, mentorship skills are often derived from learned experiences, leaving trainee experiences to vary greatly across PIs and institutions. For mentoring to be successful, formal training in mentorship for PIs and trainees is needed to create a baseline mentoring experience to support the PI and all trainees and staff in the lab; the creation and distribution of supportive resources would further such efforts. NIH can use existing mentoring programs as a model for program development, such as the Howard Hughes Medical Institute (HHMI) Gilliam Fellows Program, which incorporates the professional development of the mentor-trainee relationship into its overall training experience. The mentor is required to go through a year-long mentorship development course to help the mentor build skills to create a healthy, supportive lab environment for their trainees' success.

Mentorship should be viewed as a measurable competency. Evidence of effective mentorship could be collected by NIH regularly at intervals throughout the trainee's time with particular attention paid to the experiences of trainees on training grants and fellowships. To develop a measurable metric for

evaluation, the mentor and mentee can create a shared training plan and conduct progress checks to track the progress and execution of the training plan. To protect trainees from potential retaliation for unfavorable evaluations, the information collected should remain confidential or should be aggregated (if there is enough aggregate information to protect anonymity). Should ineffective mentoring be identified during or after the training period, care should be taken to ensure that any consequences do not indirectly harm the trainee (e.g., negative impacts on current or future funding—whether through research project grants, training grants, fellowships, etc.— could materially harm the trainee's progress and prospects). Alternatively, a final exit survey could be conducted to gather feedback about both the mentor and mentee experience.

Quality and effective mentorship is not sufficiently recognized or rewarded through the traditional academic system. PIs do not receive adequate financial support or recognition for the time and effort required to provide excellent mentorship of graduate students and postdocs. To help shift the current academic culture, NIH should consider providing more tangible support for mentors on the K series of awards and training grants, namely providing funding and protected time, as good mentorship requires substantial time and effort. Additionally, non-monetary recognition of mentorship that can be placed on curriculum vitae (CVs) and biosketches could be modeled from NIH intramural awards from ICs such as NIA and NIMH to further showcase a PI's effectiveness in mentoring.

4. Collaboration: Collaboration is important for advancing research in the U.S. and around the world and is traditionally acknowledged through authorship on publications. The ordering of authors on a manuscript often fails to highlight and recognize all critical scientific contributions. NIH should develop a subsequent RFI to identify and utilize a new recognition system to better attribute collaborative efforts and credits to manuscript authors. An existing example of such a recognition system is called Contributor Roles Taxonomy (CRediT). CRediT recognizes 14 contributor roles that are designed to represent the different types of contributions that investigators make for scholarly publications. When developing metrics to assess collaborative contributions, NIH must gather additional input from the scientific community to ensure that the myriad of ways to contribute scientifically are appropriately captured.

5. Entrepreneurship and Translation: If entrepreneurship is to be used as a metric for measuring scientific impact, NIH should note that most scientists are not educated or trained on the topic of entrepreneurship. Educational opportunities and training will be needed to develop foundational knowledge in business development, strategy, fundraising, and technology transfer. In parallel to training, NIH could consider developing a mentoring system to partner investigators who are new to entrepreneurship with those who are experienced in entrepreneurship. NIH could incentivize entrepreneurship through the incorporation of entrepreneurial training for trainees and their mentors in training grant program curriculum.

6. Foundational Scientific Exploration: We identify three considerations that should be addressed to incentivize and reward foundational scientific exploration through high-risk, high-reward initiatives. First, funding for exploratory, high-risk, high-reward projects should not detract from funding for traditional research project grants. Second, training graduate students and postdocs requires additional oversight, support, and protection when working on high-risk, high-reward projects. In this regard, NIH should advise PIs to provide their trainees with a diversified project portfolio. If a high-risk, high-reward project does not work out, trainees should have other projects with less risk to support their continued scientific training. Last, when conducting high-risk, high-reward research, there is a risk that the project will not

produce the anticipated results (i.e. yield negative data). Value and recognition for these worthwhile studies, regardless of the results, should be attributed to the researcher through publication or other means.

It is important to note that identifying and measuring the impact of high-risk, high-reward initiatives can be subjective. Study section review should be maintained as part of the scientific review process to evaluate and prioritize which high-risk, high-reward initiatives should be supported and to avoid penalizing investigators who took on high-risk, high-reward projects that did not yield groundbreaking results.

7. Public Impact: As responsible stewards of U.S. taxpayer dollars, scientists have the responsibility to share their research progress and outcomes with community members and build trust in science through public engagement. The public engagement of science is a learned skill that needs practice and refinement to maximize impact and success. Not all researchers have the opportunity to develop this skillset and put their skills to practice by speaking with non-scientists about their research.

NIH should provide workshops or other methods of science communication and public engagement training for all NIH-supported researchers. Training opportunities will make assessing and rewarding public engagement and impact more feasible and fairer. Otherwise, without such training, scientists could be unfairly penalized through the grant review process for failing to create effective public engagement plans.

The NIH should consider adopting models and practices used by agencies and organizations such as the National Science Foundation (NSF) and Patient-Centered Outcomes Research Institute (PCORI). In addition to publishing a post-study report that includes a summary for non-scientists to read, PCORI requires awardees to describe plans for the dissemination of their work beyond publications in the scientific/medical literature. NSF grant applicants are required to describe the broader impact of their work and explain how their research benefits society. NSF uses five criteria to evaluate broader impacts which includes the potential benefit to society, ability to explore transformative concepts, and feasibility. NSF does not prescribe what activities meet their broader-impacts goals, but some of their examples of desired outcomes such as increasing public scientific literacy, education, development of the STEM workforce, and increasing the economic competitiveness of the U.S. As part of the implementation process to measure public engagement and impact, the NIH should consider providing examples of meaningful engagement that will be recognized while maintaining flexibility to support novel and meaningful activities. Ideas of public engagement opportunities could include partnerships with community organizations, advocacy organizations, or science communicators, activities that specifically engage with patients or community members, or opportunities to shape policy development.

To capture, assess, and recognize researchers' efforts on the public impact of research, the NIH may need to modify the grant application to allow researchers to report their public engagement activities and outcomes. This could be done by modifying the biosketch to include a section on public engagement or by adding an additional section to the grant application itself.

Measuring and assessing the effectiveness and return on investment (ROI) as a means of quantifying scientific impact is subjective. Public impact requires both short-term and long-term monitoring and

evaluation of the target audience. Additional funding and resources are needed to support short-term and long-term monitoring of proposed efforts to more accurately measure and evaluate ROI.

Response to NOT-OD-26-087: Request for Information on Measuring and Rewarding Scientific Impact

For reference: NOT-OD-26-087: Request for Information on Measuring and Rewarding Scientific Impact

Cambridge University Press and University of Cambridge Libraries and Archives strongly support the NIH's effort to realign research incentives with the values of rigor, openness, collaboration, and societal benefit.

Meaningful reform of research assessment requires coordinated action across the research ecosystem, including publishers, institutions, funders, and researchers themselves.

Many of the commendable principles reflected in this Request for Information are already being implemented via initiatives such as the San Francisco Declaration on Research Assessment (DORA) and the Coalition for Advancing Research Assessment (CoARA). Both Cambridge University Press and the University of Cambridge are signatories of DORA. The Press is also a sustaining supporting member of DORA and serves on its Steering Committee, with University of Cambridge Libraries and Archives serving as an alternate member. Across the University of Cambridge, responsible research assessment has already been embedded into institutional practice. The University has also successfully implemented the DORA principles and is progressing changes towards responsible research assessment and open research practices. As a result, the university's recruitment, promotion and reward processes now place substantially less emphasis on publication counts and journal-based metrics.

Cambridge University Press' recent *Publishing Futures* report, a sector-wide review of more than 3,000 stakeholders in the scholarly research ecosystem, highlights the urgent need to reform research-assessment incentives and develop stronger ways to measure research impact, changes that will deliver meaningful benefits for both the scientific community and society at large.

For example, in line with NIH's note that current metrics of scientific success rely heavily on individual-level indicators of productivity, such as publication counts and citation metrics, *Publishing Futures* found that existing academic reward systems worldwide still commonly tie career advancement to the number of published journal articles. Incentivising quantity over quality has resulted in ballooning publication volumes, some of questionable quality to the research ecosystem, which in turn increases the costs of the entire research dissemination system. We know the NIH also shares our concern about these costs.

Fixing these system-wide problems will be challenging but achievable and will depend on rethinking how we measure and reward research so that incentives align with meaningful, high-quality impact.

We therefore strongly support NIH's focus on developing measurable indicators and practical implementation approaches that better recognise rigorous, transparent, and collaborative research.

Our recommendations include:

1. Implement Responsible Research Assessment Principles

DORA provides a well-established framework for improving research assessment across funders, institutions, and publishers. NIH should encourage DORA-aligned assessment practices that:

- evaluate research on its intrinsic quality and contribution rather than the prestige of the publication venue or Journal Impact Factor
- recognise the full range of research outputs, including datasets, software, protocols, and other products that enable scientific progress
- establish transparent and explicit criteria for funding and career advancement
- use quantitative indicators responsibly to support, rather than replace, expert qualitative assessment, while avoiding inappropriate reliance on institutional rankings or journal metrics

These principles are directly aligned with NIH's objective of rewarding scientific rigor, reproducibility, and long-term scientific contribution.

DORA has recently published guidelines for funders that may be particularly useful to NIH colleagues: A Practical Guide to Implementing Responsible Research Assessment at Research Funding Organizations.

2. Reward FAIR Data, software, and model sharing

NIH should explicitly recognise and reward FAIR (Findable, Accessible, Interoperable, and Reusable) research outputs as indicators of scientific impact.

Funding applications and research assessment should consider not only publication plans but also commitments to depositing well-documented datasets, software, computational models, and other research objects in FAIR-compliant repositories.

Both Cambridge University Press and the University of Cambridge actively support FAIR principles. The university’s Research Data Management Service provides institutional support for FAIR data stewardship, while the Press’ open research policies promote these practices that improve the discoverability, accessibility, interoperability, and long-term reuse of research outputs.

Rewarding FAIR-compliant sharing would create stronger incentives for reproducibility, secondary analysis, and cumulative scientific progress.

3. Recognise collaboration and scholarly service as academic labour

Research assessment must better recognise collaborative contributions that are essential to maintaining a healthy research ecosystem but are often invisible within current reward systems.

The *Publishing Futures* report highlighted widespread concern that activities such as peer review, editorial service, mentoring, community leadership, and stewardship of shared research infrastructure receive insufficient recognition despite their importance to research quality.

We encourage NIH to recognise these activities within assessment and reporting frameworks and to encourage institutions to treat peer review, editorial work, and other forms of scholarly service as valued academic research contributions, consistent with emerging practices across the sector.

Conclusion

The reforms proposed in this Request for Information represent an important opportunity to shift research assessment away from quantity-based proxies and toward demonstrable scientific contributions. By adopting responsible assessment frameworks, rewarding FAIR data and software sharing, and valuing collaboration and scholarly service, NIH can accelerate a culture change that is already underway across the global research community.

Such reforms would strengthen scientific rigor, improve reproducibility, encourage openness, and better align incentives with the activities that produce robust, trustworthy, and societally valuable research.

1. Rigor and Reproducibility: Rigor and reproducibility should be recognized as scientific contributions in their own right. Replication studies, independent validation, robustness analyses, and efforts to identify or correct limitations in existing findings may be essential to scientific progress even when they produce fewer publications or citations than novel findings.

A contribution-provenance approach could help make these contributions visible. For example, a replication or validation study could be linked to the research it evaluates and, in turn, to subsequent research that relies on the validated finding. Such relationships would provide evidence of a contribution to the reliability of the scientific record rather than simply counting the resulting publication.

NIH should therefore consider indicators such as independent replication, validation, reproducibility of methods and results, identification and correction of errors, and documented downstream use of validated findings. These measures should supplement rather than replace traditional publication and citation measures.

Importantly, the system should avoid creating incentives to pursue only easily replicable or low-risk research. The objective should be to recognize rigor and reproducibility as additional dimensions of scientific contribution while preserving appropriate incentives for exploratory, foundational, and high-risk research.

2. Data, Software, and Model Sharing: I suggest that NIH consider moving beyond counting whether data, software, and models are shared toward measuring and recognizing how those research products are subsequently used.

A scientist may spend years creating a dataset that enables dozens or hundreds of subsequent studies. Another may develop software that becomes an essential tool for an entire research community. Traditional publication and citation metrics can substantially under represent these contributions.

NIH should therefore recognize not only the creation and sharing of research products, but also their documented reuse. Potential indicators could include the number of independent research groups using a dataset or software tool, resulting publications, use in replication or validation studies, incorporation into subsequent datasets or models, and downstream contributions to clinical or translational research.

There is already substantial infrastructure on which such an approach could build. DataCite provides persistent identifiers and metadata relationships for research outputs and explicitly recognizes data citation as a mechanism for providing credit to researchers. OpenAIRE's research graph connects publications, datasets, software, researchers, projects, and other research products and records relationships among them, including provenance information. Crossref is also developing infrastructure for tracking data citations and research outputs that are reused, cited, and built upon.

This suggests that NIH need not create an entirely new system. Instead, NIH could explore whether existing scholarly infrastructure, together with NIH's own iCite system, could support a scientific contribution-provenance approach.

For example:

Dataset A → Paper B → Paper C → Review D → Clinical application E

The objective would not be to arbitrarily transfer a fraction of every downstream citation back to the creator of Dataset A. Rather, the system could make the downstream pathway visible as evidence in the researcher's assessment portfolio:

"This dataset was directly reused in 37 publications by 24 independent research groups, including studies that subsequently contributed to additional research outputs and translational activities."

This distinction is important. I would favor documenting downstream provenance rather than creating another single numerical impact score.

A portfolio-based system could retain traditional measures such as publications and citations while adding evidence of the creation, reuse, and downstream contribution of datasets, software, models, methods, and protocols.

NIH could initially pilot such an approach in several fields and career stages, compare it with conventional assessment, and evaluate both its usefulness and potential unintended consequences. The goal would be to determine whether documenting the pathway from research contribution to subsequent scientific use provides evaluators with meaningful information that is currently missing.

The broader principle is:

Scientific assessment should ask not only what a researcher produced, but how those contributions were subsequently used and what scientific activity they helped enable.

3. Training and Mentorship: N/A

4. Collaboration: Current research assessment often assigns credit primarily through publications, authorship position, citations, and grant leadership. These measures can under represent substantive contributions made by members of large or interdisciplinary teams.

A contribution-provenance approach could provide an additional way to recognize team science.

Rather than treating a publication or research project as a single unit of credit, research outputs could be connected to specific contributions using persistent identifiers and structured contributor information. Those contributions could include data generation and curation, software development, methodology, models, protocols, analysis, infrastructure, and other substantive roles.

The important next step would be to preserve evidence of what happens to those contributions downstream.

For example, if one member of a team creates a dataset, another develops software to analyze it, and a third performs the analysis that becomes the basis for subsequent studies, the research record could preserve those relationships. The resulting portfolio would show not only authorship but the contribution pathway.

This should not become a formula for mechanically dividing citations among coauthors. Rather, it should provide evaluators with additional evidence about the nature, extent, and subsequent use of an individual's contribution.

Existing infrastructures such as CRediT, persistent identifiers, DataCite, Crossref, and OpenAIRE provide components of such a system. NIH could explore integrating or extending these approaches and piloting contribution-provenance records in team-based research.

This would be particularly valuable for researchers whose major contributions are difficult to capture through first-author or senior-author counts, including data scientists, software developers, methodologists, infrastructure builders, and other members of interdisciplinary teams.

The objective should be to recognize substantive contribution rather than simply position within an authorship hierarchy.

5. Entrepreneurship and Translation: Patents and other forms of innovation should be included in scientific assessment portfolios. A patent, however, should not be treated as equivalent to a successfully translated technology. Patent filing, patent issuance, licensing, commercialization, clinical development, and demonstrated health impact represent different stages of a contribution pathway.

NIH's own technology-transfer activities illustrate the value of following such pathways. NIH has documented how licensed technologies can generate subsequent inventions, research and development, clinical trials, and ultimately health and economic benefits.

The same principle could be applied more broadly to scientific research: assessment should preserve evidence of the pathway from an original contribution through subsequent research and, where applicable, translation.

I would also recommend retaining established measures such as publications, citations, and grants rather

than attempting to replace them with a new metric. These measures have limitations, but they also have intrinsic value and provide useful evidence of scientific activity and influence. Completely discarding them would be particularly problematic for investigators whose career development was guided by the existing system and its rules.

The better approach is a portfolio of evidence.

Traditional measures could be supplemented by evidence concerning data and software reuse, replication, mentorship, collaboration, patents, translation, and downstream scientific utilization.

This is particularly important for foundational and high-risk research. Scientific value may not become apparent for years or decades, and an assessment system that rewards only immediate citations, applications, or public attention could systematically disadvantage research whose eventual contribution is substantial but delayed.

I therefore recommend against a single composite "scientific impact score." Different forms of scientific contribution are not interchangeable, and a new metric would inevitably become a new target for optimization.

Instead, NIH could develop a multidimensional portfolio in which traditional metrics remain visible alongside evidence of additional contributions and their subsequent use.

The guiding question should be:
What did this scientist contribute, how was that contribution used, and what subsequent scientific activity did it help enable?

That approach would broaden recognition without pretending that the diverse forms of scientific value can be reduced to one number.

6. Foundational Scientific Exploration: Scientific assessment should preserve and recognize foundational and exploratory research even when its eventual impact is not immediately apparent. Scientific value may emerge years or decades after an initial discovery, and foundational work may enable subsequent research in ways that are difficult to anticipate when the original work is evaluated.

This is another reason to avoid replacing existing measures with a single "scientific impact score." A metric based primarily on immediate citations, applications, commercialization, or public attention could systematically disadvantage high-risk, exploratory, or foundational research whose importance becomes apparent only over time.

Instead, NIH should consider a multidimensional portfolio in which traditional measures such as publications, citations, and grants remain visible alongside evidence of other forms of contribution, including subsequent reuse of datasets, methods, software, models, and findings.

The emerging infrastructure for linking research outputs also creates an opportunity to document these longer-term contribution pathways. A foundational discovery could be linked to subsequent publications,

methods, datasets, technologies, or clinical applications that build upon it. Such provenance would provide evidence of downstream scientific contribution without requiring NIH to predict in advance which research will ultimately prove important.

The goal should therefore not be to determine a single numerical value for every scientific contribution, but to provide evaluators with a richer body of evidence about what was contributed, how it was subsequently used, and what scientific activity it helped enable.

This approach would preserve incentives for both foundational exploration and practical application while recognizing that the time horizon and pathway to impact can differ dramatically across fields and individual research programs.

7. Public Impact: N/A

8. Other Areas: I encourage NIH to consider the overall structure of scientific assessment as an additional area for consideration. In my view, the scientific community is unlikely to reach agreement on a single metric of scientific impact, and attempting to create one would likely be counterproductive.

A better approach would be a portfolio of complementary measures. Established indicators such as publications, citations, and grants should be retained because they provide useful evidence of scientific activity and influence. They should be supplemented by measures of contributions that are currently less visible, including datasets, software, methods, replication, collaboration, mentorship, patents, translation, and downstream reuse.

The objective should be to provide evaluators with a richer body of evidence rather than to generate a new composite score. Different investigators, disciplines, career stages, and types of research will appropriately have different patterns of contribution.

The emerging ability to link research products through persistent identifiers and scholarly knowledge graphs creates an opportunity to make these contributions—and their subsequent use—more visible. NIH could help develop and test such a portfolio-based approach while studying its feasibility and unintended consequences.

In short, I would encourage NIH to move from asking "What is this scientist's impact score?" toward asking "What did this scientist contribute, how was it used, and what subsequent scientific activity did it help enable?"

Date Submitted: 8/17/2026

1. Rigor and Reproducibility: Reproducibility and replicability are foundational elements of rigorous biomedical research. As biomedical technologies become increasingly sophisticated and data-intensive, ensuring that experimental findings can be reproduced within and across institutions requires standardized methodologies, comprehensive documentation, transparent reporting, robust data stewardship including provenance tracking for shared data, and effective incentive mechanisms. All aspects of scientific data, in this context, are the key to unlocking the ground truths of many studies. In that regard, shared resource and core facilities are uniquely positioned to advance these goals because they operate at the intersection of technology, experimental design, data generation and management, and investigator training. Unlike individual laboratories, core facilities routinely implement standardized operating procedures, instrument calibration and maintenance programs, quality assurance measures, and metadata capture workflows that reduce technical variability and support consistent data generation. Core facilities maintain records of instrument settings, analytical pipelines, reagent lots, quality control metrics, and sample processing procedures, providing the detailed provenance information necessary to reproduce experiments. Core facilities frequently generate data for PIs; tagging it with accurate metadata and formatting it to community standards ensures FAIR compliance when sharing. This process also saves PIs time and effort for publications or DMS policy requirements.

Establishing institutional mechanisms and infrastructure that allow datasets, workflows, and analytical pipelines generated in core facilities to be systematically archived and reused would create opportunities for independent validation studies and cross-institutional replication efforts. Additionally, core facilities can be foundational for inter-institutional proficiency testing, developing reference standards, and replication studies. Funding to expand this inter-institutional activity would strengthen confidence in experimental findings, accelerate adoption of robust methodologies and streamline the data management process.

Developing Incentives to Reward Replication Science. Incentives for rigor and reproducibility must start with data generation. Institutions and funding agencies should recognize and reward activities such as data curation, standards development, protocol validation, quality assurance, and replication studies. Creation of widely accepted metrics that acknowledge the generation of reusable datasets, adherence to

community standards, successful independent validation of findings, and reuse/ impact of shared data would encourage broader participation in reproducibility efforts. In addition, researchers who use and reuse data to replicate/validate previous findings as well as reveal novel scientific discovery should be given credits and incentives to do so where scientific data is one of the key research products along with publications, software, patents, or clinical trials. Recently, the NEI-led S-Index Challenge called on the broad community to develop data sharing metrics to incentivize researchers for rigor and reproducibility studies. Other mechanisms of incentives are cash prize awards, such as NINDS's Replication Prize, and community-driven data use events to democratize scientific data for validation and research findings such as NCI's Data Jamboree and other hackathons would be very helpful.

179. Federation of American Societies for Experimental Biology (FASEB)

I am responding: On behalf of an organization

Name: Crytal J. Neely

Name of Organization: Federation of American Societies for Experimental Biology (FASEB)

Type of Organization: Professional Organization/Association

Role: Organizational Official

Date Submitted: 8/17/2026

1. Rigor and Reproducibility: The Federation of American Societies for Experimental Biology (FASEB) appreciates the opportunity to respond to the National Institutes of Health (NIH) Request for Information (NOT-OD-26-087), Measuring and Rewarding Scientific Impact. Representing 21 American scientific societies and more than 100,000 researchers across the biological and biomedical sciences, FASEB commends NIH's efforts to develop approaches that more fully recognize the full range of contributions that advance biological and biomedical research while maintaining the highest standards of scientific rigor and public trust.

FASEB's member societies steward critical components of the biological and biomedical research enterprise by publishing peer-reviewed journals, convening scientific meetings, and providing mentoring and career development programs that help ensure federally funded discoveries are rigorously evaluated, disseminated, and built upon by the broader research community, including industry. FASEB approaches this RFI both as a representative of individual investigators and as a steward of the infrastructure that translates NIH-funded research into scientific and public value, consistent with the principles of Executive Order 14303, Restoring Gold Standard Science (May 23, 2025). FASEB believes that rigorous, expert peer review remains the cornerstone of evaluating scientific quality, maintaining the credibility of science, and ensuring responsible stewardship of federal research investments.

NIH's reporting and evaluation frameworks represent only one component of the broader research assessment ecosystem. Many meaningful indicators of scientific quality, rigor, and impact already exist but are not consistently recognized or incorporated into evaluation processes. These indicators should complement—not replace—expert scientific peer review, which remains the most effective mechanism for evaluating rigor, originality, significance, and scientific quality in both funding decisions and scholarly publication. Peer-reviewed publications remain an essential indicator of scientific productivity; however, publication counts alone do not capture the full value of a scientist's contributions. Notably, even journals evaluate their own performance using a portfolio of complementary metrics rather than publication volume alone.

FASEB encourages NIH to partner with scientific societies, research institutions, and other stakeholders to modernize research assessment in ways that are evidence-based, practical, and appropriate across disciplines, career stages, institution types, and resource levels. FASEB stands ready to support NIH by identifying meaningful scientific impact indicators and assessment approaches, evaluating

implementation strategies, and helping minimize unnecessary administrative burden, particularly for smaller and less-resourced institutions.

Topic 1: Rigor and Reproducibility
FASEB recommends NIH:
Establish clear definitions of reproducibility and causal research before incorporating them into scientific impact assessment. NIH should clearly define these concepts and communicate consistent expectations before incorporating them into evaluation or reporting. Scientific societies can help ensure these definitions are interpreted consistently across disciplines and implemented equitably.

Complement traditional productivity measures with evidence of rigorous scientific practice. Where measurable indicators are appropriate, NIH should emphasize established practices that support rigor, including authentication of key biological and chemical resources, adherence to community reporting standards, appropriate preregistration of confirmatory studies, and successful independent validation. These indicators provide an additional layer of value and understanding of the incentive structure at institutions.

Integrate transparency for generative AI into existing reproducibility policies. As AI becomes increasingly integrated into biological and biomedical research, NIH should incorporate documentation of AI tools, such as the model, provider, and version where appropriate, within existing authentication and reporting requirements rather than creating separate reporting systems. Building on NIH's existing Enhancing Reproducibility through Rigor and Transparency guidance (NIH, 2025), this approach will promote transparency, support computational reproducibility, and minimize additional administrative burden while allowing expectations to evolve alongside advances in AI.

Invest in infrastructure that enables rigorous science. Reproducibility depends on sustained access to shared research resources, core facilities, modern instrumentation, and skilled technical staff. NIH should ensure that investments in reproducibility are matched by investments in the infrastructure needed to support them; otherwise, expectations for rigor may outpace institutional capacity.

Recognize replication as a valuable scientific contribution. Independent replication strengthens confidence in scientific findings but remains underrecognized within traditional systems of academic reward. NIH should recognize replication studies as distinct scholarly contributions within existing reporting mechanisms and continue developing funding opportunities that support high-priority replication efforts. To foster this commitment to replication, today, many societies have at least one journal in their portfolio that allows for recognition of and publication of replication studies, and several societies have supported the community further by dedicating special issues to replication studies.

Support scientific societies as critical to the research ecosystem as they seek to advance reproducibility. Biological and biomedical scientific societies are uniquely positioned to develop discipline-specific standards, identify high-priority opportunities for replication, disseminate best practices, and provide training in rigorous and reproducible research methods. NIH should continue to support society-led initiatives, including the development of training resources and the integration of rigor and reproducibility modules into programs serving researchers across career stages, including predoctoral

trainees, postdoctoral researchers, and early-career investigators.

Scientific impact cannot be meaningfully assessed without confidence in the quality and reliability of the underlying science. FASEB encourages NIH to build its scientific impact framework on the foundation of rigorous, expert peer review, which remains the cornerstone of research assessment and the credibility of science. Responsible indicators of rigor should supplement, not substitute for, expert scientific judgment and should be implemented in partnership with the scientific community, consistent with the principles of Executive Order 14303, Restoring Gold Standard Science.

2. Data, Software, and Model Sharing: Peer-reviewed publications remain the primary scholarly output of biological and biomedical research and an essential means of communicating scientific discoveries. The value of biological and biomedical research, however, also extends to data, software, computational models, and other enduring research outputs that enable validation, reuse, and new lines of investigation. NIH has made considerable progress through its Data Management and Sharing Policy (NIH, 2023). Building on this progress, NIH should recognize and reward the creation, stewardship, and sharing of high-quality research resources to maximize the return on the nation's investment in biological and biomedical research.

FASEB recommends NIH:
Recognize data, software, and computational models as additional scholarly products alongside publications. These outputs should be evaluated in addition to publications in funding decisions and progress reporting. NIH should continue incorporating these contributions into existing investigator reporting mechanisms, including the Biographical Sketch Common Form and Contributions to Science, so that researchers receive appropriate credit for developing resources that enable discovery across the biological and biomedical enterprise.

Reward quality, reuse, and interoperability. The value of shared research resources lies in their accessibility, reliability, interoperability, and scientific utility, not simply whether they are deposited. Assessment systems that prioritize quantity over quality, usability, or scientific value risk encouraging compliance-driven behavior without meaningfully advancing research. Where measurable indicators are appropriate, NIH should emphasize adherence to the FAIR Principles (Wilkinson et al., 2016), documented reuse, appropriate citation, interoperability, and downstream scientific impact. Consistent with FASEB's longstanding position on data management and access, incentives should encourage the sharing of high-value research resources while avoiding requirements that create unnecessary administrative burden with limited scientific benefit.

Recognize stewardship as a valuable contribution. Long-term stewardship of datasets, software, repositories, and other shared research resources requires sustained scientific expertise. NIH should recognize activities such as curation, quality control, documentation, and long-term maintenance as distinct, valuable contributions within investigator assessment. Recognizing stewardship will encourage sustained investment in high-quality research resources that remain reliable, reusable, and valuable over time.

Invest in the infrastructure that enables responsible sharing and long-term stewardship of research resources. Expectations for sharing data, software, biospecimens, model organisms, reagents, and other

valuable research resources should be matched by sustained investments in repositories, biobanks, research resource centers, core infrastructure, cloud resources, metadata standards, and the skilled technical workforce required to curate and maintain them. Without this support, valuable scientific resources may become inaccessible, limiting reproducibility, reducing reuse, and diminishing the long-term return on NIH's investment. Long-term stewardship of these resources should not depend solely on individual research grants.

Promote transparency and reproducibility for computational models. As artificial intelligence and computational modeling become increasingly integrated into biological and biomedical research, NIH should encourage transparent documentation of model provenance, versioning, computational workflows, and other information needed to support reproducibility, as appropriate. Building these expectations into existing reporting practices will improve transparency, strengthen confidence in AI-enabled research, and allow guidance to evolve alongside advances in computational science.

Providing funding for, and rewarding, the creation and stewardship of the comprehensive knowledge ecosystem, including peer-reviewed publications, data, software, and computational models, is essential to maximizing the return on the nation's investment in research.

3. Training and Mentorship: NIH's mission depends on a strong, sustainable biological and biomedical research workforce, and mentorship is among the most important contributions scientists make to that workforce. Yet mentorship remains largely invisible in traditional measures of scientific productivity and impact. As a federation of scientific societies, FASEB has extensive experience advancing research skill development, mentorship, and workforce development through NIH-funded programs, scientific society initiatives, and evidence-based policy recommendations. Drawing on this experience, FASEB encourages NIH to recognize mentorship as a valuable contribution, reward high-quality training environments, and adopt assessment approaches that reflect the various career pathways essential to the biological and biomedical research enterprise.

FASEB recommends NIH:
Recognize mentorship as a valuable contribution. Effective mentorship should be recognized alongside scientific achievement in NIH assessment and reporting. Building on recommendations from the NIH Advisory Committee to the Director Working Group on Re-envisioning NIH-Supported Postdoctoral Training (NIH ACD, 2023), NIH should incorporate structured documentation of mentoring activities, mentor development, and scholar outcomes into relevant existing reporting mechanisms. Assessment should emphasize mentoring quality and scholar success rather than simply the number of scholars supervised, while recognizing participation in evidence-based mentor training as an indicator of scientific leadership.

Leverage existing NIH training programs rather than creating new assessment systems. Institutional training grants, particularly T32 programs, represent NIH's most established framework for evaluating research training because they already incorporate structured training plans, mentor oversight, career development activities, and longitudinal scholar outcome reporting. NIH should build on these established mechanisms to identify effective mentoring practices, evaluate training environments, and disseminate evidence-based approaches while minimizing additional administrative burden.

Evaluate training through meaningful scholar outcomes that recognize various career pathways. NIH should recognize successful career outcomes across academia, industry, government, nonprofit organizations, education, and other sectors. Building on existing trainee outcome reporting and standardized career taxonomies such as Unified Career Outcomes Taxonomy (UCOT; Stayart et al., 2020), indicators including degree completion, career transitions, K99-to-R00 transition, K-to-R conversion, and time to research independence can provide meaningful measures of program effectiveness when interpreted within program context.

Recognize competency-based development as an indicator of quality. Effective research training develops competencies in scientific rigor, leadership, communication, professionalism, responsible conduct of research, and career development. NIH should encourage competency-based assessment that complements traditional research outputs while remaining flexible across career stages and career pathways.

Support mentoring networks that reflect today's biological and biomedical workforce. Scientists increasingly benefit from mentoring networks that include research, career, peer, and cross-sector mentors. NIH should recognize and encourage distributed mentoring models that strengthen career development, broaden access to expertise, and better reflect the collaborative nature of today's biological and biomedical research enterprise.

Recognize the complementary role of scientific societies in workforce development. Scientific societies provide mentoring, leadership development, networking, career exploration, and professional communities that complement institutional training. These activities expand access to expertise, strengthen professional networks, and complement institutional training across career stages. NIH should continue partnering with scientific societies to extend the reach and impact of its workforce development investments.

Mentorship is among the most consequential—and least recognized—contributions scientists make to the biological and biomedical research enterprise. Assessment approaches should support long-term program improvement rather than short-term funding decisions and account for institutional context, discipline, career stage, and the time required for meaningful career outcomes to emerge. By recognizing mentoring excellence and high-quality training environments, NIH can strengthen the biological and biomedical workforce and, in turn, the nation's innovation economy.

4. Collaboration: Collaboration has become a defining feature of modern biological and biomedical research, with discoveries increasingly emerging from multidisciplinary teams that span institutions, sectors, and scientific disciplines. Through its member societies, scientific meetings, and collaborative initiatives, FASEB has long supported team science and interdisciplinary collaboration. As NIH develops approaches for recognizing and assessing scientific impact, assessment should recognize the range of scientific contributions that enable collaborative research while remaining appropriate across disciplines, career stages, and research settings.

FASEB recommends NIH:

Recognize the full range of scientific contributions that enable team science. Scientific impact should not be inferred solely from a singular metric; a matrix approach is recommended. Rigorous peer review should continue evaluating the quality of collaborative science, while structured contribution taxonomies such as the Contributor Roles Taxonomy (CRediT) developed by the National Information Standards Organization (NISO) provide additional context regarding individual contributions. NIH should incorporate these taxonomies into existing reporting mechanisms to provide additional context regarding individual contributions.

Evaluate collaboration based on scientific contributions rather than team size. Assessment should recognize interdisciplinary integration, shared leadership, effective coordination among collaborators, and the scientific advances enabled by collaboration rather than relying on coauthor counts or other quantitative measures.

Recognize cross-sector collaboration as an indicator of valuable impact. Biological and biomedical discovery increasingly depends on partnerships among academia, industry, government, healthcare systems, nonprofit organizations, patient communities, and scientific societies. NIH should recognize collaborations that meaningfully advance scientific discovery, translation, workforce development, or public health.

Recognize collaborative leadership within NIH assessment and reporting. NIH should continue recognizing multiple principal investigators, co-investigators, and other collaborative leadership roles within its funding and research assessment processes, reinforcing institutional recognition of team-based science.

Ensure collaborative science supports early-career investigators. Assessment approaches should enable students, postdoctoral scholars, and early-stage investigators to clearly document their individual scientific contributions within collaborative projects. Participation in team science should provide opportunities to demonstrate scientific independence rather than obscure individual contributions.

Avoid metrics that create unintended incentives. Measures based solely on coauthor counts, collaboration team size, or other quantitative proxies are poor indicators of meaningful collaboration and may encourage honorary authorship or unnecessary expansion of research teams. Collaboration should instead be evaluated based on documented scientific contributions, the quality and impact of the collaborative work, and disciplinary norms.

Scientific progress increasingly depends on effective collaboration across disciplines, institutions, and sectors. By recognizing meaningful contributions to team science, NIH can strengthen collaborative innovation while ensuring assessment remains equitable, transparent, and reflective of modern biological and biomedical research.

5. Entrepreneurship and Translation: Biological and biomedical research creates value by generating new knowledge and translating discoveries into improved health. Successful translation depends on sustained investment in investigator-initiated foundational research together with effective cross-sector partnerships. Through their peer-reviewed journals, scientific meetings, and professional networks, FASEB's member societies help advance discoveries from the laboratory to practical application. As NIH

develops approaches for recognizing scientific impact, entrepreneurial and translational activities should be recognized as important scientific contributions without diminishing the vital importance of foundational discovery research.

FASEB recommends NIH:
Recognize translational research as a valuable scientific contribution. NIH should recognize contributions that advance discoveries toward clinical practice, public health, diagnostics, therapeutics, medical technologies, and other real-world applications. Assessment should recognize progress across the translational continuum, including advancement through the research and development pipeline and the maturation of early-stage discoveries, rather than focusing solely on commercial endpoints.

Recognize entrepreneurial and innovation activities that responsibly advance biological and biomedical discoveries. Activities such as technology development, invention disclosure, patenting, licensing, startup formation, and regulatory advancement can represent meaningful scientific contributions when they advance the translation of NIH-supported discoveries into products, services, and technologies that improve health. Recognizing these activities within existing reporting mechanisms will encourage investigators to pursue translational research while preserving support for foundational discovery. Because commercialization infrastructure, including technology transfer offices, industry partnerships, and access to capital, is unevenly distributed, NIH should avoid indicators that disadvantage investigators at smaller or less-resourced institutions or reward patenting activity without evidence of meaningful translational or public benefit.

Recognize the role of the Bayh-Dole framework in moving federally funded discoveries toward public benefit. For more than four decades, the Bayh-Dole Act has enabled discoveries made with federal support to advance toward application through invention disclosure, patenting, and licensing, catalyzing the development of new drugs, diagnostics, and medical technologies. NIH's assessment framework should reinforce the successful incentives established under the Bayh-Dole Act by recognizing technology transfer, patenting, licensing, and related translational activities as legitimate scientific contributions while continuing to value the foundational research on which these activities depend.

Support cross-sector partnerships that accelerate bench-to-bedside translation. Successful translation depends on collaboration among academic institutions, industry, government agencies, healthcare systems, patient organizations, philanthropies, and scientific societies. NIH should recognize meaningful partnerships that move discoveries toward application and improve public health, while ensuring that individual investigator contributions within these partnerships remain visible in assessment.

Evaluate translation using meaningful evidence of scientific advancement. Assessment should emphasize evidence that discoveries are progressing toward application, including adoption of new methods or technologies, advancement through the development pipeline, and incorporation into clinical practice or public health. Quantitative measures should be interpreted within the context of discipline, career stage, and the long timelines, often a decade or more for new therapeutics, that translation frequently requires, so that early-career researchers are not disadvantaged when translational outcomes fall outside their typical evaluation windows.

Translation is one of the principal ways biological and biomedical research delivers benefits to patients and society, but it depends on sustained investments in rigorous, peer-reviewed basic research. By recognizing entrepreneurship and translation as complementary dimensions of scientific impact and continuing to support the Bayh-Dole framework, NIH can strengthen the continuum from discovery to application while preserving incentives for foundational science.

6. Foundational Scientific Exploration: Foundational scientific exploration is the wellspring of biological and biomedical progress. The discoveries that ultimately transform human health frequently originate in curiosity-driven investigation whose applications cannot be foreseen at the outset and may take years or decades to emerge. Sustained progress in translational and clinical research depends on a continuous supply of the new knowledge, mechanisms, and targets that fundamental research generates. As NIH develops approaches to measuring scientific impact, FASEB encourages the agency to also recognize, protect, and reward foundational biological and biomedical exploration, recognizing that assessment systems built solely around near-term or easily quantified outcomes risk undervaluing the basic science on which future advances depend.

FASEB recommends NIH:
Protect foundational research from assessment systems that favor near-term outcomes. Because the impact of basic biological and biomedical science often emerges years or decades later through unpredictable pathways, NIH should adopt approaches to evaluation that account for the long and uncertain timelines of discovery research.

Recognize the advancement of fundamental knowledge as a core indicator of scientific impact. Expanding our understanding of biological systems, including fundamental cell, molecular, and organismal biology and the discovery of new biological concepts and therapeutic targets, is a foundational contribution to the biological and biomedical research enterprise, independent of near-term application. NIH should recognize contributions that advance fundamental knowledge, generate new concepts and tools, or open new lines of inquiry as meaningful indicators of impact within existing evaluation and reporting mechanisms.

Support high-risk, high-reward research through appropriate assessment. Transformative discovery often depends on investigations that carry significant uncertainty and may not yield the anticipated result. NIH should ensure that assessment approaches do not penalize scientifically rigorous research that does not produce the anticipated findings and should recognize well-executed negative or null results as meaningful contributions to scientific knowledge.

Account for long and unpredictable timelines in evaluating foundational research. Measures tied to short reporting windows cannot capture the trajectory of basic science. NIH should favor evaluation approaches that accommodate extended timeframes, avoid drawing conclusions about impact prematurely, and allow the significance of foundational biological and biomedical discoveries to emerge over time. Because foundational discovery is inherently unpredictable, impact assessment frameworks should continue to support a diverse portfolio of investigator-initiated, curiosity-driven research rather than directing resources primarily toward predefined priorities or readily measurable near-term outcomes.

Foundational biological and biomedical science exploration is the source of discoveries that ultimately transform health, yet its value is the hardest to capture through conventional measures of impact. FASEB urges NIH to design assessment approaches that recognize, protect, and reward curiosity-driven science, thereby safeguarding the discovery research from which tomorrow's advances will arise.

7. Public Impact: Biological and biomedical research generates value through publications, datasets, software, computational models, and other enduring scientific outputs. It also delivers value in improving health, strengthening the economy, informing clinical practice, building public trust, and benefiting society in ways that often emerge over many years. As NIH develops approaches to assess public impact, FASEB encourages the agency to recognize the many pathways through which research benefits the public. Public impact is multidimensional and should be assessed through a matrix of complementary indicators that reflect NIH's mission.

FASEB recommends NIH:
Recognize improvements in health and clinical practice as core indicators of public impact. NIH should also recognize contributions that improve health outcomes, inform clinical care, support implementation of evidence-based interventions, and broaden access to effective care, including the responsible return of research results where appropriate.

Incorporate validated measures of economic and societal benefit. NIH-supported research drives innovation, economic growth ($2.57 for each $1.00 invested), workforce development, and national competitiveness. Where appropriate, NIH should also incorporate validated measures of economic impact alongside other metrics to better communicate the broad public return on federal investment in biological and biomedical research.

Recognize public engagement and trustworthy science communication as scientific contributions. Building and maintaining public trust requires sustained engagement with patients, communities, educators, policymakers, and the public. NIH should also recognize meaningful contributions to science communication, patient and community engagement, transparency, and other activities that strengthen confidence in biological and biomedical research. Scientific societies are important partners in developing and disseminating evidence-based communication practices and fostering public trust.

Avoid simplistic measures of public impact. No single metric can adequately capture the many ways biological and biomedical research benefits society, and a matrix of indicators is warranted. Likewise, economic measures should complement, not replace, assessment of health outcomes and broader public benefit. NIH should instead adopt a balanced framework that recognizes health outcomes, clinical practice, economic growth, accessibility, public trust, and societal benefit as complementary dimensions of impact.

Recognize public impact within existing application, reporting, and research assessment processes. Investigators should be able to document meaningful public impacts, including contributions to clinical guidelines, public policy, accessibility, community engagement, the responsible return of research results, and public understanding of science. Narrative descriptions should complement quantitative indicators by capturing important additional impacts.

Partner with scientific societies to strengthen public engagement and scientific literacy. Scientific societies play an essential role in communicating biological and biomedical scientific advances, convening experts, engaging communities across the country, and developing trusted educational resources. NIH should continue partnering with scientific societies to strengthen public understanding of biological and biomedical research and ensure that measures of public impact reflect the range of disciplines and communities they serve.

Public impact is the ultimate expression of NIH's mission. FASEB encourages NIH to adopt assessment approaches that recognize the various ways biological and biomedical research improves lives by valuing publications alongside datasets, software, computational models, and other scientific contributions, while remaining flexible, evidence-based, and appropriate across scientific disciplines and stages of research.

In conclusion, FASEB supports NIH's efforts to develop a more comprehensive approach to measuring and rewarding scientific impact that recognizes the full range of contributions advancing biological and biomedical research. As NIH develops this framework, we encourage the agency to preserve rigorous, expert peer review as the foundation for evaluating scientific quality while adopting responsible, evidence-based indicators that complement—not replace—scientific judgment.

FASEB urges NIH to adopt the recommendations outlined above to ensure that scientific impact is assessed in ways that strengthen rigor, encourage innovation, recognize the range of contributions across the biological and biomedical research enterprise, and minimize unnecessary administrative burden. FASEB and its member societies welcome the opportunity to provide additional information and to work with NIH to develop and implement an assessment framework that advances scientific excellence while maximizing public benefit.

Description: FASEB's Response Letter to NIH's RFI on Measuring and Rewarding Scientific Impact

FASEB
FEDERATION OF AMERICAN SOCIETIES FOR EXPERIMENTAL BIOLOGY

REPRESENTING OVER 100,000 RESEARCHERS
6120 Executive Boulevard | Suite 230 | Rockville, MD 20852
faseb.org

August 17, 2026

Submitted electronically via the [Comment Form: Measuring and Rewarding Scientific Impact - Office of Science Policy]

The Honorable Jayanta Bhattacharya, M.D., Ph.D.
Director, National Institutes of Health
9000 Rockville Pike
Bethesda, MD 20892

Re: Comments of the Federation of American Societies for Experimental Biology (FASEB) on the National Institutes of Health Request for Information (NOT-OD-26-087), *Measuring and Rewarding Scientific Impact*

Dear Director Bhattacharya:

The Federation of American Societies for Experimental Biology (FASEB) appreciates the opportunity to respond to the National Institutes of Health (NIH) Request for Information (NOT-OD-26-087), M*easuring and Rewarding Scientific Impact*. Representing 21 American scientific societies and more than 100,000 researchers across the biological and biomedical sciences, FASEB commends NIH's efforts to develop approaches that more fully recognize the full range of contributions that advance biological and biomedical research while maintaining the highest standards of scientific rigor and public trust.

FASEB's member societies steward critical components of the biological and biomedical research enterprise by publishing peer-reviewed journals, convening scientific meetings, and providing mentoring and career development programs that help ensure federally funded discoveries are rigorously evaluated, disseminated, and built upon by the broader research community, including industry. FASEB approaches this RFI both as a representative of individual investigators and as a steward of the infrastructure that translates NIH-funded research into scientific and public value, consistent with the principles of Executive Order 14303, *Restoring Gold Standard Science* (May 23, 2025). FASEB believes that rigorous, expert peer review remains the cornerstone of evaluating scientific quality, maintaining the credibility of science, and ensuring responsible stewardship of federal research investments.

NIH's reporting and evaluation frameworks represent only one component of the broader research assessment ecosystem. Many meaningful indicators of scientific quality, rigor, and impact already exist but are not consistently recognized or incorporated into evaluation processes. These indicators should complement—not replace—expert scientific peer review, which remains the most effective mechanism for evaluating rigor, originality, significance, and

scientific quality in both funding decisions and scholarly publication. Peer-reviewed publications remain an essential indicator of scientific productivity; however, publication counts alone do not capture the full value of a scientist's contributions. Notably, even journals evaluate their own performance using a portfolio of complementary metrics rather than publication volume alone.

FASEB encourages NIH to partner with scientific societies, research institutions, and other stakeholders to modernize research assessment in ways that are evidence-based, practical, and appropriate across disciplines, career stages, institution types, and resource levels. FASEB stands ready to support NIH by identifying meaningful scientific impact indicators and assessment approaches, evaluating implementation strategies, and helping minimize unnecessary administrative burden, particularly for smaller and less-resourced institutions.

Topic 1: Rigor and Reproducibility

FASEB recommends NIH:

Establish clear definitions of reproducibility and causal research before incorporating them into scientific impact assessment. NIH should clearly define these concepts and communicate consistent expectations before incorporating them into evaluation or reporting. Scientific societies can help ensure these definitions are interpreted consistently across disciplines and implemented equitably.

Complement traditional productivity measures with evidence of rigorous scientific practice. Where measurable indicators are appropriate, NIH should emphasize established practices that support rigor, including authentication of key biological and chemical resources, adherence to community reporting standards, appropriate preregistration of confirmatory studies, and successful independent validation. These indicators provide an additional layer of value and understanding of the incentive structure at institutions.

Integrate transparency for generative AI into existing reproducibility policies. As AI becomes increasingly integrated into biological and biomedical research, NIH should incorporate documentation of AI tools, such as the model, provider, and version where appropriate, within existing authentication and reporting requirements rather than creating separate reporting systems. Building on NIH's existing *Enhancing Reproducibility through Rigor and Transparency* guidance (NIH, 2025), this approach will promote transparency, support computational reproducibility, and minimize additional administrative burden while allowing expectations to evolve alongside advances in AI.

Invest in infrastructure that enables rigorous science. Reproducibility depends on sustained access to shared research resources, core facilities, modern instrumentation, and skilled technical staff. NIH should ensure that investments in reproducibility are matched by

investments in the infrastructure needed to support them; otherwise, expectations for rigor may outpace institutional capacity.

Recognize replication as a valuable scientific contribution. Independent replication strengthens confidence in scientific findings but remains underrecognized within traditional systems of academic reward. NIH should recognize replication studies as distinct scholarly contributions within existing reporting mechanisms and continue developing funding opportunities that support high-priority replication efforts. To foster this commitment to replication, today, many societies have at least one journal in their portfolio that allows for recognition of and publication of replication studies, and several societies have supported the community further by dedicating special issues to replication studies.

Support scientific societies as critical to the research ecosystem as they seek to advance reproducibility. Biological and biomedical scientific societies are uniquely positioned to develop discipline-specific standards, identify high-priority opportunities for replication, disseminate best practices, and provide training in rigorous and reproducible research methods. NIH should continue to support society-led initiatives, including the development of training resources and the integration of rigor and reproducibility modules into programs serving researchers across career stages, including predoctoral trainees, postdoctoral researchers, and early-career investigators.

Scientific impact cannot be meaningfully assessed without confidence in the quality and reliability of the underlying science. FASEB encourages NIH to build its scientific impact framework on the foundation of rigorous, expert peer review, which remains the cornerstone of research assessment and the credibility of science. Responsible indicators of rigor should supplement, not substitute for, expert scientific judgment and should be implemented in partnership with the scientific community, consistent with the principles of Executive Order 14303, *Restoring Gold Standard Science*.

Topic 2: Data, Software, and Model Sharing

Peer-reviewed publications remain the primary scholarly output of biological and biomedical research and an essential means of communicating scientific discoveries. The value of biological and biomedical research, however, also extends to data, software, computational models, and other enduring research outputs that enable validation, reuse, and new lines of investigation. NIH has made considerable progress through its *Data Management and Sharing Policy* (NIH, 2023). Building on this progress, NIH should recognize and reward the creation, stewardship, and sharing of high-quality research resources to maximize the return on the nation's investment in biological and biomedical research.

FASEB recommends NIH:

Recognize data, software, and computational models as additional scholarly products alongside publications. These outputs should be evaluated in addition to publications in funding decisions and progress reporting. NIH should continue incorporating these contributions into existing investigator reporting mechanisms, including the Biographical Sketch Common Form and Contributions to Science, so that researchers receive appropriate credit for developing resources that enable discovery across the biological and biomedical enterprise.

Reward quality, reuse, and interoperability. The value of shared research resources lies in their accessibility, reliability, interoperability, and scientific utility, not simply whether they are deposited. Assessment systems that prioritize quantity over quality, usability, or scientific value risk encouraging compliance-driven behavior without meaningfully advancing research. Where measurable indicators are appropriate, NIH should emphasize adherence to the FAIR Principles (Wilkinson et al., 2016), documented reuse, appropriate citation, interoperability, and downstream scientific impact. Consistent with FASEB's longstanding position on data management and access, incentives should encourage the sharing of high-value research resources while avoiding requirements that create unnecessary administrative burden with limited scientific benefit.

Recognize stewardship as a valuable contribution. Long-term stewardship of datasets, software, repositories, and other shared research resources requires sustained scientific expertise. NIH should recognize activities such as curation, quality control, documentation, and long-term maintenance as distinct, valuable contributions within investigator assessment. Recognizing stewardship will encourage sustained investment in high-quality research resources that remain reliable, reusable, and valuable over time.

Invest in the infrastructure that enables responsible sharing and long-term stewardship of research resources. Expectations for sharing data, software, biospecimens, model organisms, reagents, and other valuable research resources should be matched by sustained investments in repositories, biobanks, research resource centers, core infrastructure, cloud resources, metadata standards, and the skilled technical workforce required to curate and maintain them. Without this support, valuable scientific resources may become inaccessible, limiting reproducibility, reducing reuse, and diminishing the long-term return on NIH's investment. Long-term stewardship of these resources should not depend solely on individual research grants.

Promote transparency and reproducibility for computational models. As artificial intelligence and computational modeling become increasingly integrated into biological and biomedical research, NIH should encourage transparent documentation of model provenance, versioning, computational workflows, and other information needed to support reproducibility, as appropriate. Building these expectations into existing reporting practices will improve

transparency, strengthen confidence in AI-enabled research, and allow guidance to evolve alongside advances in computational science.

Providing funding for, and rewarding, the creation and stewardship of the comprehensive knowledge ecosystem, including peer-reviewed publications, data, software, and computational models, is essential to maximizing the return on the nation's investment in research.

Topic 3: Training and Mentoring

NIH's mission depends on a strong, sustainable biological and biomedical research workforce, and mentorship is among the most important contributions scientists make to that workforce. Yet mentorship remains largely invisible in traditional measures of scientific productivity and impact. As a federation of scientific societies, FASEB has extensive experience advancing research skill development, mentorship, and workforce development through NIH-funded programs, scientific society initiatives, and evidence-based policy recommendations. Drawing on this experience, FASEB encourages NIH to recognize mentorship as a valuable contribution, reward high-quality training environments, and adopt assessment approaches that reflect the various career pathways essential to the biological and biomedical research enterprise.

FASEB recommends NIH:

Recognize mentorship as a valuable contribution. Effective mentorship should be recognized alongside scientific achievement in NIH assessment and reporting. Building on recommendations from the NIH Advisory Committee to the Director Working Group on Re-envisioning NIH-Supported Postdoctoral Training (NIH ACD, 2023), NIH should incorporate structured documentation of mentoring activities, mentor development, and scholar outcomes into relevant existing reporting mechanisms. Assessment should emphasize mentoring quality and scholar success rather than simply the number of scholars supervised, while recognizing participation in evidence-based mentor training as an indicator of scientific leadership.

Leverage existing NIH training programs rather than creating new assessment systems. Institutional training grants, particularly T32 programs, represent NIH's most established framework for evaluating research training because they already incorporate structured training plans, mentor oversight, career development activities, and longitudinal scholar outcome reporting. NIH should build on these established mechanisms to identify effective mentoring practices, evaluate training environments, and disseminate evidence-based approaches while minimizing additional administrative burden.

Evaluate training through meaningful scholar outcomes that recognize various career pathways. NIH should recognize successful career outcomes across academia, industry, government, nonprofit organizations, education, and other sectors. Building on existing trainee outcome reporting and standardized career taxonomies such as Unified Career Outcomes

Taxonomy (UCOT; Stayart et al., 2020), indicators including degree completion, career transitions, K99-to-R00 transition, K-to-R conversion, and time to research independence can provide meaningful measures of program effectiveness when interpreted within program context.

Recognize competency-based development as an indicator of quality. Effective research training develops competencies in scientific rigor, leadership, communication, professionalism, responsible conduct of research, and career development. NIH should encourage competency-based assessment that complements traditional research outputs while remaining flexible across career stages and career pathways.

Support mentoring networks that reflect today's biological and biomedical workforce. Scientists increasingly benefit from mentoring networks that include research, career, peer, and cross-sector mentors. NIH should recognize and encourage distributed mentoring models that strengthen career development, broaden access to expertise, and better reflect the collaborative nature of today's biological and biomedical research enterprise.

Recognize the complementary role of scientific societies in workforce development. Scientific societies provide mentoring, leadership development, networking, career exploration, and professional communities that complement institutional training. These activities expand access to expertise, strengthen professional networks, and complement institutional training across career stages. NIH should continue partnering with scientific societies to extend the reach and impact of its workforce development investments.

Mentorship is among the most consequential—and least recognized—contributions scientists make to the biological and biomedical research enterprise. Assessment approaches should support long-term program improvement rather than short-term funding decisions and account for institutional context, discipline, career stage, and the time required for meaningful career outcomes to emerge. By recognizing mentoring excellence and high-quality training environments, NIH can strengthen the biological and biomedical workforce and, in turn, the nation's innovation economy.

Topic 4: Collaboration

Collaboration has become a defining feature of modern biological and biomedical research, with discoveries increasingly emerging from multidisciplinary teams that span institutions, sectors, and scientific disciplines. Through its member societies, scientific meetings, and collaborative initiatives, FASEB has long supported team science and interdisciplinary collaboration. As NIH develops approaches for recognizing and assessing scientific impact, assessment should recognize the range of scientific contributions that enable collaborative research while remaining appropriate across disciplines, career stages, and research settings.

FASEB recommends NIH:

Recognize the full range of scientific contributions that enable team science. Scientific impact should not be inferred solely from a singular metric; a matrix approach is recommended. Rigorous peer review should continue evaluating the quality of collaborative science, while structured contribution taxonomies such as the Contributor Roles Taxonomy (CRediT) developed by the National Information Standards Organization (NISO) provide additional context regarding individual contributions. NIH should incorporate these taxonomies into existing reporting mechanisms to provide additional context regarding individual contributions.

Evaluate collaboration based on scientific contributions rather than team size. Assessment should recognize interdisciplinary integration, shared leadership, effective coordination among collaborators, and the scientific advances enabled by collaboration rather than relying on coauthor counts or other quantitative measures.

Recognize cross-sector collaboration as an indicator of valuable impact. Biological and biomedical discovery increasingly depends on partnerships among academia, industry, government, healthcare systems, nonprofit organizations, patient communities, and scientific societies. NIH should recognize collaborations that meaningfully advance scientific discovery, translation, workforce development, or public health.

Recognize collaborative leadership within NIH assessment and reporting. NIH should continue recognizing multiple principal investigators, co-investigators, and other collaborative leadership roles within its funding and research assessment processes, reinforcing institutional recognition of team-based science.

Ensure collaborative science supports early-career investigators. Assessment approaches should enable students, postdoctoral scholars, and early-stage investigators to clearly document their individual scientific contributions within collaborative projects. Participation in team science should provide opportunities to demonstrate scientific independence rather than obscure individual contributions.

Avoid metrics that create unintended incentives. Measures based solely on coauthor counts, collaboration team size, or other quantitative proxies are poor indicators of meaningful collaboration and may encourage honorary authorship or unnecessary expansion of research teams. Collaboration should instead be evaluated based on documented scientific contributions, the quality and impact of the collaborative work, and disciplinary norms.

Scientific progress increasingly depends on effective collaboration across disciplines, institutions, and sectors. By recognizing meaningful contributions to team science, NIH can strengthen collaborative innovation while ensuring assessment remains equitable, transparent, and reflective of modern biological and biomedical research.

Topic 5: Entrepreneurship and Translation

Biological and biomedical research creates value by generating new knowledge and translating discoveries into improved health. Successful translation depends on sustained investment in investigator-initiated foundational research together with effective cross-sector partnerships. Through their peer-reviewed journals, scientific meetings, and professional networks, FASEB's member societies help advance discoveries from the laboratory to practical application. As NIH develops approaches for recognizing scientific impact, entrepreneurial and translational activities should be recognized as important scientific contributions without diminishing the vital importance of foundational discovery research.

FASEB recommends NIH:

Recognize translational research as a valuable scientific contribution. NIH should recognize contributions that advance discoveries toward clinical practice, public health, diagnostics, therapeutics, medical technologies, and other real-world applications. Assessment should recognize progress across the translational continuum, including advancement through the research and development pipeline and the maturation of early-stage discoveries, rather than focusing solely on commercial endpoints.

Recognize entrepreneurial and innovation activities that responsibly advance biological and biomedical discoveries. Activities such as technology development, invention disclosure, patenting, licensing, startup formation, and regulatory advancement can represent meaningful scientific contributions when they advance the translation of NIH-supported discoveries into products, services, and technologies that improve health. Recognizing these activities within existing reporting mechanisms will encourage investigators to pursue translational research while preserving support for foundational discovery. Because commercialization infrastructure, including technology transfer offices, industry partnerships, and access to capital, is unevenly distributed, NIH should avoid indicators that disadvantage investigators at smaller or less-resourced institutions or reward patenting activity without evidence of meaningful translational or public benefit.

Recognize the role of the Bayh-Dole framework in moving federally funded discoveries toward public benefit. For more than four decades, the Bayh-Dole Act has enabled discoveries made with federal support to advance toward application through invention disclosure, patenting, and licensing, catalyzing the development of new drugs, diagnostics, and medical technologies. NIH's assessment framework should reinforce the successful incentives established under the

Bayh-Dole Act by recognizing technology transfer, patenting, licensing, and related translational activities as legitimate scientific contributions while continuing to value the foundational research on which these activities depend.

Support cross-sector partnerships that accelerate bench-to-bedside translation. Successful translation depends on collaboration among academic institutions, industry, government agencies, healthcare systems, patient organizations, philanthropies, and scientific societies. NIH should recognize meaningful partnerships that move discoveries toward application and improve public health, while ensuring that individual investigator contributions within these partnerships remain visible in assessment.

Evaluate translation using meaningful evidence of scientific advancement. Assessment should emphasize evidence that discoveries are progressing toward application, including adoption of new methods or technologies, advancement through the development pipeline, and incorporation into clinical practice or public health. Quantitative measures should be interpreted within the context of discipline, career stage, and the long timelines, often a decade or more for new therapeutics, that translation frequently requires, so that early-career researchers are not disadvantaged when translational outcomes fall outside their typical evaluation windows.

Translation is one of the principal ways biological and biomedical research delivers benefits to patients and society, but it depends on sustained investments in rigorous, peer-reviewed basic research. By recognizing entrepreneurship and translation as complementary dimensions of scientific impact and continuing to support the Bayh-Dole framework, NIH can strengthen the continuum from discovery to application while preserving incentives for foundational science.

Topic 6: Foundational Scientific Exploration

Foundational scientific exploration is the wellspring of biological and biomedical progress. The discoveries that ultimately transform human health frequently originate in curiosity-driven investigation whose applications cannot be foreseen at the outset and may take years or decades to emerge. Sustained progress in translational and clinical research depends on a continuous supply of the new knowledge, mechanisms, and targets that fundamental research generates. As NIH develops approaches to measuring scientific impact, FASEB encourages the agency to also recognize, protect, and reward foundational biological and biomedical exploration, recognizing that assessment systems built solely around near-term or easily quantified outcomes risk undervaluing the basic science on which future advances depend.

FASEB recommends NIH:

Protect foundational research from assessment systems that favor near-term outcomes. Because the impact of basic biological and biomedical science often emerges years or decades

later through unpredictable pathways, NIH should adopt approaches to evaluation that account for the long and uncertain timelines of discovery research.

Recognize the advancement of fundamental knowledge as a core indicator of scientific impact. Expanding our understanding of biological systems, including fundamental cell, molecular, and organismal biology and the discovery of new biological concepts and therapeutic targets, is a foundational contribution to the biological and biomedical research enterprise, independent of near-term application. NIH should recognize contributions that advance fundamental knowledge, generate new concepts and tools, or open new lines of inquiry as meaningful indicators of impact within existing evaluation and reporting mechanisms.

Support high-risk, high-reward research through appropriate assessment. Transformative discovery often depends on investigations that carry significant uncertainty and may not yield the anticipated result. NIH should ensure that assessment approaches do not penalize scientifically rigorous research that does not produce the anticipated findings and should recognize well-executed negative or null results as meaningful contributions to scientific knowledge.

Account for long and unpredictable timelines in evaluating foundational research. Measures tied to short reporting windows cannot capture the trajectory of basic science. NIH should favor evaluation approaches that accommodate extended timeframes, avoid drawing conclusions about impact prematurely, and allow the significance of foundational biological and biomedical discoveries to emerge over time. Because foundational discovery is inherently unpredictable, impact assessment frameworks should continue to support a diverse portfolio of investigator-initiated, curiosity-driven research rather than directing resources primarily toward predefined priorities or readily measurable near-term outcomes.

Foundational biological and biomedical science exploration is the source of discoveries that ultimately transform health, yet its value is the hardest to capture through conventional measures of impact. FASEB urges NIH to design assessment approaches that recognize, protect, and reward curiosity-driven science, thereby safeguarding the discovery research from which tomorrow's advances will arise.

Topic 7: Public Impact

Biological and biomedical research generates value through publications, datasets, software, computational models, and other enduring scientific outputs. It also delivers value in improving health, strengthening the economy, informing clinical practice, building public trust, and benefiting society in ways that often emerge over many years. As NIH develops approaches to assess public impact, FASEB encourages the agency to recognize the many pathways through

which research benefits the public. Public impact is multidimensional and should be assessed through a matrix of complementary indicators that reflect NIH's mission.

FASEB recommends NIH:

Recognize improvements in health and clinical practice as core indicators of public impact. NIH should also recognize contributions that improve health outcomes, inform clinical care, support implementation of evidence-based interventions, and broaden access to effective care, including the responsible return of research results where appropriate.

Incorporate validated measures of economic and societal benefit. NIH-supported research drives innovation, economic growth ($2.57 for each $1.00 invested), workforce development, and national competitiveness. Where appropriate, NIH should also incorporate validated measures of economic impact alongside other metrics to better communicate the broad public return on federal investment in biological and biomedical research.

Recognize public engagement and trustworthy science communication as scientific contributions. Building and maintaining public trust requires sustained engagement with patients, communities, educators, policymakers, and the public. NIH should also recognize meaningful contributions to science communication, patient and community engagement, transparency, and other activities that strengthen confidence in biological and biomedical research. Scientific societies are important partners in developing and disseminating evidence-based communication practices and fostering public trust.

Avoid simplistic measures of public impact. No single metric can adequately capture the many ways biological and biomedical research benefits society, and a matrix of indicators is warranted. Likewise, economic measures should complement, not replace, assessment of health outcomes and broader public benefit. NIH should instead adopt a balanced framework that recognizes health outcomes, clinical practice, economic growth, accessibility, public trust, and societal benefit as complementary dimensions of impact.

Recognize public impact within existing application, reporting, and research assessment processes. Investigators should be able to document meaningful public impacts, including contributions to clinical guidelines, public policy, accessibility, community engagement, the responsible return of research results, and public understanding of science. Narrative descriptions should complement quantitative indicators by capturing important additional impacts.

Partner with scientific societies to strengthen public engagement and scientific literacy. Scientific societies play an essential role in communicating biological and biomedical scientific advances, convening experts, engaging communities across the country, and developing trusted

educational resources. NIH should continue partnering with scientific societies to strengthen public understanding of biological and biomedical research and ensure that measures of public impact reflect the range of disciplines and communities they serve.

Public impact is the ultimate expression of NIH's mission. FASEB encourages NIH to adopt assessment approaches that recognize the various ways biological and biomedical research improves lives by valuing publications alongside datasets, software, computational models, and other scientific contributions, while remaining flexible, evidence-based, and appropriate across scientific disciplines and stages of research.

In conclusion, FASEB supports NIH's efforts to develop a more comprehensive approach to measuring and rewarding scientific impact that recognizes the full range of contributions advancing biological and biomedical research. ***As NIH develops this framework, we encourage the agency to preserve rigorous, expert peer review as the foundation for evaluating scientific quality while adopting responsible, evidence-based indicators that complement—not replace—scientific judg*ment**.

FASEB urges NIH to adopt the recommendations outlined above to ensure that scientific impact is assessed in ways that strengthen rigor, encourage innovation, recognize the range of contributions across the biological and biomedical research enterprise, and minimize unnecessary administrative burden. FASEB and its member societies welcome the opportunity to provide additional information and to work with NIH to develop and implement an assessment framework that advances scientific excellence while maximizing public benefit.

Respectfully submitted,

Name: Caroline Dilworth

Name of Organization: UNC Center for Health Promotion and Disease Prevention

Type of Organization: Not Applicable

Role: Other

Role - Other: Deputy Director

Date Submitted: 8/17/2026

1. Rigor and Reproducibility: o Significance of the health problem addressed - # people impacted, severity of the issue, benefit of prevention
o Potential for scale up and dissemination
o Feasibility of broad implementation of evidence-informed interventions
o Evidence of community-engagement and input on research priorities
o Cost-effectiveness
o Evidence of clinical significance of change/improvement in proposed mechanisms and outcomes (rather than statistical significance only)

2. Data, Software, and Model Sharing: o University financial support and personnel effort for data management, storage, and sharing across disciplines

3. Training and Mentorship: o Joint publications with community partners
o Evidence of broad reach/impact
o Evidence of prioritizing trainees – for example, as first author on publications
o Interdisciplinary collaborations

4. Collaboration: o Collaboration across disciplines
o Rewarding more than first author publications, expecting multiple

5. Entrepreneurship and Translation: o Balancing encouragement for innovation with restrictions related to COI
o Recognition of social entrepreneurship and the role in translation to the community

6. Foundational Scientific Exploration: o Apply this approach to translational as well as technological research

7. Public Impact: o Implementation research including cost-effectiveness
o Importance of community engaged research related to economic development
o Importance of science communication and training
o Potential utility of “Ripple Effects Mapping”:

5. Entrepreneurship and Translation: The gap in current reporting

NIH states that more can be done to incentivize, assess, and integrate the impact of innovation and entrepreneurial efforts, and separately identifies economic growth among the dimensions of public impact worth recognizing.

The barrier is not willingness. Investigators pursue this work, and institutions fund offices to support it. What is missing is a defined category for these outputs in the instruments through which scientific contribution gets recorded.

The structure of progress reporting shows this plainly. Research Performance Progress Reports provide a dedicated field for websites and internet sites, a field for technologies or techniques, and a field for other products that resolves in practice to publications and shared research resources. Publications are captured as structured identifiers and carry compliance enforcement. A licensed technology, a formed company, a regulatory clearance, or an adopted device design has no comparable field.

The same asymmetry appears at program level. NCATS supporting instructions for hub progress reports in the Clinical and Translational Science Awards Program require recipients to report on funded pilot projects, and provide a recommended format of roughly twenty structured fields per project, publications among them as indexed identifiers. Return on investment is collected as free text, limited to 250 characters. NCATS states that the recommended format exists to support aggregation of pilot data and reporting on program impact. Publication output can therefore be compared across the consortium. Translational progression cannot.

The categories through which hubs report key outcomes reflect the same gap. They span disease areas,

populations, workforce, and health equity. None covers a product, a technology transferred, an industry partnership, or economic activity. A program cannot report an outcome for which its reporting vocabulary has no term.

I direct a medical device development program within a CTSA hub, and the practical effect is familiar. A multi-year device development effort and a one-hour consultation are recorded as the same unit of service activity. Work that reaches a regulatory or design milestone has no field to occupy, so it goes into narrative and drops out of anything that can be counted.

The consequence extends past individual credit. NIH cannot presently answer, at the portfolio level, how often its investments reach the point of delivering something a patient can receive.

Recommendation 1: Define a category for translational outputs where contribution is recorded

NIH should add a named, structured category for translational outputs to the biosketch and to progress reporting, populated by verifiable identifiers rather than narrative assertion. Anchors already exist: patent numbers, FDA submission and clearance or approval identifiers, SBIR and STTR award numbers, and invention and licensing records already reported to the government under existing obligations.

This asks for no new data collection. Much of the information is already reported. It is reported as an institutional compliance obligation to the government rather than as a record of individual scientific contribution, and it never returns to the investigator or reaches reviewers in any form. Route what exists into the instruments where merit is assessed.

Feasibility across institution types is high, because the category records events that either occurred or did not. An investigator at a small institution with one licensed technology can report it as readily as an investigator at a large one with many. No institutional infrastructure is required to participate.

Recommendation 2: Measure translational progression, not market outcomes

What goes into the category matters as much as its existence, and an outcome-anchored indicator would do harm.

Commercial outcomes materialize years after any award period ends. They depend on capital availability, corporate strategy, market size, and reimbursement, none of which an investigator controls. An indicator anchored to market outcomes would reward timing and market conditions rather than scientific contribution. It would penalize work in rare disease, pediatrics, maternal health, and other areas where clinical need is high and commercial return is limited. It would also create pressure to sustain projects that should be stopped.

The more defensible unit of measure is the completed de-risking transition. Candidate indicators include:

- Regulatory pathway determined, with predicate or comparator identified where applicable
- Pre-submission or equivalent agency meeting requested and held

- Investigational application filed (IND, IDE, or equivalent)
- Design specification frozen, or verification and validation testing completed
- Invention disclosed, and patent application filed or claim allowed
- Technology optioned or licensed to a development partner
- Sponsored research or co-development agreement executed with a commercial partner
- Translational funding secured downstream of the award (SBIR, STTR, or equivalent)
- Documented decision not to proceed, with the technical or clinical basis recorded

Each occurs inside an award period, falls within the investigator's control, and is documentable when it happens rather than years later.

That last item carries more weight than its placement suggests. A well-reasoned decision not to proceed should count as a completed transition, not as an absence of output. Recognizing negative determinations removes the incentive to keep unviable work alive for reporting purposes, and it treats efficient failure as what it is: a contribution to translational efficiency.

There is a further reason to measure progression rather than outcomes. Translational projects frequently receive federal support several development cycles before any commercial event, and reporting obligations end when the supporting award ends. An indicator that waits for a market outcome will capture nothing, whatever the underlying work achieved.

Verification

Every indicator above is anchored to a record generated by a third party: a patent office, a regulatory agency, a funding agency, or an executed agreement between institutions. None depends on self-assessment. Each can be audited against an external source. This is what separates the proposed category from narrative impact statements, which cannot be verified, compared, or aggregated.

Feasibility across career stages

The current gap falls hardest on early-career investigators. Translational development routinely runs five to ten years, overlapping the period during which an investigator assembles a promotion and tenure record. An assistant professor who commits effort to advancing a technology toward clinical use spends that time against a record that counts publications and grants, and receives nothing in the formal accounting for the technology itself. The rational response is to defer the work until after promotion, or to decline it.

Institutions largely follow NIH in what they count. A defined category at the federal level would give promotion committees a recognized reference point, at no cost to NIH beyond the definition itself. That is the mechanism by which a reporting change becomes a change in behavior.

Thank You

1. Rigor and Reproducibility: In the grant review process, there should be consideration for the value of Rigor and Reproducibility, particularly for grants that are deemed as addressing topics that are not novel. For example, a new grant application that is on a topic that already has some existence of prior art, could be still highly valuable from the standpoint of Reproducibility and broaden understanding of previously reported findings.

2. Data, Software, and Model Sharing: Scientific impact should include creation of high-quality, reusable data, software, and research resources. However, there is no one-size-fits-all approach to data sharing across biomedical disciplines. Current data-sharing requirements often represent substantial, unfunded effort for investigators, while long-term maintenance and curation exceed the capacity of individual laboratories. Institutions are increasingly responsible for ensuring regulatory compliance but require sustained federal investment in infrastructure, personnel, and data stewardship. NIH should recognize institutional support for data sharing and provide dedicated resources rather than relying on unfunded mandates.

3. Training and Mentorship: Impact should extend beyond publications to developing the next generation of scientists. Indicators could include mentoring quality, trainee career outcomes across multiple career paths, and contributions to research integrity and independence. Expanding mentorship will require recognizing the significant time commitment of senior investigators. NIH should consider in-kind or other mechanisms that compensate mentoring effort, creating incentives for experienced researchers to mentor while strengthening career development and independence of early-stage investigators. In addition to the often-uncompensated time and effort of mentors, host laboratories and institutions provide substantial in kind contribution for trainees including laboratory equipment, access to highly specialized core facilities, access to and maintenance of animal colonies and laboratory space. None of these critical elements in the success of emerging scientists/investigators are compensated for in the current funding opportunities

4. Collaboration: Modern biomedical research depends on multidisciplinary teams. NIH should recognize meaningful contributions to collaborative science through leadership, shared infrastructure, cross-disciplinary partnerships, and coordination of multi-site studies. Evaluation systems could better recognize substantive contributions from all members of successful research teams. The new requirements and rules related to international collaborations are particularly limiting. With globalization in all areas of science, it is unavoidable that lead laboratories and scientists will have multiple

international collaborations and publications. Even for review articles, most leading journals require multiple authorship from different countries/continents.

5. Entrepreneurship and Translation: Appropriate indicators should include clinical implementation, regulatory milestones, licensing, industry partnerships, incorporation into clinical guidelines, and demonstrated public benefit. Evaluation should recognize that meaningful translation often requires long timelines and collaborative partnerships.

6. Foundational Scientific Exploration: Basic and high-risk research should be rewarded even when outcomes are uncertain. Assessment should recognize development of transformative methods, foundational datasets, and new scientific concepts that enable future advances. Evaluation should emphasize scientific quality and long-term influence.

7. Public Impact: Public engagement should be recognized as a core component of scientific impact. Researchers are uniquely positioned to improve public understanding of science, yet outreach and science communication are rarely supported or rewarded. This represents a missed opportunity that contributes to misunderstanding and mistrust of science. NIH should provide dedicated funding for public engagement activities by individual investigators or through coordinated institutional programs, ensuring that communication with the public is recognized as an important and supported component of the research enterprise.

Re: NOT-OD-26-087 — Request for Information on Measuring and Rewarding Scientific Impact

Dear NIH Office of Science Policy,

Weill Cornell Medicine is committed to excellence in patient care, scientific discovery and the education of future physicians in New York City and around the world. The doctors and scientists of Weill Cornell Medicine — faculty from Weill Cornell Medical College, Weill Cornell Graduate School of Medical Sciences, and Weill Cornell Physician Organization — are engaged in world-class clinical care and cutting-edge research that connect patients to the latest treatment innovations and prevention strategies. Located in the heart of the Upper East Side's scientific corridor, Weill Cornell Medicine's powerful network of collaborators extends to its parent university Cornell University and through affiliations and collaborations across the globe. Weill Cornell Medicine faculty provide exemplary patient care at NewYork-Presbyterian/Weill Cornell Medical Center, NewYork-Presbyterian Westchester Behavioral Health Center, NewYork-Presbyterian Lower Manhattan Hospital, NewYork-Presbyterian Queens and NewYork-Presbyterian Brooklyn Methodist Hospital. Weill Cornell Medicine is also affiliated with Houston Methodist.

On behalf of Weill Cornell Medicine, thank you for the opportunity to provide comments in response to the NIH Request for Information (RFI) on Measuring and Rewarding Scientific Impact. We commend the NIH for continuing to seek external input as it considers policy changes with broad implications for the research community. Meaningful stakeholder engagement is essential to ensuring that new policies are informed by the perspectives of those who will be directly affected by them.

We preface our response to the individual topics with three limitations about NIH's effort to identify measurable indicators and incentives of scientific success beyond publication counts and citation metrics.

First, scientists' incentives are largely intrinsic. Curiosity and professional purpose are the motivators and progress and discovery are the incentives. Scientists require adequate resources and institutional support. When these resources are more abundant, scientists may be able to achieve more, and when resources are withdrawn from one line of research and made available for another, scientists may change course accordingly. Based on our anecdotal observations, if resources are held equal, scientists do not become more creative or more productive in proportion to external incentives.

Second, scientific success is defined more broadly than the rigor, reproducibility, data sharing, mentorship, collaboration, and translational impact criteria NIH proposes to measure. Success can mean answering a question or formulating a better one. It can mean discovering something with no obvious utility today that may, decades later, prove foundational to drug

discovery - or it can mean solving the last, technically modest but functionally essential step in a multi-step process built on many other scientists' work over preceding decades. Importantly, we would like to emphasize that foundational knowledge is required before any applied use can be undertaken. As an example, without a firm understanding of the basics of DNA base-pairing, we could not develop gene editing nor advance its applications for patients.

Third, scientists, through their advanced content expertise, remain the best available judges of scientific success. The indicators of an individual scientist's success extend beyond publication counts and citation metrics but are rooted largely in the impact of their published work, whether a sustained, often-cited body of work or a single paper too recent to have accrued citations. These indicators include, but are not limited to, winning competitive fellowships and grants; being sought out by students and postdoctoral fellows who wish to join their lab; being invited to speak at, chair, or organize national and international scientific conferences; being asked to serve on or lead national guidelines panels; being asked to review manuscripts for leading journals; being invited to join journal editorial boards or scientific advisory boards for foundations, NGOs, and companies; election to honorific scientific societies; and prizes for exceptional achievement. These indicators vary by career stage and field. They are qualitative, not quantitative, and in that sense, evaluable but not measurable.

Considering the noted limitations of quantitative metrics, we propose initial ideas for developing frameworks with measurable indicators.

1. Rigor and Reproducibility

Reproducible and replicable biomedical approaches are foundational to rigorous research. New strategies are needed to identify areas ripe for replication and reproducibility efforts, as well as incentives and infrastructure to support the reproduction and replication of existing findings.

Response:

- Reproducibility is foundational to scientific progress. Rigor should be assessed at the level of study design and methodology in addition to after-the-fact judgments about whether results can be replicated. Institutions already support this by building rigor training into graduate and postdoctoral curricula and by ensuring institutional review processes (IRB, IACUC, biostatistics cores) are adequately resourced to support investigators in study design.

- Infrastructure and incentives for replication should be separated from the incentives that drive original discovery. A dedicated funding mechanism for replication studies would allow institutions and investigators to pursue reproducibility work without diverting resources from novel research and would give replication studies a clear, fundable, and publishable home.

- Reproducibility efforts are most productive when targeted rather than universal. NIH should prioritize replication investment in areas where a reproducibility failure carries the greatest downstream cost, e.g., findings poised to inform clinical trials or policy changes, rather than mandating uniform replication requirements across all funded research.

2. Data, Software, and Model Sharing

Sharing scientific data and tools accelerates biomedical research discovery, in part, by enabling validation of research results, providing accessibility to high-value datasets, and promoting data reuse for future research studies. NIH seeks to incentivize and reward these activities to maximize the value of research investments, catalyze collaborations, and accelerate scientific impact.

Response:

- Academic medical centers face difficulty reconciling multiple, sometimes conflicting regulatory frameworks governing the protection and sharing of data. A clearer NIH statement on standards for sharing de-identified data without risk of penalty paired with resources to help institutions meet those standards and support for the considerable costs of sharing, would substantially advance high-quality, widespread data sharing.

- Existing NIH initiatives, including the Data Management and Sharing Policy (DMSP) and the Data Sharing Index (S-Index), provide useful guidance for investigators and administrators. Clarifying in DMSP guidance that investigators need not pay publisher fees to comply with PubMed Central posting requirements would reduce friction and increase compliance. In addition, DMSP and S-Index measures should explicitly account for sensitive data (e.g., protected health information) and direct investigators and administrators to institutional secure enclaves and legal data-sharing agreements that enable cross-organizational data sharing.

- Models and software that leverage statistical techniques, such as machine learning and artificial intelligence, may contain sensitive data (e.g., protected health information) that, while challenging to reidentify, present a challenge for sharing. Coordination among NIH and partners regarding expectations and requirements for sharing of AI/ML-based models and software can potentially reduce friction for investigators and administrators going forward.

3. Training and Mentorship

NIH recognizes that advancing its mission requires promoting the growth and stability of the biomedical research workforce. While NIH supports training and protects time through existing policies and programs, additional indicators are needed to assess and quantify the impact of these efforts.

Response:

- A best practice could be for training programs to track outcomes beyond publications, including attainment of independent funding; career advancement and retention in research and academic medicine; leadership roles among alumni and former trainees; and contributions to science communication. Mentorship impact can be assessed through trainee engagement, career progression, and the development of mentoring networks that sustain the next generation of investigators.

- At the medical student level, useful indicators could include: the percentage of students participating in research; the percentage receiving competitive funding during medical school; the percentage taking a dedicated research year; and the percentage with presentations or publications during medical school.

- Current NIH evaluation criteria commonly capture trainee outcomes, mentorship quality, workforce development, and training activities, but give less weight to science communication with public audiences, STEM outreach and community education, leadership development and service contributions and the extent to which trainees “pay it forward” by mentoring others. These activities strengthen the biomedical workforce, build public trust in science, expand pathways into research careers, and improve retention, yet are not consistently captured in traditional measures of training success.

4. Collaboration

As biomedical research becomes increasingly interdisciplinary and convergent, collaboration is growing in both scale and complexity. NIH seeks new approaches for assessing and recognizing contributions to team-based science.

Response:

- Team-based science is now essential to progress. In fields such as cancer research, where interventions targeting oncogenic signaling can have favorable or unfavorable effects, assembling multidisciplinary teams of experts across these domains is often necessary for meaningful advances.

- NIH should recognize contributions to team-based science by expanding programs such as the Collaborative Program Grant for Multidisciplinary Teams (RM1) beyond NIGMS to other institutes. While other institutes have their own team-science mechanisms, the RM1's key distinguishing feature, a single application with one unified project, rather than a collection of sub-projects as in P01/P50/U54 structures, led by three to six principal investigators sharing management responsibility, merits broader adoption.

5. Entrepreneurship and Translation

To advance the translation of discoveries into products for people, NIH fosters the maturation of discoveries from bench to bedside and promotes innovation across sectors. More can be done to incentivize, assess, and integrate the impact of innovation and entrepreneurial efforts as critical to the NIH mission.

Response:
Any single measure would be imperfect, but the following offer a starting point:

Short-term indicators
- Number of technology disclosures made to the institution's technology transfer office
- Number of filed U.S. patent applications
- Number of active licenses or options transferring faculty IP to commercial partners
- Number of corporate-sponsored research agreements (and associated funding)

Longer-term indicators
- Products on the market based on faculty IP
- Licensing revenue received from licensed faculty IP, as a proxy for economic impact
- Number of start-up companies founded on faculty IP that have received at least $2–5M in institutional or professional investment

6. Foundational Scientific Exploration

Basic research and high-risk, high-reward initiatives represent foundational scientific exploration with an inherent risk of failure but the potential for paradigm-shifting breakthroughs. Further embedding these approaches within the academic enterprise is essential to ensuring continued support for bold and innovative research directions.

Response:
- To insulate foundational research from risk-averse review, NIH should evaluate proposals on the significance of the scientific question and the originality of the approach using metrics tailored to protect early-stage investigators rather than on the extent of preliminary data or perceived certainty of success. Success should be assessed using long-horizon indicators of scientific value, including adoption of new methods and tools, reuse of FAIR datasets, independent replication, and dissemination of rigorous null or negative findings. For clinical conditions where progress has been limited (i.e. Alzheimer's disease given the historical focus on amyloid and tau), recalibrating funding to include exploring mechanisms of newly recognized targets could bring novel ideas and renewed energy to a field.

- NIH should expand investigator-centered funding mechanisms that sustain promising research directions beyond milestone-driven project awards, and should consider tracking “exploratory yield” metrics, such as the proportion of

grant budgets allocated to unproven mechanistic hypotheses and the rate at which basic-science findings generate unanticipated follow-on discoveries. Dedicated failure-tolerant award mechanisms (e.g., expanded NIH Director's Pioneer Award/EUREKA-style programs) should base renewal criteria on rigor of inquiry rather than positive results.

- Additional indicators of success for foundational science include whether findings later seed new subfields, spin out new research programs, or attract follow-on funding from other agencies or industry, even if an immediate patent or product is absent. NIH institutes should also track "long-horizon citation lag", the time between initial publication and eventual translational impact, as a complement to immediate citation counts, since basic science findings often take a decade or more to yield clinical or technological impact.

- Study sections and promotion and tenure committees should be instructed to credit well-designed studies that produce null or negative results. Penalizing negative outcomes disincentivizes the risk-taking this initiative aims to protect.

- Lastly, feasibility varies by career stage. Early-stage investigators need protected, failure-tolerant funding lines distinct from R01 renewal pressure.

7. Public Impact

NIH seeks approaches for assessing and recognizing the broader public impact of biomedical research, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit.

Response:

- One measure of the impact of medical research is the incorporation of findings into clinical guidelines. Research that changes practice guidelines has substantial clinical impact. Research that increases the speed with which findings reach the patient in their physicians' office or at the point of care should be prioritized and incentivized.

- The Translational Science Benefits Model (TSBM) offers a structured framework for identifying and assessing the broader public and societal impacts of translational science beyond traditional publication and citation metrics. The TSBM identifies benefits across four domains, making it a potentially useful model for NIH to consider in assessing public impact:
    - Clinical and Medical Benefits: Person-involved care, procedures and guidelines, tools and products
    - Community and Public Health Benefits: Community engagement and wellness, health activities and products, health care characteristics, health promotion
    - Economic Benefits: Commercial products, financial savings and benefits, healthcare workforce
    - Policy and Legislative Benefits: Advisory activities, community-centered policy, policies and legislation

Sincerely,

Hugh C. Hemmings, Jr, MD, PhD, FRCA
Senior Associate Dean for Research

184. Make Data Count

I am responding: On behalf of an organization

Name: John Chodacki

Name of Organization: Make Data Count

Type of Organization: Non-Profit Research Organization

Role: Organizational Official

Date Submitted: 8/17/2026

1. Rigor and Reproducibility: We encourage NIH to recognize the creation, documentation, stewardship, and reuse of research data as contributions to rigor and reproducibility. Useful indicators could include structured data citations and documented examples of datasets being used for replication, validation, aggregation, methodological development, or comparison with new findings.

Because a citation or download alone does not reveal whether data contributed to reproducibility, we recommend combining quantitative evidence such as standardized dataset citations, views, and downloads with qualitative descriptions of how the data were used and contextual information about the discipline, dataset type, access conditions, intended users, career stage, and contributor roles.

NIH could explore these approaches through pilots across several Institutes and Centers, disciplines, career stages, repository types, and institutional settings. These pilots could examine the completeness of the underlying information, whether reviewers interpret it consistently, whether particular communities are disadvantaged, and whether the indicators create incentives for gaming or superficial compliance.

We also encourage NIH to account for controlled-access and sensitive human-subject data. Such datasets may contribute substantially to replication and validation even when their use cannot be measured through public downloads or other conventional open-access indicators.

2. Data, Software, and Model Sharing: We recommend that NIH treat research data as first-class research outputs and explicitly recognize their creation, curation, documentation, sharing, stewardship, and reuse throughout the grant lifecycle. Researchers could be enabled to identify datasets as distinct contributions in applications, biosketches, progress reports, and final reports. Recognition could extend beyond data producers to those who curate, document, steward, and enable the responsible reuse of data.

Evaluation could consider the quality and significance of a data contribution, rather than focusing only on whether data were deposited or made publicly available. A portfolio of evidence might include:
• Quantitative measures, including standardized dataset citations, views, and downloads;
• Qualitative evidence of replication, validation, subsequent research, clinical application, policy use, education, or collaborations enabled by the data; and

• Context about the discipline, dataset type, access conditions, intended users, career stage, and contributor roles.

We caution against creating a composite data-impact score or using raw citation, view, or download counts to rank researchers. These measures can provide useful evidence, but are most meaningful when interpreted in the appropriate disciplinary and research context.

We encourage NIH-supported repositories to assign persistent identifiers to datasets; provide complete, machine-readable metadata; identify contributor roles and relationships among research outputs; support structured data citation; collect views and downloads using common standards such as the COUNTER Code of Practice for Research Data; and make citation and usage metadata openly available for aggregation and auditing.

The NIH-supported Generalist Repository Ecosystem Initiative provides a practical foundation for this work. Its recommendations for collecting, exposing, and aggregating data citations could serve as a starting point. NIH could also draw upon the open Data Citation Corpus as an evidence and learning resource, while recognizing that citation coverage and metadata completeness continue to vary across repositories and disciplines.

3. Training and Mentorship: N/A

4. Collaboration: We encourage NIH to recognize the full range of roles involved in producing and sustaining reusable research data, including data creation, curation, documentation, quality assurance, stewardship, repository management, and support for responsible reuse. These contributions are essential to team science but are frequently invisible in publication-centered assessment.

Repositories and reporting systems could capture contributor roles in machine-readable metadata and connect contributors, datasets, grants, publications, software, and other outputs through persistent identifiers. Researchers could also be given opportunities to describe their specific data-related contributions in biosketches, applications, progress reports, and final reports.

Assessment could consider both structured contribution information and qualitative evidence of collaborations enabled by shared data. We caution against inferring individual credit solely from citation or download counts. Pilot programs could examine whether proposed indicators appropriately recognize team-based contributions and work performed by data stewards, curators, technical specialists, and other research professionals at different career stages.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: We encourage NIH to consider not only whether research data were accessed, but also how they were subsequently used. Evidence of public impact could include documented uses of data in clinical applications, public-health decisions, policy development, education, community resources, methodological improvements, and research that produces subsequent health or societal benefits.

NIH could support the development and adoption of contextual classifications, such as the Make Data

Count Typology of Data Uses, to distinguish among replication, validation, aggregation, methodological development, education, clinical application, and policy development. Connecting data citations and other usage evidence to these purposes could help NIH understand how its investments contribute to health, scientific progress, and public benefit.

Because many benefits emerge slowly or cannot be reduced to numerical counts, we recommend supplementing quantitative indicators with concise qualitative impact narratives. We also encourage recognition of controlled-access, specialized, and smaller-community datasets whose public benefit may be substantial despite relatively low citation or download totals.

8. Other Areas: Before data-related indicators are used in consequential funding or evaluation decisions, we recommend that NIH explore them through pilots across disciplines, career stages, repository types, Institutes and Centers, and institutional settings. These pilots could evaluate data quality and coverage, disciplinary differences, equity effects, recognition of team contributions, reviewer consistency, and the potential for gaming.

We encourage the involvement of researchers, data stewards, repositories, infrastructure providers, research administrators, evaluators, and affected communities in designing and evaluating these pilots. NIH could also support the open infrastructure and research needed to improve metadata completeness, establish appropriate contextual benchmarks, and make the resulting evidence transparent and auditable.

The objective would not be to replace publication-based metrics with another narrow set of counts, but to create a more complete, responsible, and transparent account of the many contributions through which modern biomedical science advances.

File Upload: https://osp.od.nih.gov/wp-content/uploads/ninja-forms/77/NOT-OD-26-087-RFI-on-Measuring-and-Rewarding-Scientific-Impact.pdf

Description: Make Data Count response to NOT-OD-26-087, Request for Information on Measuring and Rewarding Scientific Impact. The attached letter provides recommendations for recognizing research data as first-class outputs; combining quantitative indicators with qualitative and contextual evidence; building on open standards and infrastructure; identifying the purposes and outcomes of data reuse; and piloting these approaches before using them in consequential decisions.

August 10, 2026

Re: NOT-OD-26-087, Request for Information on Measuring and Rewarding Scientific Impact

Dear NIH Office of Science Policy,

Make Data Count welcomes NIH's effort to identify better ways of measuring and rewarding scientific impact. Our response focuses on data sharing and reuse, an area in which NIH has an opportunity to recognize important research contributions that are largely invisible in current assessment systems.

Make Data Count is a global, community-led initiative that has been working to develop open, transparent, and meaningful measures of how research data are used since 2014. Following a rigorous selection process, the Global Sustainability Coalition for Open Science Services (SCOSS) selected Make Data Count as infrastructure essential to open science. Make Data Count has worked over the years with NIH on recommendations and implementations of best practices, including chairing a virtual conference on data metrics[1] and publishing in an NIH data policy special issue of Harvard Data Science Review[2]. Our central recommendation is that NIH treat data as first-class research outputs and explicitly recognize the creation, curation, documentation, sharing, stewardship, and reuse of data in funding and evaluation processes in ways that incentivize researcher behavior.

We offer the following recommendations:

1. **Recognize data contributions throughout the grant lifecycle**

We recommend that NIH enable researchers to identify datasets as distinct research contributions in applications, biosketches, progress reports, and final reports. These processes should recognize not only data producers, but also those who curate, document, steward, and enable the responsible reuse of data.

Evaluation should consider the quality and significance of the contribution, not simply whether data were made publicly available. Controlled-access data, sensitive human-subject data, dynamic datasets, and data created for small or specialized communities may have substantial value even when their use cannot be captured through conventional public-access measures.

2. **Combine quantitative measures with qualitative evidence and context**

[1] https://datascience.nih.gov/sites/g/files/mnhszr336/files/01_Opening_Remarks_Dawei_Lin_508.pdf
[2] Lowenberg, D. (2022). Recognizing Our Collective Responsibility in the Prioritization of Open Data Metrics. Harvard Data Science Review, 4(3). https://doi.org/10.1162/99608f92.c71c3479

No individual indicator can adequately represent the impact of a dataset. A portfolio approach combining the following would give NIH a more complete picture: :

- Quantitative measures, including standardized dataset citations, views, and downloads;
- Qualitative evidence, such as descriptions of replication, validation, new research, clinical application, policy use, education, or collaborations enabled by the data; and
- Contextual information about the discipline, dataset type, access conditions, intended users, career stage, and contributor roles.

Our preprint, *Make Data Count: Driving metrics for the meaningful evaluation of data*[3], describes why all three components are needed for data metrics to be meaningful, comparable, and trusted.

We caution against a composite data-impact score or use raw citation, view, or download counts to rank researchers. Such counts may provide useful evidence, but they should be interpreted within the relevant research and disciplinary context.

3. **Build upon open standards and infrastructure**

Indicators should be derived from transparent, auditable information rather than proprietary or opaque systems. NIH-supported repositories should be encouraged or required to:

- Assign persistent identifiers to datasets;
- Provide complete, machine-readable metadata, including contributor roles and relationships between datasets and other research outputs;
- Support structured citation of data;
- Collect views and downloads using common standards, such as the COUNTER Code of Practice for Research Data[4]; and
- Make citation and usage metadata openly available for aggregation, analysis, and auditing.

The NIH-supported Generalist Repository Ecosystem Initiative (GREI)[5] has already provided a practical foundation for this work. The GREI recommendations for collecting, exposing, and aggregating data citations[6] could serve as a starting point for broader NIH implementation. NIH can also draw upon the open Data Citation Corpus[7] to explore how NIH-funded data are cited and reused. The Corpus should initially be treated as an evidence and learning resource and not as a comprehensive or definitive ranking system because citation coverage and metadata completeness continue to vary across repositories and disciplines.

4. **Capture how data are used, not merely whether they are used.**

A citation, view, or download does not by itself explain the purpose or significance of data use. We encourage NIH to support the development and adoption of contextual classifications, such

---

[3] Puebla, I.& Chodacki, J. (2024). Make Data Count: Driving metrics for the meaningful evaluation of data. Zenodo. https://doi.org/10.5281/zenodo.14261211

[4] https://coprd.countermetrics.org/

[5] https://datascience.nih.gov/data-ecosystem/generalist-repository-ecosystem-initiative

[6] https://makedatacount.org/read-our-blog/grei-data-citation-recommendations/

[7] https://makedatacount.org/find-a-tool/data-citation-corpus-documentation/

as the Typology of Data Uses[8], to distinguish uses including replication, validation, aggregation, methodological development, education, clinical application, and policy development. Capturing these different pathways would help NIH connect data reuse more directly to rigor, reproducibility, collaboration, translation, and public benefit.

5. **Pilot, evaluate, and improve these approaches before using them in consequential decisions**

We recommend that NIH begin with pilots across several Institutes, Centers, disciplines, career stages, repository types, and institutional settings. These pilots should assess:

- Whether the underlying information is sufficiently complete and reliable;
- Whether indicators disadvantage particular disciplines, institutions, career stages, or research communities;
- Whether measures appropriately recognize team-based contributions;
- Whether measures create incentives for gaming or superficial compliance; and
- Whether reviewers can interpret the information consistently and responsibly.

These pilots should involve researchers, data stewards, repositories, infrastructure providers, research administrators, evaluators, and affected communities in the design and evaluation of these pilots. It should also fund the open infrastructure and research necessary to improve coverage, establish appropriate benchmarks, and understand disciplinary differences.

Better recognition of data will strengthen incentives for rigorous data stewardship and sharing while helping NIH understand how its investments enable subsequent discovery and public benefit. The objective should not be to replace publication-based metrics with another narrow set of counts. It should be to create a more complete, responsible, and transparent account of the many contributions through which modern science advances.

Make Data Count would welcome the opportunity to share its experience, infrastructure, standards, and community resources as NIH develops and tests these approaches.

Sincerely,

[redacted]

185. Digital Science & Research Solutions Inc.

I am responding: On behalf of an organization

Name: Digital Science

Name of Organization: Digital Science & Research Solutions Inc.

Type of Organization: Commercial Entity (Biotech/Device/Pharmaceutical Company/Small Business)

Role: Organizational Official

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: Rigorous and reproducible science is most effectively assessed through observable and documented research practices rather than publication outcomes alone. This directly reflects the priorities set out in Executive Order 14303, Restoring Gold Standard Science, which identifies reproducibility, transparency, communication of uncertainty, and a willingness to subject scientific findings and assumptions to continued scrutiny as foundational tenets of trustworthy federal research.

Successful replication remains one of the strongest indicators of scientific robustness. However, replication is inherently retrospective, resource-intensive and feasible for only a fraction of published research. NIH should therefore complement direct replication with measurable indicators of the research practices and outputs that make findings independently assessable, reproducible, and ultimately replicable.

Use connected research to identify where replication is needed most
Persistent identifiers, interoperable metadata and connected research information have fundamentally changed what can be observed across the research lifecycle. Publications can increasingly be linked to grants, datasets, software, protocols, biological resources, organizations, researchers, and subsequent research outputs. This provides NIH with a substantially broader evidence base for assessing scientific rigor than publication counts and citation metrics alone. These evidence-based indicators reflect transparency, methodological rigor and the stewardship of research outputs.

This same connected evidence base can also help address a critical question: Where would additional replication effort have the greatest scientific value?
Rather than prioritizing replication primarily in response to highly visible failures or individual nominations, NIH could develop an evidence-based framework for identifying research areas where independent verification is most warranted. Such framework could combine multiple signals, including:
availability and accessibility of quality underlying datasets and analytical code;
availability of sufficiently detailed protocols and methods;
use of trusted repositories and persistent identifiers;
preregistration where scientifically appropriate;
transparent reporting of methods, including negative and confirmatory findings;
citation and demonstrated reuse of datasets, software and research resources; and
independent validation or replication of published results.

Natural language processing and structured metadata applied to the full text of published research can now detect the presence or absence of specific transparency markers at scale, including disclosed funding, stated ethical approval, data and code availability, declared competing interests, validated across multiple fields to avoid disciplinary bias. This allows NIH to move from a largely reactive and subjective model of replication toward a more systematic, evidence-informed model: identifying consequential findings or research areas that have limited independent verification, weaker reproducibility signals, or substantial downstream scientific dependence. NIH could use such evidence to help prioritize replication investments, including expansion of existing efforts to independently replicate significant lines of NIH-supported research.

Reward the work required to make science reliable
Identifying where replication is needed does not resolve why so little of it happens. Academic incentive structures are built almost entirely around individual achievement, including first or last authorship, novel-discovery outputs, principal investigator status, publication volume, grant funding, and citation-based indicators. These measures can undervalue the collaborative and often less glamorous and less visible work required to verify, reproduce, challenge, or strengthen existing findings. Researchers undertaking rigorous replication largely absorb the professional cost of that work personally, while the resulting benefit of a more reliable scientific evidence base accrues broadly to the field as a whole.

NIH can help change this incentive structure by making contributions to reproducibility and replication visible, attributable, and creditable. When replication studies are linked to the original finding through persistent identifiers a contributor's specific role in it, replication design, execution, data verification, methodology, software, resource development, and experimental execution are captured through structured contributor taxonomies such as CRediT, those contributions can become part of an investigator’s documented scientific record independent of authorship position high citation counts.

NIH could extend this further by formally recognizing verification and replication contributions in biosketches, progress reports, grant review criteria, and other assessment processes and by continuing to explore dedicated funding and recognition mechanisms for high-value replication research.

Measure practices and outcomes, not compliance alone
These indicators should prioritize evidence of accessibility, reuse, verification and scientific utility, rather than simple compliance with reporting requirements. A dataset that is discoverable, interoperable and reused by multiple research communities provides considerably stronger evidence of scientific value than one that is merely deposited.

Potential measurable indicators could include:
proportion of applicable research outputs with accessible underlying datasets;
proportion with accessible analytical code or computational workflows;
availability and completeness of protocols and methodological documentation;
use of trusted repositories and persistent identifiers;
preregistration where scientifically appropriate;
transparent reporting of methods, limitations, negative findings, and confirmatory findings;

demonstrated reuse of datasets, software, protocols, and research resources;
successful computational or methodological reproduction by independent researchers;
documented independent validation or replication;
links between original findings and subsequent replication or validation studies; and
continued accessibility of research outputs over time.

Create infrastructure for negative and confirmatory findings
Transparent reporting of negative and null findings, named explicitly above as an indicator, and named directly among the Gold Standard Science tenets as a marker of trustworthy research culture, depends on more than researcher willingness. It requires infrastructure through which these outputs can be persistently identified, discovered, cited, connected to the original research, and recognized as legitimate scientific contributions regardless of journal publication.

Repository infrastructure capable of assigning persistent identifiers to diverse research outputs can provide a durable mechanism for making negative confirmatory findings part of the scientific record. Connecting these outputs to grants, investigators, datasets, protocols and origination studies would also allow NIH to evaluate their subsequent attention, reuse, and scientific influence.

This is important because an incentive to report negative findings will have limited effect if those findings remain effectively invisible within research assessment systems.

Minimize reporting burden through interoperability
Implementation should build upon existing community standards, including DOIs, ORCID iDs, ROR identifiers, RRIDs and grant identifiers, and structured contributor roles. Wherever possible, NIH should derive indicators from existing research infrastructure rather than requiring investigators to repeatedly report on information already available elsewhere.
The objective should be to create a connected evidence layer around NIH-supported research, not another administrative reporting layer.

Protect the independence of replication review
Replication also presents distinct review-integrity considerations. A proposal to replicate an influential finding may be reviewed by researchers who collaborated with, trained with, competed with, or have other significant scientific relationships to investigators associated with the original work.
For replication-focused funding, NIH could therefore consider conflict-of-interest screening that examines relevant relationships to both the replication applicant and the research being replicated. Connected publication, funding, institutional, and collaboration information could assist NIH in identifying relationships requiring additional review while preserving appropriate scientific expertise on review panels.

Distinguish transparency, reproducibility, and replication
Finally, NIH should avoid collapsing transparency, reproducibility, and replication into a single composite measure.

They represent related but distinct dimensions of scientific quality:

Transparency asks whether the evidence, methods, materials, assumptions, and limitations necessary to evaluate the research are available.
Reproducibility asks whether the reported result can be obtained using the original data, methods, or analytical procedures, as appropriate to the research domain.
Replication asks whether a finding can be independently tested and supported using new data, experiments, samples, or other appropriate independent approaches.
Each provides different information about the reliability of a scientific claim. NIH assessment frameworks should preserve these distinctions while recognizing their complementary value.

Research assessment itself should also be treated as an evidence-based scientific endeavor. Any indicators NIH adopts should be evaluated for construct validity, disciplinary and methodological bias, susceptibility to gaming, administrative burden, and unintended behavioral consequences, and should evolve as evidence accumulates.

The opportunity for NIH is therefore broader than developing another set of research metrics. By connecting information already generated throughout the research lifecycle, NIH can build an evidence-informed system that helps determine which findings most warrant independent replication, which practices make research more reproducible, and which researchers and teams are contributing to the collective reliability of biomedical science. Such a framework would allow NIH to direct replication investment based on evidence rather than visibility while creating meaningful incentives for researchers to produce science that can be independently evaluated, reproduced, and trusted.

2. Data, Software, and Model Sharing: Scientific publications are increasingly one component of a much broader ecosystem of research objects. The publication should be viewed as an entry point into the research record, rather than the research record itself. Contemporary biomedical discovery depends upon interconnected datasets, software, computational models, protocols, workflows and other digital research assets that enable verification, reuse and cumulative knowledge generation.

NIH assessment frameworks should recognize these outputs as first-class scientific contributions whose value extends well beyond their role in supporting individual publications.

The central objective should not simply be to incentivize sharing, but to incentivize useful and reusable sharing. A binary measure of whether a dataset, software package, or model was deposited provides limited information about whether the resource can be discovered, understood, accessed, reused, and built upon by other researchers.
The more meaningful question is:
Did the shared research asset continue to generate scientific value after the originating project ended?
This distinction is important for maximizing the return on NIH's research investment.

Move from measuring deposition to measuring reuse
Persistent identifiers, interoperable metadata, repositories, and connected research information increasingly make it possible to observe how research objects move through the research ecosystem, from creation and deposit to discovery, citation, integration, reuse, and subsequent scientific outcomes.

NIH therefore has an opportunity to evolve from measuring whether sharing occurred toward measuring

whether shared assets are findable, accessible,understandable, reusable, and demonstrably used by others.

Potential measurable indicators could include:
deposition in appropriate trusted repositories;
assignment and continued resolution of persistent identifiers;
completeness and quality of metadata;
linkage to originating grants, publications, investigators, and institutions;
adherence to relevant FAIR principles and community standards;
availability of documentation sufficient to understand and reuse the resource;
software versioning, documentation, dependency information, and maintenance;
model documentation, including relevant assumptions, parameters, provenance, limitations, and versioning;
use of appropriate licenses or terms that clearly communicate conditions of reuse;
citation or formal acknowledgment of datasets, software, models, protocols, and other research assets;
evidence of reuse in subsequent publications or research projects;
reuse by investigators or institutions independent of the originating research team;
integration into subsequent datasets, software, models, clinical research, public resources, or other research infrastructure;
evidence of continued maintenance and accessibility over time; and
breadth and diversity of downstream reuse across research communities.

These indicators should not necessarily be combined into a single score. Different research objects and disciplines have different reuse patterns, and assessment should account for those differences.

Reward stewardship, not compliance alone
NIH should distinguish deposit, stewardship, and reuse.
Deposit establishes that an output has been made available.

Stewardship establishes that the output remains accessible, documented, interpretable, interoperable, and usable.
Reuse demonstrates that the output has generated value beyond the originating research project.
These are related but distinct dimensions of responsible research sharing.

A dataset deposited to satisfy a policy requirement but lacking sufficient metadata or documentation to permit meaningful reuse should not be treated as equivalent to a well-curated dataset that is independently reused across multiple research projects. Similarly, software that is deposited but cannot be executed because dependencies, documentation, or version information are absent provides different scientific value from software that remains maintained, documented, and adopted by other research teams.

NIH incentives should recognize this continuum.

Give researchers credit for creating reusable research assets

Researchers continue to receive substantially more professional recognition for publications than for the creation and stewardship of reusable research resources. This creates a structural incentive problem: producing high-quality datasets, maintaining software, documenting models, curating metadata, and supporting reusable resources require significant scientific effort, yet those contributions may remain largely invisible in traditional research assessment.
NIH can help change this by making these contributions visible and creditable.

Dataset, software, model, and resource contributions could be incorporated more explicitly into NIH biosketches, progress reporting, grant review, and other assessment processes. Where contributor roles can be reliably attributed, NIH could recognize activities such as data curation, software development, validation, visualization, methodology development, and resource stewardship alongside more traditional publication-based evidence of contribution.
Importantly, credit should not depend solely upon citation counts. Dataset and software citation practices remain inconsistent across disciplines. NIH should therefore consider multiple forms of evidence, including formal citation, persistent-identifier linkages, documented reuse, integration into downstream research, and other appropriate indicators of adoption.

Treat software and computational models as scientific methodology
Software and computational models warrant particular attention because they are increasingly integral to biomedical methodology.
Where software materially contributes to scientific findings, its documentation, versioning, provenance, dependencies, accessibility, and maintenance directly affect the ability of other researchers to evaluate or reproduce the work. Similarly, computational and AI/ML models may require documentation not only of the model itself but also of relevant training or validation data, versioning, parameters, assumptions, limitations, and appropriate conditions of use.

Assessment frameworks should therefore recognize software and model stewardship as part of scientific rigor rather than treating these outputs as secondary technical products.

NIH should also recognize that maintenance itself is a scientific contribution. A widely used software package or research resource can continue enabling NIH-funded science for many years after its original grant has concluded. Traditional assessment approaches may substantially underestimate this continuing return on federal investment.

Use connected evidence to understand downstream value
A major opportunity is the ability to connect shared research assets to subsequent scientific activity. Persistent identifiers and connected metadata can increasingly link a dataset or software resource to its originating grant and publication and then trace subsequent citations, publications, grants, investigators, institutions, clinical research, or other outputs that make use of it.

This creates the possibility of measuring research asset lineage: not simply whether an asset exists, but where it came from, who subsequently used it, and what additional scientific activity it helped enable.

For NIH, this could provide a new way to understand return on research investment. A dataset generated

through one NIH award may subsequently support research conducted by dozens of investigators, across multiple institutions and funding programs. Those downstream uses represent scientific value created by the original investment but are largely invisible in publication-centered assessment.

NIH could therefore consider indicators such as:
Reuse rate: whether and how often a resource is independently reused.
Reuse breadth: the number and diversity of investigators, institutions, disciplines, or projects using it.
Reuse longevity: whether the resource continues to generate research activity over time.
Research lineage: the subsequent publications, grants, clinical studies, resources, software, or other outputs connected to the original asset.
Independent reuse: whether reuse extends beyond the originating investigators or institution.
Together, these measures would provide a substantially richer view of scientific impact than deposit counts alone.

Build upon NIH's work on measuring data sharing
NIH has already explored this challenge through efforts such as the Data Sharing Index (S-Index) Challenge, which examined approaches for moving beyond a binary determination of whether data were shared toward more scalable measures of data sharing and reuse.

Experience from that effort demonstrates both the importance and feasibility of connecting repository information, persistent identifiers, research metadata, and downstream scholarly activity to better understand the lifecycle of shared data.

Digital Science's participation in NIH's S-Index Challenge demonstrated the practical feasibility of this approach. Our submission combined repository infrastructure supporting persistent identification and FAIR-aligned metadata with connected research information capable of tracing relationships among datasets, publications, grants, researchers, institutions, and subsequent research activity. Importantly, these capabilities were based on established infrastructure already operating at scale rather than systems created solely for the Challenge. That experience suggests that many of the indicators described above can be derived from existing infrastructure and metadata, rather than requiring NIH to create new reporting systems or impose additional reporting requirements on researchers.

Existing research infrastructure already indexes datasets distributed across many repositories and connects research objects with publications, grants, researchers, organizations, and other outputs. This provides a practical foundation for evaluating not only whether data have been deposited, but whether those assets are subsequently discovered, cited, reused, and connected to additional scientific activity.

NIH can therefore build upon existing community and commercial infrastructure, standards, persistent identifiers, and metadata to develop and validate indicators before introducing additional reporting requirements.

Reduce burden through interoperability
Implementation should prioritize interoperability and automation.
DOIs, ORCID iDs, ROR identifiers, grant identifiers, software identifiers, repository metadata, and other

established standards can provide much of the connective infrastructure required to understand research asset creation and reuse.

Where information can be derived reliably from existing systems, researchers should not be required to report it again.
This principle is particularly important if NIH expands assessment beyond publications. The goal should be to recognize a broader range of scientific contributions without creating a correspondingly broader administrative burden.

NIH should also recognize that no single indicator will adequately capture the value of all data, software, or models. Indicators should be validated for disciplinary differences, field maturity, resource type, susceptibility to gaming, and unintended incentives. Measures of reuse should complement, rather than replace, qualitative scientific judgment.

Ultimately, NIH has an opportunity to shift the incentive structure from "Did you share it?" to "Did you make it reusable, and did it continue to create value?"

That shift would better recognize the researchers who create and steward high-value scientific resources, provide NIH with a more complete picture of the return generated by federal research investments, and encourage a research ecosystem in which data, software, and models remain active scientific assets long after the projects that created them have ended.

3. Training and Mentorship: The continued strength of the biomedical research ecosystem depends not only on generating new knowledge but on developing the people, skills and research practices, and cultures that make future discovery possible. Training and mentorship should therefore be assessed not simply as activities that occurred, but by the scientific capacity they create over time.

Traditional indicators such as the number of trainees supported, fellowships completed, or training activities delivered provide important administrative information but only a partial measure of impact. They establish that training occurred; they do not establish what that training produced.

NIH has an opportunity to shift from measuring training activity toward measuring researcher development, mentorship effectiveness, and sustained scientific capacity.

Follow outcomes beyond the training period
The impact of NIH-supported training frequently becomes apparent years after an award or fellowship ends. Assessment should therefore follow researcher trajectories over longer periods rather than relying predominantly on outcomes observable within a single grant cycle.
Potential longitudinal indicators could include:
progression to subsequent career stages;
time to research independence, where independence is an appropriate career objective;
subsequent participation or leadership in funded research;
movement into scientific leadership positions;
continued participation in biomedical research across academia, healthcare, government, industry, nonprofit organizations, and other sectors;

participation in interdisciplinary and multi-institutional research;
development of sustained collaborative research networks;
subsequent contributions to data, software, methods, protocols, and shared research resources;
adoption and leadership of rigorous and reproducible research practices;
subsequent mentoring and supervision of other researchers; and
continued contribution to the biomedical research ecosystem over time.

Importantly, successful training should not be defined solely as progression toward a tenure-track faculty position or principal investigator status. NIH-supported researchers contribute to biomedical science through many pathways, including industry, clinical research, regulatory science, public health, government, research infrastructure, data science, software engineering, and other technical and collaborative roles.

An assessment framework that defines success too narrowly risks categorizing valuable scientific careers as attrition when they may instead represent substantial returns on NIH's training investment.

Measure mentorship by what it enables
Mentorship itself should be recognized as a scientific contribution.
Effective mentors do more than supervise research activity. They help researchers develop scientific judgment, methodological rigor, professional networks, collaborative skills, responsible research practices, and the ability to mentor others.

NIH could therefore consider indicators of mentorship effectiveness that examine the subsequent development of trainees over time. These might include trainee progression, continued participation in biomedical research, transition into appropriate leadership or independent roles, development of collaborative networks, contributions to rigorous and reproducible research, and evidence that former trainees subsequently become effective mentors themselves.
This creates an important potential indicator of long-term impact: mentorship propagation.

Rather than viewing the completion of an NIH-supported fellowship or training award as the endpoint of measurement, NIH could examine the longer arc of the investment:
NIH-supported training → mentorship → researcher development → continued contribution to the biomedical research ecosystem → creation of new research, data, software, methods, or other scientific resources → subsequent mentorship and development of additional researchers.

Viewed in this way, the impact of NIH-supported training is not limited to the career outcome of a single trainee. It can propagate through subsequent research contributions, collaborations, institutions, sectors, and generations of researchers. A training investment made in one individual may ultimately contribute to the development of an extended scientific network whose collective impact substantially exceeds what can be observed at the conclusion of the original award.

Persistent identifiers and connected research information increasingly make portions of this longitudinal pathway observable. By linking training awards and mentors to subsequent grants, research outputs, affiliations, collaborative networks, contribution roles, and later mentorship relationships, NIH could

begin to understand not simply whether an individual completed training, but how that investment propagated through the biomedical research ecosystem over time.

Such evidence should not be reduced to a simplistic mentor ranking or score. Trainee outcomes are influenced by discipline, institution, career goals, economic conditions, personal choices, and many factors beyond an individual mentor's control. Longitudinal evidence should therefore inform qualitative assessment rather than substitute for it.

Use longitudinal research information to understand career trajectories
Advances in research information infrastructure make it increasingly possible to understand researcher development over longer periods.
Persistent researcher identifiers, grant information, publications, affiliations, contribution metadata, and collaborative relationships can help connect an individual's research activity across career stages. With appropriate safeguards and validation, these data can provide NIH with a portfolio-level view of what happens to researchers following NIH-supported training.

For example, connecting persistent researcher information across successive grants, research outputs, affiliations, and sectors can help NIH understand whether trainees subsequently participate in academic research, industry, government, healthcare, public health, regulatory science, or other parts of the biomedical ecosystem; whether they develop sustained research collaborations; and where appropriate, whether they progress toward independent funding or scientific leadership.

This would allow NIH to ask questions that are difficult to answer from administrative completion data alone:
What kinds of careers do NIH-supported trainees build?
Which training environments consistently produce sustained participation in biomedical research?
Which programs produce researchers who subsequently develop other researchers?
Where does NIH-supported talent remain within the biomedical research ecosystem, and where is scientific capacity being lost?
Which training approaches are associated with stronger long-term outcomes across different career pathways?
The objective should not be to prescribe a preferred career destination, but to understand whether NIH training investments generate durable scientific capability.

Recognize the full range of contributions that sustain research careers
Many activities that underpin high-quality biomedical research, including mentorship, data stewardship, software development, research infrastructure, peer review, methodological support, and collaborative leadership remain less visible within publication and PI-centered assessment frameworks.
This can particularly disadvantage researchers whose scientific contribution occurs through technical, collaborative, or infrastructure leadership rather than through conventional principal investigator roles.

Structured contributor information and recognized contribution taxonomies can help make these roles more visible. Rather than inferring contribution predominantly from authorship position or PI status, NIH could recognize documented roles in areas such as data curation, software development, methodology,

validation, project administration, supervision, and other contributions essential to modern team science.

This is relevant to workforce stability because NIH cannot effectively understand retention if its assessment systems recognize only a subset of the careers through which people contribute to biomedical research.

A researcher who moves from an NIH-supported training program into scientific software development, data stewardship, research infrastructure, regulatory science, or another research-enabling role should not automatically disappear from NIH's understanding of the workforce simply because that individual does not subsequently become a PI.

Recognize contributions to training culture
Mentorship also occurs beyond traditional one-to-one supervisory relationships.
Researchers contribute to workforce development by creating openly available training resources, developing interdisciplinary training programs, teaching responsible research practices, supporting reproducibility initiatives, participating in peer review, building research communities, and creating shared technical or methodological resources.

Potential indicators could therefore include:
development and demonstrated use of openly available educational or training resources;
contributions to interdisciplinary or cross-institutional training programs;
leadership in research integrity, responsible conduct of research, and reproducibility initiatives;
documented mentorship and supervision contributions;
contributions to shared research methods, infrastructure, data, or software that enable other researchers;
sustained collaborative relationships involving junior researchers;
participation in peer review and other forms of scientific community stewardship; and
evidence that trainees subsequently contribute to mentorship and workforce development themselves.

Where possible, assessment should emphasize evidence of use and downstream impact, rather than simply counting activities. For example, an openly available training resource that is adopted across multiple institutions provides stronger evidence of training impact than the existence of the resource alone.

Build on existing information rather than creating new reporting burdens
Much of the information needed to develop these indicators already exists across research systems. Persistent identifiers and connected research information can increasingly link researchers with grants, publications, affiliations, research outputs, collaborative networks, and documented contribution roles over time. These data can complement NIH administrative information and targeted qualitative evidence to provide a richer understanding of researcher development.

The goal should be to derive longitudinal evidence from existing information wherever it can be done reliably, rather than requiring mentors and trainees to repeatedly report information NIH or the broader

research ecosystem already holds.

NIH should also be cautious about the limitations of these indicators. Persistent identifier coverage varies; affiliation and career information can be incomplete; some sectors produce fewer visible scholarly outputs; career trajectories are not linear; and quantitative indicators may systematically underrepresent important forms of scientific contribution.

For these reasons, longitudinal data, structured contribution statements, trainee and mentor perspectives, and narrative evidence should complement one another.

Measure durable scientific capacity
Ultimately, NIH should assess training and mentorship according to the durable scientific capacity created by its investment.
A successful training investment is not simply a completed fellowship. It is a researcher who develops skills, contributes meaningfully to biomedical science, participates in productive scientific networks, and potentially develops the next generation of researchers.

A successful mentor is not simply someone who supervises a large number of trainees. It is someone whose mentorship contributes to the development of capable researchers and strengthens the culture and practice of science.

And a stable biomedical workforce should not be defined solely by the number of researchers who become principal investigators. It should encompass the diverse scientific, technical, clinical, public-sector, and collaborative careers required for modern biomedical research.

By following researcher trajectories over time, recognizing the full range of scientific contributions, and examining how mentorship propagates through subsequent careers and generations, NIH can move from counting training activities to understanding whether its investments are building and sustaining the biomedical research capacity required for its mission.

4. Collaboration: Authorship remains one of the dominant mechanisms for recognizing scientific contribution, yet it captures only a fraction of what contemporary team-based science requires. As biomedical research becomes increasingly interdisciplinary, computational, collaborative, and cross-sector, NIH assessment frameworks should recognize collaboration as the integration of complementary expertise and contributions toward a scientific objective, not simply as co-authorship.

This distinction is increasingly important. Scientific teams now depend upon specialized contributions spanning experimental science, clinical expertise, statistics, data science, software development, methodology, research infrastructure, project leadership, community engagement, and other capabilities. Assessment systems that focus predominantly on first or last authorship risk overlooking many of the contributions upon which modern biomedical research depends.
NIH therefore has an opportunity to address two related but distinct questions:
What did each person contribute to the team?
and
Did the collaboration create scientific capability or value that the participants would have been unlikely

to achieve independently?
Both should inform the assessment and recognition of team science.

Recognize contribution, not simply authorship position
Author order is an imperfect proxy for scientific contribution and becomes increasingly inadequate as teams grow larger and roles become more specialized.
NIH could place greater emphasis on structured contributor information, including recognized taxonomies such as CRediT, to make individual roles within collaborative research more visible. Contributions such as methodology development, software, data curation, validation, statistical analysis, visualization, supervision, project administration, resource development, and other activities should be recognizable as scientific contributions in their own right where appropriate.

This would be particularly valuable for researchers whose contributions are essential to multiple projects but who may rarely appear as first or last author or principal investigator.

The objective should not be to replace authorship, but to supplement it with evidence that better reflects who contributed what.
Over time, structured contribution information could enable NIH to recognize patterns of scientific contribution across multiple projects. A researcher who repeatedly provides essential methodological, computational, clinical, data, or infrastructure expertise across collaborative programs may be making an important contribution to NIH's mission even if traditional publication metrics systematically understate that role.

Distinguish collaboration from scientific integration
NIH should also distinguish between the size of a collaboration and the quality or depth of scientific integration.
More investigators, institutions, disciplines, or sectors do not necessarily indicate more effective collaboration. Indicators that simply reward larger teams could unintentionally encourage collaboration for its own sake.

More meaningful evidence would examine whether collaborators combine complementary expertise, share research resources, create sustained intellectual or technical relationships, and produce outputs or capabilities that cross traditional disciplinary or organizational boundaries.

Potential indicators could include:
diversity and complementarity of documented contributor roles;
interdisciplinary participation appropriate to the scientific question;
sustained collaboration across projects or funding periods;
cross-institutional or cross-sector research relationships;
shared datasets, software, methods, protocols, infrastructure, or other scientific resources;
joint development of community research resources;
evidence of knowledge exchange across disciplines or sectors;
subsequent reuse or adoption of collaborative outputs;
development of new collaborations or research communities arising from the original team;

translation of research across scientific, clinical, public-sector, or commercial environments where appropriate; and
evidence that the collaboration creates capabilities or outputs beyond those attributable to a single participating group.

These indicators should complement expert assessment rather than be combined Mechanically into a collaboration score.

Understand collaboration as a network, not an event
Collaboration should also be assessed longitudinally.
A co-authored publication provides evidence that researchers worked together on the output. It provides considerably less information about whether the relationship developed into a sustained and productive scientific partnership.

Persistent identifiers and connected research information increasingly make it possible to examine collaborative relationships across grants, publications, datasets, software, clinical studies, organizations and other research activity over time.

This allows collaboration to be understood as a network that develops and evolves, rather than a characteristic of an individual publication.
For example, NIH could examine whether a funded interdisciplinary collaboration:
NIH investment → brings together complementary expertise → produces shared research and resources → develops sustained collaborative relationships → generates additional research or capabilities → expands into new institutions, disciplines, or sectors → produces downstream scientific or translational value.
This provides a richer conception of collaborative impact than counting co-authored publications or participating institutions.

It also allows NIH to distinguish between first-order and downstream effects of collaborative investments. The immediate output may be a publication, dataset, software resource, or clinical finding. The longer-term return may include a durable interdisciplinary network, shared infrastructure, subsequent jointly funded research, movement of methods between fields, or new collaborations that continue after the original award ends.

Evaluate whether funded collaborations become genuinely integrated
Connected research evidence could also help NIH evaluate collaborative programs, centers, and consortia at the portfolio level.
Relationships among funding, researchers, organizations, publications, datasets, software, research resources, and documented contributor roles can provide evidence about whether collaborations develop scientific connections beyond the administrative structure of the original award.

For example, NIH could examine whether participating groups subsequently produce joint outputs, share or reuse research resources, establish new cross-institutional relationships, develop interconnected research programs, or continue collaborating after the initial funding period.

This would not by itself determine whether a collaboration is scientifically successful; expert judgment remains essential. It could, however, help NIH distinguish between collaborations showing evidence of deep and sustained scientific integration and those showing comparatively limited evidence of interaction.
For large collaborative investments, this could provide valuable evidence for program evaluation and future funding decisions.

Recognize cross-sector collaboration
Team science increasingly extends beyond academic institutions.
Biomedical research may bring together academic researchers, healthcare organizations, government laboratories, industry, nonprofit organizations, patient or community groups, data and technology organizations, and other participants.

Assessment frameworks should recognize the value of these collaborations without assuming that all sectors produce the same kinds of outputs.
A successful academic-industry collaboration, for example, may generate software, data resources, methods, technologies, patents, clinical applications, or other outputs that are not adequately represented by publication counts. Similarly, collaborations involving healthcare or public-sector organizations may produce implementation, policy, clinical, or population-health effects that require different forms of evidence.

NIH should therefore assess collaboration according to the scientific objective and intended contribution of the participants rather than imposing a single publication-centered definition of collaborative success.

Use connected information to help form teams as well as assess them
The same research information that supports assessment can also help NIH facilitate future collaboration.
Disambiguated researcher profiles connected to publications, grants, research topics, methods, datasets, affiliations, and previous collaborations can help identify relevant expertise beyond established professional networks.

This creates an opportunity for NIH not simply to measure collaboration after it occurs, but to help identify complementary expertise before teams are formed.
At a portfolio level, such approaches could help identify researchers or institutions working on related problems from different disciplinary perspectives, reveal capabilities that are missing from existing research networks, and identify opportunities to connect investigators who might not otherwise encounter one another.

Similar information could assist with identifying potential reviewers with appropriate expertise while supporting conflict-of-interest screening, although such systems should augment rather than replace established NIH review procedures.

Minimize burden and avoid unintended incentives

Implementation should build upon persistent identifiers, structured contributor roles, existing grant and publication information, and interoperable research infrastructure wherever possible.

Researchers should not be required to produce extensive new collaboration reporting when relevant evidence can be derived reliably from information already generated through the research process.

NIH should also be cautious about creating incentives that reward collaboration numerically. Number of collaborators, institutions, disciplines, or countries may describe a research team but should not automatically be interpreted as evidence of quality.

Network-based measures should likewise be used carefully. Highly connected researchers are not necessarily the most valuable collaborators, and important specialists may contribute deeply to relatively small numbers of projects.

Quantitative evidence should therefore support expert assessment of contribution, complementarity, integration, durability, and scientific value, rather than become an end in itself.

Recognize collaboration as a scientific capability
Ultimately, NIH should move from treating collaboration primarily as an authorship pattern toward recognizing it as a scientific capability.
The relevant questions are not simply how many researchers participated or how many institutions appeared on an award. They are:
Were complementary capabilities brought together?
Can the contributions of individual team members be recognized?
Did participants genuinely integrate their expertise and resources?
Did the collaboration create something that would have been difficult to achieve independently?
Did the relationships, resources, or capabilities created through the collaboration continue to generate value?

A funding agency that cannot distinguish integrated collaboration from a shared cover page cannot reliably reward the former or understand the return generated by its collaborative investments.

By combining structured contribution information, persistent identifiers, longitudinal research information, network evidence, and expert scientific assessment, NIH can develop a more defensible framework for recognizing the individuals who make team science possible while also identifying the collaborative structures that produce genuine scientific integration and sustained biomedical value.

5. Entrepreneurship and Translation: Patents, licenses, company formation, and commercialization are among the most visible and readily measurable outcomes of biomedical innovation. They are important indicators, but they capture only a portion of the process through which NIH-supported discoveries ultimately improve human health.

NIH should therefore assess not only translational outcomes, but also contributions to translational pathways: the cumulative, often non-linear process through which knowledge moves from fundamental discovery toward clinical, commercial, public-health, policy, or other forms of application.

This distinction matters because biomedical translation rarely results from a single publication, investigator, institution, or funding award. It frequently develops through successive contributions from researchers, organizations, funding programs, healthcare systems, government, industry, and other participants over extended periods.
A framework that recognizes those contributions would better reflect how biomedical innovation actually occurs and allow NIH to understand more fully how its investments contribute to downstream health, economic, and societal value.

Measure pathways, not simply endpoints
Traditional translational indicators tend to emphasize observable endpoints: patents, licenses, spinouts, products, or clinical applications.
NIH should retain these measures while also examining the intermediate steps through which research progresses toward application.

Potential indicators could include:
progression of NIH-supported research into subsequent translational or development funding;
patent applications and granted patents linked to NIH-supported research;
licensing activity and technology transfer, where appropriate;
formation of companies or other commercialization vehicles;
industry partnerships and cross-sector research relationships;
progression into clinical studies or clinical trials;
incorporation into clinical guidelines or standards of care;
citations or incorporation into regulatory documents;
incorporation into public policy or public-health guidance;
development and adoption of diagnostic tools;
development and adoption of research or clinical software;
development of standards, methods, protocols, or shared research resources;
use within healthcare systems or clinical practice;
development of public-health interventions;
subsequent investment or funding that builds upon the original research; and
demonstrated adoption or use by organizations beyond the originating research team.

These indicators should be interpreted according to the scientific field and intended pathway to impact. Not all valuable NIH-funded research should result in a patent, company, clinical trial, or commercial product.

Understand translation as a connected pathway
Advances in connected research information increasingly make it possible to observe translational pathways empirically.
Persistent identifiers and linked research information can connect publications with grants, patents, clinical trials, datasets, software, researchers, organizations, policy documents, clinical guidelines, and other downstream activity.

Rather than viewing these outputs independently, NIH could increasingly examine the pathways connecting them:
NIH investment → fundamental discovery → subsequent research and validation → translational development → cross-sector engagement → clinical testing or other application → adoption → health, economic, or societal value.

Importantly, these pathways will not always be linear.

A fundamental discovery may contribute to multiple subsequent research programs. A dataset may enable a diagnostic technology. Software may move directly into clinical research without generating a patent. A methodological advance may be incorporated into clinical guidelines. An NIH-supported discovery may contribute to a commercial product years later through research conducted by investigators and organizations that were not part of the original award.
Understanding these connections provides a more realistic model of translation than attempting to attribute an eventual societal outcome to a single publication or investigator.

Distinguish contribution from attribution
NIH should be cautious about attempting to assign exclusive credit for downstream impact.
Translation is cumulative. A successful therapeutic, diagnostic, clinical practice, or public-health intervention may depend upon decades of foundational research funded through multiple programs and performed across numerous institutions.
The appropriate question is often not: “Which investigator caused this outcome?” but rather: “What NIH-supported research contributed to the pathway that made this outcome possible?”

Connected evidence can help identify these contributions without implying simplistic causality.
This approach would also allow NIH to recognize foundational research that creates important translational value even when the originating investigators never participate directly in commercialization.

Identify translational inflection points earlier
The same evidence used to evaluate translation retrospectively could potentially help NIH identify emerging translational opportunities prospectively.
Today, important translational signals may appear across disconnected systems. A body of NIH-supported research may begin generating patent activity, follow-on funding, industry collaboration, clinical investigation, new software or diagnostic applications, or increasing attention from organizations outside the originating research community.

Individually, these signals provide incomplete information. Considered together, they may indicate that a line of research is approaching a translational inflection point.
NIH could explore whether combinations of signals such as: “research maturation + independent validation + follow-on funding + patent activity + cross-sector engagement + clinical activity” can help identify research areas where targeted translational support, expertise, partnership, or additional funding might accelerate progress.
This would move the assessment beyond asking “What translated?” toward also asking “What may be

ready to translate next?”
Such approaches should be validated carefully and used to support, rather than automate, scientific and programmatic judgment. Translational potential is inherently uncertain, and indicators should not create pressure to commercialize research prematurely.

Recognize the people who enable translation
Entrepreneurial and translational activity should also be recognized as a legitimate scientific contribution.
Researchers may contribute to translation through invention, company formation, technology development, industry collaboration, clinical development, standards development, software creation, regulatory science, implementation, or other activities that move knowledge toward use.
These contributions can be difficult to see in publication-centered assessment.

NIH could recognize documented translational contributions within biosketches, progress reports, portfolio assessment, and other appropriate review processes. Structured contributor information and connected evidence could help make these activities more visible.

Prior entrepreneurial and translational experience may also provide useful contextual evidence, for example, previous involvement in technology transfer, industry collaboration, clinical development, licensing, or company formation. However, such experience should not become a prerequisite or simplistic score for evaluating future potential.

Researchers at institutions with mature technology-transfer ecosystems have substantially different opportunities from researchers at smaller or less-resourced institutions. Similarly, some biomedical fields offer clearer commercial pathways than others. Assessment should recognize entrepreneurial contribution without creating a structural advantage for investigators who already have access to established commercialization networks.

Recognize multiple routes to impact
Commercialization is one route through which NIH-supported research creates value, but it is not the only one.
Translation may occur through clinical practice, healthcare delivery, public-health interventions, regulatory science, government policy, clinical guidelines, standards, open-source software, shared research infrastructure, diagnostic methods, or widespread adoption of a new research technique.

NIH should therefore avoid equating entrepreneurship exclusively with company formation or translation exclusively with commercialization.
Different types of research should be assessed against pathways appropriate to their intended contribution.

This is particularly important for foundational research. Basic science may have enormous long-term translational significance despite having little immediate commercial potential. An assessment framework overly weighted toward near-term translation could inadvertently discourage the fundamental discovery upon which future biomedical innovation depends.

Measure time to translation carefully
Translation also operates across very different timescales.
Some computational tools or methods can move rapidly into use. Therapeutic development may take many years. Foundational discoveries may generate little visible translational activity for decades before becoming critical to a new technology or treatment.

NIH should therefore consider time-to-translation and translational persistence as contextual rather than purely performance indicators.
Longitudinal analysis can help NIH understand how different types of research move toward application, where pathways commonly stall, and which interventions are associated with successful progression.

This could help answer important portfolio-level questions:
Where do promising NIH-supported discoveries most commonly stall?
Which types of support are associated with successful movement between translational stages?
Where are collaborations with industry, healthcare, or other sectors accelerating translation?
Which foundational investments ultimately contribute to multiple downstream innovations?
Which NIH programs are generating translational value that conventional publication metrics fail to capture?

Use connected evidence for portfolio intelligence
At sufficient scale, these indicators could provide NIH with more than an assessment framework. They could provide portfolio intelligence.

Connected evidence across grants, publications, patents, clinical trials, organizations, researchers, and downstream outputs could help program officers and institute leadership identify emerging areas of translational activity across an entire portfolio rather than relying exclusively on individual investigators or technology-transfer offices to surface opportunities.

This could help NIH identify clusters of related discoveries, emerging cross-sector engagement, technologies progressing toward clinical investigation, and areas where additional translational support may be warranted.

It could also help NIH understand the comparative pathways through which different institutes, programs, fields, or funding mechanisms generate downstream value.
The objective should not be to predict commercial success. It should be to provide decision-makers with additional evidence about where translation appears to be occurring, where it may be emerging, and where potentially valuable research is encountering barriers.

Build upon existing research information infrastructure
Many of the relationships required for this type of assessment can already be observed through existing research information infrastructure.
Large-scale connected research databases link publications with grants, patents, clinical trials, researchers, institutions, and other research outputs, making it increasingly possible to examine

translational relationships across entire research portfolios rather than reconstructing them manually one project at a time.

Digital Science's experience connecting grants, publications, patents, clinical trials, researchers, and organizations demonstrates the practical feasibility of examining these pathways at research-system scale. Dimensions, for example, links research activity across these different stages, allowing relationships between foundational funding, subsequent research, patent activity, and clinical investigation to be examined within a common evidence environment. This type of existing commercial infrastructure provides NIH with an opportunity to test and validate translational indicators using evidence already available today, rather than first constructing an entirely new reporting or tracking system.

This infrastructure provides a practical starting point for NIH to test translational indicators, examine research pathways retrospectively, and evaluate whether combinations of signals can reliably inform prospective portfolio analysis.

Implementation should build upon existing identifiers, standards, and data sources wherever possible, supplementing these with NIH administrative information and expert assessment rather than creating additional investigator reporting requirements.

Assess contribution while preserving discovery
Ultimately, NIH should expand its assessment of entrepreneurship and translation from counting visible endpoints toward understanding the pathways through which federally funded knowledge becomes useful.

The relevant questions are not simply:
Was there a patent?
Was a company formed?
Was a product commercialized?

They also include:
What research made the eventual application possible?
Who contributed to moving that research toward use?
What intermediate steps indicate meaningful translational progress?
Where are promising discoveries encountering barriers?
Can NIH recognize emerging translational opportunities early enough to help accelerate them?

A discovery that becomes visible as translational only when it reaches a technology-transfer office may already have traveled a substantial portion of its translational pathway.

By connecting evidence across the research lifecycle, NIH can develop a more complete understanding of how its investments contribute to innovation, identify translational momentum earlier, recognize the researchers and teams who enable it, and support pathways that deliver sustained health, economic,

and societal value, while continuing to protect the foundational science upon which future translation depends.

6. Foundational Scientific Exploration: Any indicator built around short-term productivity will systematically penalize the research most likely to produce paradigm-shifting results. NIH's challenge is therefore not to predict which individual foundational or high-risk research project will ultimately transform a field, but to protect sufficient space for exploration within a research portfolio that also rewards more predictable scientific progress.

Transformative advances frequently arise from fundamental research, enabling technologies, methodological innovation, exploratory investigation, unexpected findings, and new combinations of ideas that may initially appear incremental, uncertain, or disconnected from immediate application.

These contributions expand the scientific landscape by creating new questions, methods, resources, and capabilities rather than necessarily producing immediate translational outcomes.

Assessment of foundational scientific exploration should therefore recognize both the contributions created by exploratory research and NIH's broader success in maintaining a portfolio in which scientific risk and uncertainty can be sustained.

Do not require exploratory research to predict its own impact
One of the fundamental difficulties in assessing foundational research is that its eventual importance may be unknowable when the research is proposed or even when the original award concludes.

A discovery, method, dataset, biological resource, or enabling technology may acquire significance only years later, when another scientific development makes it newly useful. Research initially regarded as highly specialized may become foundational to an emerging field. A negative result may eliminate an unproductive direction and redirect subsequent research. A tool created for one purpose may eventually enable discoveries its creators never anticipated.

NIH should therefore avoid assessment frameworks that require foundational research to demonstrate short-term downstream impact as evidence of success.
Instead, potential indicators could include:
development of novel methodologies, computational approaches, or instrumentation;
creation of foundational datasets, biological resources, software, or other enabling infrastructure;
introduction of new concepts, hypotheses, or research questions;
development of novel combinations of methods or disciplines;
establishment of new interdisciplinary research directions;
production and dissemination of negative or null findings that meaningfully refine scientific understanding;
subsequent adoption of methods, resources, or concepts by researchers outside the originating team;
diffusion of methods or resources across disciplines;
emergence of new research communities building upon foundational work; and
evidence, over longer timescales, that exploratory work enabled subsequent scientific advances.

These indicators should describe contribution and influence without implying that every exploratory project must ultimately generate a transformative outcome.

Evaluate foundational contribution over longer timescales
Foundational research frequently operates on timescales poorly aligned with conventional research assessment.
By the time the importance of a foundational contribution is apparent through citation counts, clinical applications, patents, or other downstream indicators, the funding decisions that enabled it may have occurred many years earlier.

Longitudinal research information provides an opportunity to examine these contributions differently. Persistent identifiers and connected evidence can increasingly link grants, publications, methods, datasets, software, patents, clinical studies, researchers, institutions, and other outputs over extended periods. This can help reveal how an initially exploratory investment subsequently contributes to scientific capability.

For example:
NIH exploratory investment → new concept, method, resource, or capability → adoption by other researchers → diffusion across research communities → new questions and combinations → subsequent discoveries → potentially transformative scientific or translational impact.

The important point is that the original project's value should not be judged solely by whether it reaches the end of this pathway.
Creating a method or resource that opens new scientific possibilities may itself represent a valuable outcome of foundational research.

Identify emerging science before conventional metrics can see it
Connected research evidence also creates an opportunity to move beyond retrospective assessment.

Citation-based measures are inherently lagging indicators. By the time an emerging research area accumulates substantial citation activity, its importance may already be widely recognized.

NIH could complement conventional assessment with horizon-scanning approaches designed to identify nascent scientific directions while they are still forming.
Potential signals could include:
emergence of new concepts or terminology;
rapid development or adoption of new methods;
unusual combinations of previously separate research areas;
growth of new interdisciplinary research networks;
migration of methods or technologies between fields;
increasing creation or reuse of specialized datasets, software, or research resources;
formation of new clusters of investigators around emerging questions; and
changes in funding, publication, or collaboration patterns that suggest the development of a new research direction.

Natural language processing, topic analysis, network analysis, and connected research information can help identify such patterns across large bodies of scientific activity.
These signals should not be interpreted as automatic indicators of scientific quality or future breakthrough potential. Emergence is not synonymous with importance, and novelty is not synonymous with scientific merit. Expert scientific judgment remains essential.

Their value is instead in helping NIH see where the scientific landscape may be changing early enough to investigate further.

Use horizon scanning to inform funding strategy
Applied prospectively, these approaches could provide NIH with a form of scientific horizon scanning.

Rather than waiting until an emerging field has accumulated years of conventional evidence, program officers and institute leadership could receive evidence about where new concepts, methods, technologies, interdisciplinary combinations, and research communities appear to be forming.

This could help NIH ask:
Which potentially important scientific directions are emerging?
Which established fields are being disrupted by new methods or technologies?
Where are previously separate disciplines beginning to converge?
Which enabling technologies are beginning to diffuse across biomedical research?
Where is scientific activity emerging faster than NIH investment?
Are there potentially important areas of exploration that fall between existing programmatic structures?
The objective should not be to automate funding decisions or predict the next breakthrough. It should be to expand the evidence available to scientific leaders deciding where additional exploration may be warranted.

Assess NIH's portfolio risk, not just investigator risk
Perhaps the more important opportunity is to apply these approaches to NIH's own funding portfolio.

High-risk, high-reward research is inherently uncertain at the individual-project level. Some projects will fail to produce their intended results. That is a characteristic of genuine scientific risk, not necessarily evidence of poor funding decisions.

Assessment is therefore more meaningful at the portfolio level.

NIH could examine the distribution of investment across established, developing, and emerging research directions and how that distribution changes over time.
Potential portfolio-level indicators could include:
concentration of funding within established research areas;
proportion of funding supporting emerging or exploratory areas;
entry of new investigators or disciplines into established research fields;
funding for novel combinations of methods or disciplines;

diversity of scientific approaches supported within a portfolio;
changes in the distribution of funding as scientific fields mature;
persistence of support for exploratory areas during periods of uncertainty;
subsequent development of research communities around previously exploratory investments; and
evidence that earlier exploratory investments created methods, resources, or capabilities subsequently used across NIH-supported science.
These measures could help NIH evaluate an important question that cannot be answered by examining individual grant productivity:
Is NIH maintaining a research portfolio with sufficient capacity for scientific exploration and responsible risk-taking?

Detect portfolio drift toward predictability
Portfolio analysis could also help identify risk drift.
Funding systems can gradually become more concentrated around established investigators, methods, topics, or scientific approaches even without an explicit decision to become more conservative.

Each individual funding decision may be scientifically defensible while the cumulative portfolio nevertheless becomes increasingly concentrated around areas with established evidence, established communities, and predictable outputs.
NIH could therefore examine changes in portfolio concentration and scientific novelty longitudinally.

For example: Portfolio at time 1 → distribution across established and emerging areas → subsequent funding decisions → changing concentration of investment → portfolio at time 2.
This would allow NIH to examine whether the agency, an institute, or a program is maintaining its intended balance between exploitation of established scientific opportunity and exploration of less certain directions.

Importantly, such analysis should not assume that a particular percentage of funding to emerging areas is inherently optimal. Appropriate risk tolerance will vary across institutes, programs, scientific opportunities, and public-health needs.
The objective is to make the portfolio's risk characteristics visible enough to be managed intentionally.

Learn from unsuccessful high-risk research
NIH should also distinguish between scientific failure and unproductive investment.

A high-risk project that does not confirm its original hypothesis may nevertheless produce important negative findings, eliminate an unproductive scientific direction, generate a useful method or dataset, reveal methodological limitations, or create knowledge that informs subsequent research.

If high-risk programs are assessed primarily according to whether projects achieve their original anticipated outcomes, researchers will have a rational incentive to propose projects whose outcomes are more predictable.

NIH should therefore recognize informative failure as a legitimate potential outcome of exploratory

research, provided the work was rigorous and the resulting knowledge is made available to the scientific community.

This is also why transparent reporting of negative and null results, addressed elsewhere in this RFI, is particularly important for high-risk research.

Protect unconventional combinations of expertise
Transformative research may also arise at the boundaries between established disciplines.
Connected research information can help identify unusual combinations of expertise, methods, concepts, or research communities that differ from established collaboration patterns.
NIH could examine whether funding mechanisms intended to support innovation are actually enabling these unconventional combinations or predominantly supporting teams whose structures resemble already successful research networks.

Again, unusual combinations should not automatically be rewarded. Novelty without scientific rationale has little value.
But the ability to observe disciplinary and methodological combinations provides NIH with another way to assess whether programs intended to encourage convergence and exploration are actually broadening the scientific landscape.

Build on existing evidence infrastructure
Many of the signals required for this type of analysis already exist within research information systems.
Large-scale connected evidence across grants, publications, researchers, organizations, datasets, software, methods, patents, clinical research, and other outputs can support longitudinal analysis of emerging fields, knowledge diffusion, interdisciplinary convergence, and funding concentration.
Natural language processing and network analysis can further help identify changes in concepts and relationships that are difficult to detect through traditional publication and citation measures alone.

NIH could use this existing evidence base to test and validate horizon-scanning and portfolio-risk indicators retrospectively before applying them prospectively.
For example, NIH could examine historical research areas now recognized as transformative and ask: Would the proposed indicators have detected their emergence before conventional metrics did?

Similarly, NIH could examine previous high-risk funding portfolios to determine whether proposed measures meaningfully distinguish exploratory investment from established research.

This type of retrospective validation would be important before incorporating new indicators into funding strategy.

Protect the conditions for discovery
Ultimately, foundational scientific exploration presents a different assessment problem from research intended to produce predictable near-term outcomes.
The objective should not be to develop a metric that predicts which high-risk project will succeed. Doing so would risk eliminating the uncertainty that makes the research high-risk in the first place.

Instead, NIH should ask:
Is exploratory research creating new scientific possibilities?
Can NIH identify emerging directions early enough to investigate them?
Is the agency maintaining sufficient diversity of scientific approaches?
Are programs intended to support high-risk research actually funding research that differs meaningfully from established patterns?
Is NIH's portfolio gradually becoming more conservative without intending to do so?
Does the system recognize rigorous, informative failure as part of scientific exploration?
A portfolio that cannot see its own risk profile cannot knowingly protect it.

By combining longitudinal research information, horizon scanning, portfolio analysis, and expert scientific judgment, NIH can make the conditions for exploration more visible without attempting to make uncertain science artificially predictable. This would help preserve the scientific risk, curiosity, and methodological innovation from which future paradigm-shifting discoveries are most likely to emerge.

7. Public Impact: Public impact is too often measured by visibility rather than uptake. Media attention is not the same as influence on clinical practice or policy. NIH's assessment framework should draw that distinction explicitly.

Scientific knowledge creates public value through diverse and interconnected pathways, including clinical practice, public health, regulatory science, public policy, education, industrial innovation, healthcare delivery, accessibility of knowledge, and public engagement. These pathways often interact, reinforce one another, and develop over extended periods.

NIH should therefore assess public impact as a pathway from attention to uptake, application, and ultimately societal benefit, rather than attempting to represent it through a single impact metric.

Distinguish attention, uptake, application, and outcome
Different indicators provide evidence of fundamentally different things.
Attention indicates that research has been noticed or discussed.

Uptake indicates that research has been incorporated into a professional, scientific, policy, clinical, educational, or other decision-making context.
Application indicates that knowledge has influenced a practice, intervention, technology, policy, guideline, or other activity.
Outcome indicates evidence of resulting health, economic, accessibility, or broader societal benefit.

These should not be treated as equivalent.
For example: NIH-supported research → publication → clinical guideline citation → adoption in clinical practice → change in patient care → improved health outcome.
Similarly: NIH-supported research → evidence base → public-health guidance → implementation → population-level intervention → measurable health benefit.
Or: NIH-supported research → enabling discovery → technology development → commercial adoption → economic activity → broader health or societal benefit.

A media mention may provide evidence of public attention. A citation in a clinical guideline provides stronger evidence that research has entered professional decision-making. Demonstrated implementation of that guideline represents a further stage of impact. Evidence that implementation contributed to improved outcomes represents something different again.

NIH should preserve these distinctions rather than collapsing them into a single measure of "impact."

Measure multiple pathways to public value
Because NIH supports an extraordinarily diverse biomedical research portfolio, no single pathway will adequately describe public impact.
Potential measurable indicators could include:

Clinical impact
incorporation of NIH-supported research into clinical guidelines or standards of care;
citations in clinical decision-support resources;
progression of research into clinical studies or trials;
adoption of evidence-based interventions within healthcare systems;
development or adoption of diagnostics, therapeutics, devices, software, or other clinical tools;
changes in clinical practice associated with research findings; and
where evidence permits, contribution to improved patient outcomes.

Public-health and policy impact
incorporation into public-health guidance;
citation or use in federal, state, local, or international policy documents;
incorporation into regulatory science or regulatory decision-making;
contribution to standards or technical guidance;
adoption within public-health programs or interventions; and
evidence of changes in population-health practice associated with the research.

Economic and innovation impact
patents and licensing associated with NIH-supported research;
company formation and entrepreneurial activity;
industrial research partnerships;
subsequent private-sector investment;
development of products, technologies, services, or research tools;
employment or economic activity associated with NIH-supported innovation; and
downstream commercial use of NIH-supported knowledge or resources.

Accessibility and knowledge diffusion
public accessibility of NIH-supported research outputs;
availability and reuse of datasets, software, protocols, models, and other research resources;
use of research in educational or professional training materials;
adoption of research resources by communities beyond the originating investigators;
accessibility of findings to patients, practitioners, policymakers, and other intended audiences; and

sustained availability of publicly funded research resources.

Public engagement and trust
evidence of responsible communication of scientific findings, including uncertainty and limitations;
engagement with patients, communities, and relevant public stakeholders;
use of NIH-supported evidence in trusted public-information resources;
transparent correction or updating of scientific findings as evidence changes; and
where methodologically defensible, changes in understanding or confidence associated with sustained engagement.
These categories should remain distinct. A research project should not be expected to demonstrate impact across all of them.

Measure contribution, not simplistic attribution
NIH should distinguish between attribution and contribution when assessing public impact.

Most improvements in health and society cannot credibly be attributed to a single publication, investigator, grant, or institution. A change in clinical practice may depend upon decades of fundamental research, validation studies, clinical trials, systematic reviews, professional guidelines, healthcare implementation, and public-health activity.

The appropriate question is therefore often not: "Did this NIH award cause this societal outcome?" but: "What role did NIH-supported research play in the pathway that contributed to this outcome?"
Connected research evidence can help reconstruct these pathways without implying causality that the evidence cannot support.
For example: multiple NIH investments → body of evidence → clinical synthesis → professional guideline → healthcare implementation → patient benefit.
This provides a more scientifically defensible account of public impact while recognizing the cumulative nature of biomedical progress.

Trace public impact longitudinally
Public impact frequently occurs years or decades after the original research is funded.
Assessment should therefore connect evidence across longer timescales rather than requiring investigators to demonstrate societal impact within the period of an individual award.

Persistent identifiers and connected research information increasingly make it possible to link grants, publications, datasets, software, patents, clinical trials, policy documents, clinical guidelines, researchers, and organizations over time.

This creates an opportunity for NIH to examine impact pathways across its portfolio.

Rather than relying predominantly on individual success stories, NIH could ask:
Which NIH-supported research contributes to clinical guidelines?
Which research areas are subsequently reflected in public-health or regulatory decision-making?
Which NIH investments contribute to technologies or industries?

Which datasets, software, and research resources continue to create public value after the originating grant concludes?
How long does it typically take different forms of NIH-supported research to move from discovery to uptake and application?
Where does research appear to reach an uptake stage but fail to progress toward implementation?
This would provide a more systematic understanding of the return generated by NIH investment.

Assess impact at the portfolio level
Portfolio-level assessment is particularly important for public impact.
A single project may contribute only one component of a much larger pathway. At the level of an institute, disease area, program, or NIH as a whole, however, the cumulative relationship between federal investment and downstream activity becomes more visible.

NIH could therefore develop public-impact profiles for different portfolios rather than attempting to reduce all impact to one score.
For example, one portfolio may demonstrate substantial influence on clinical practice. Another may primarily create foundational resources used throughout biomedical research. Another may generate significant economic and industrial activity. Another may contribute heavily to public-health policy.

These are different forms of mission value, not necessarily different levels of value.
This approach would also enable NIH to demonstrate impact consistently across Institutes and Centers and research areas rather than depending primarily on highly visible individual examples.

Treat public trust as an outcome requiring particular care
Public trust warrants special treatment because it is both central to NIH's mission and particularly difficult to measure.
NIH has explicitly connected rigor and reproducibility with strengthening confidence and trust in biomedical research.
However, public trust should not be reduced to popularity, positive sentiment, media volume, or social-media engagement.

Trustworthy science and popular science are not necessarily the same thing.

More defensible indicators may include evidence of:
transparent communication of methods, limitations, and uncertainty;
accessibility of underlying research and supporting evidence;
correction of the scientific record when findings change;
responsible communication of negative or conflicting findings;
meaningful engagement with affected communities;
accessibility of research findings to intended audiences; and
demonstrable use of NIH-supported evidence by trusted clinical, public-health, and professional institutions.

Where surveys or public-opinion measures are used, they should be interpreted carefully and should not

create incentives for researchers or NIH to optimize scientific communication for popularity rather than accuracy.

NIH's own current replication and reproducibility efforts recognize that rigorous, transparent, reliable science is foundational to public confidence. Public-impact assessment should reinforce that relationship.

Distinguish public communication from public impact
Media, news, online attention, and other public-facing sources can provide useful evidence, but they should be interpreted according to what they actually measure.
Media attention can identify research entering public discourse.

It does not establish that the research changed policy, clinical practice, health outcomes, or public understanding.
NIH could therefore use public-attention indicators as pathway signals rather than endpoint measures. For example: “research → public attention → stakeholder engagement → policy consideration → policy adoption” may represent a legitimate pathway worth examining.
But attention alone should not be rewarded as equivalent to demonstrated uptake.

This distinction would also reduce incentives for sensationalism and help ensure that responsible communication of uncertainty remains compatible with NIH's impact framework.

Identify where evidence fails to become impact
One of the most valuable applications of a connected public-impact framework may be identifying translation and implementation gaps.

NIH traditionally asks whether research generated important knowledge. Connected evidence could increasingly help it ask what happened next.
For example:
strong scientific evidence → no guideline uptake
guideline incorporation → limited clinical adoption
effective intervention → limited accessibility
valuable public-health evidence → inconsistent implementation

These gaps matter because generating knowledge is only one part of delivering value to the American public.

NIH could use portfolio-level analysis to identify areas where strong research evidence exists but downstream uptake appears limited, providing an evidence base for considering whether additional implementation research, dissemination, partnerships, accessibility efforts, or other interventions may be warranted.
This would transform public-impact assessment from a retrospective reporting exercise into a tool for identifying where additional NIH action could help research generate greater public value.

Build upon existing evidence infrastructure
Many components required for this framework can already be observed through existing research information infrastructure.

Research can increasingly be connected across grants, publications, clinical trials, patents, policy documents, clinical guidelines, researchers, institutions, and public-facing sources. Combining these evidence streams provides a practical starting point for reconstructing pathways from federal investment toward downstream uptake.

Digital Science's experience working with research funders and institutions demonstrates the feasibility of this type of cross-source analysis at portfolio scale. Connected research information can link funding and scholarly outputs with downstream evidence such as patents, clinical activity, policy references, and public attention, helping organizations move beyond individual impact anecdotes toward systematic evidence of where research is being taken up and used.

This type of infrastructure could provide NIH with an existing evidence base for testing and validating public-impact indicators across different Institutes, Centers, disease areas, disciplines, and timescales rather than requiring a new reporting system to be created before assessment can begin.

Avoid creating an "impact burden"
NIH should be cautious about requiring every investigator to produce an extensive narrative demonstrating public impact.
Such an approach could create substantial administrative burden, advantage investigators with access to professional communications or research-impact staff, and encourage overstatement of downstream effects.

Where possible, NIH should derive evidence from existing research information, persistent identifiers, administrative systems, and downstream sources and allow investigators to provide contextual or qualitative evidence where automated information is incomplete.

Assessment should also recognize differences among disciplines, institution types, career stages, and research objectives. Early-career researchers and investigators conducting foundational science should not be disadvantaged because the societal effects of their work may not become visible for many years.
Measure value to the public, not simply visibility

Ultimately, public impact assessment should help NIH answer a straightforward but difficult question: What happened because the knowledge NIH supported entered the world?

Answering that question requires more than counting publications, citations, patents, news stories, or social-media mentions.

NIH should examine whether research was noticed, taken up, applied, and ultimately associated with meaningful health, economic, clinical, accessibility, or societal benefit, while recognizing that different forms of research travel through different pathways and on different timescales.

Public trust in NIH-funded science also depends upon NIH being able to demonstrate these contributions consistently, not only through a small number of highly visible success stories, but across the breadth of its research portfolio.

By connecting evidence from funding, scholarship, clinical practice, policy, innovation, public health, and public engagement, NIH can develop a more rigorous account of the value generated by federal research investment: one that distinguishes attention from impact, contribution from attribution, and anecdote from systematic evidence.

8. Other Areas: One overarching opportunity cuts across each of the areas addressed in this RFI: the need to shift from metric-based assessment toward evidence-based assessment.
For many decades, research evaluation has relied heavily on a relatively small number of publication- and citation-based indicators because these represented some of the most consistently available evidence of scientific activity. The research landscape has changed fundamentally.

Contemporary biomedical research now generates rich, interconnected evidence spanning grants, publications, datasets, software, protocols, methods, clinical trials, patents, policy documents, clinical guidelines, contributor roles, researchers, organizations, and collaborative relationships.

The opportunity for NIH is therefore not to identify a new metric to replace publication counts or citations. It is to integrate complementary evidence streams to develop a more complete understanding of how scientific knowledge is generated, validated, shared, reused, extended, translated, and ultimately contributes to public benefit.
Move from counting outputs to understanding pathways

Across the topics addressed in this RFI, a common principle emerges: individual outputs provide only a partial view of scientific contribution.

NIH increasingly has the opportunity to understand the pathways connecting its investments to subsequent scientific activity and value.
For example:
Rigor and reproducibility: research → transparency → reproducibility → independent verification → replication → more reliable knowledge
Data, software, and models: creation → sharing → stewardship → discovery → reuse → new research and scientific value
Training and mentorship: training investment → mentorship → researcher development → continued scientific contribution → development of subsequent researchers
Collaboration: investment → complementary expertise → scientific integration → shared outputs and capabilities → durable research networks → downstream value
Entrepreneurship and translation: fundamental discovery → validation → translational development → cross-sector engagement → application → adoption
Foundational scientific exploration: exploratory investment → new concept, method, resource, or capability → diffusion → new scientific directions → subsequent discovery

Public impact: research → attention → uptake → application → health, economic, clinical, or societal benefit

These pathways are neither universal nor linear, and they should not become rigid models against which every research project is evaluated. Their value is conceptual: they illustrate why assessment focused predominantly on individual outputs can miss much of the value created by federal research investment. NIH should increasingly ask not only "What was produced?" but "What did it enable?"

Assess contribution without overstating attribution

A second principle running across these topics is the importance of distinguishing contribution from attribution.

Biomedical progress is cumulative. Important discoveries frequently depend upon decades of foundational research, multiple investigators and institutions, shared datasets and infrastructure, methodological advances, validation studies, collaborations, funding programs, and subsequent translational activity.

Assessment systems should resist the temptation to attribute complex outcomes to individual publications, grants, or investigators simply because those relationships are easiest to measure.

Connected evidence instead provides an opportunity to identify credible contributions to longer scientific pathways.

This distinction is particularly important when assessing societal impact. NIH should be able to demonstrate that federally funded research contributed to advances in health, clinical practice, innovation, policy, and economic activity without implying causal attribution where the available evidence cannot support it.

Recognize the scientific contributions that conventional metrics miss

Scientific progress emerges through the interaction of people, infrastructure, methods, data, software, organizations, and institutions over extended periods.

Many activities that make this system function remain poorly represented in conventional assessment, including:

stewardship of shared datasets and research resources;
development and maintenance of scientific software;
methodological and statistical contributions;
creation and maintenance of research infrastructure;
mentorship and supervision;
peer review;
replication and validation;
development of standards and protocols;
technical and collaborative leadership; and
community building and scientific stewardship.

These activities should not automatically receive credit simply because they can be documented. Rather, NIH should develop mechanisms for recognizing when they make meaningful contributions to research

quality, capability, efficiency, reliability, or impact.

Persistent identifiers, structured contributor roles, interoperable metadata, and connected research information increasingly make these contributions observable.
The challenge is to convert that increased visibility into responsible evidence for assessment, rather than simply creating additional things to count.

Treat research assessment as a scientific endeavor
NIH should also treat research assessment itself as an object of scientific investigation.

Any indicator creates incentives. Poorly designed indicators can change researcher behavior in ways that undermine the objective the indicator was intended to support.
New assessment approaches should therefore be treated as hypotheses to be tested rather than metrics to be institutionalized immediately.

Candidate indicators should be evaluated for:
construct validity: whether the indicator actually measures the contribution it is intended to represent;
robustness across disciplines, research types, institutions, and career stages;
sensitivity to differences in scientific timescale;
completeness and quality of the underlying data;
susceptibility to gaming or strategic behavior;
potential inequities or structural biases;
administrative burden;
unintended behavioral consequences; and
incremental value beyond information already available to expert reviewers and program staff.

Where possible, NIH should test proposed indicators retrospectively before using them prospectively. For example, NIH could ask whether proposed indicators of emerging science would have identified historically important research directions before conventional metrics did; whether proposed translational indicators reliably distinguish meaningful progression from incidental activity; or whether proposed mentorship indicators accurately reflect successful researcher development across different career pathways.

This would allow NIH to validate the assessment system before attaching significant incentives to it.

Use indicators as evidence, not answers
No quantitative indicator should substitute for scientific judgment.

Connected evidence, natural language processing, network analysis, persistent identifiers, and other analytical approaches can make patterns visible that would be impossible for an individual reviewer or program officer to observe across an entire research system.

Their purpose should be to improve the evidence available to decision-makers, not to automate decisions that require scientific judgment.

This distinction is particularly important as the volume and sophistication of research information increase.
The appropriate model is: data → evidence → interpretation → expert judgment → decision
rather than: data → score → decision.

NIH should be cautious about composite scores that collapse fundamentally different dimensions of scientific contribution into a single ranking.
A researcher, project, program, or portfolio can be strong in one dimension and intentionally different in another. Foundational research should not be penalized because it lacks immediate translational impact. A high-value dataset should not be judged as though it were a publication. A collaborative specialist should not be assessed according to PI-oriented measures. A high-risk research portfolio should not be expected to produce the same success pattern as a program designed around predictable deliverables.

Evidence-based assessment should preserve those distinctions.

Evaluate portfolios as well as people
Many of the questions raised by this RFI cannot be answered adequately at the level of an individual investigator or award.
NIH should therefore complement researcher- and project-level assessment with portfolio-level assessment.

At portfolio scale, NIH can examine questions such as:
Are investments producing reusable research resources?
Are training programs generating durable scientific capacity?
Are collaborative programs producing genuinely integrated research networks?
Where are translational pathways progressing or stalling?
Is strong scientific evidence reaching clinical practice and public-health application?
Are emerging scientific areas receiving appropriate attention?
Is the balance between established and exploratory research changing over time?
Which NIH investments continue generating value long after the originating awards have ended?

This changes assessment from an exercise focused primarily on evaluating researchers into a capability NIH can also use to evaluate and improve its own funding strategy.
That distinction is important. Responsible research assessment should not only ask whether researchers are producing the right behaviors and outcomes. It should also allow the funding agency to ask whether its own policies, programs, incentives, and portfolio decisions are producing the research ecosystem it intends to create.

Build upon shared infrastructure and community standards
Continued investment in open scholarly infrastructure, persistent identifiers, trusted repositories, and community standards remains essential.
Digital Science has participated in this work directly, including through NIH's Generalist Repository Ecosystem Initiative (GREI). Initiatives of this kind demonstrate the value of interoperable infrastructure that enables research outputs to remain discoverable, accessible, connected, and reusable beyond the

systems or projects in which they originated.

Shared standards such as DOIs, ORCID iDs, ROR identifiers, RRIDs, grant identifiers, structured contributor roles, and interoperable metadata improve not only assessment but also reproducibility, transparency, collaboration, data stewardship, and research efficiency.

NIH should continue supporting this foundational infrastructure while taking advantage of the broader public, community, institutional, and commercial research-information ecosystem that has developed around it.

Where evidence can be obtained reliably from existing infrastructure, researchers should not be required to report it again.

The goal should be a richer evidence base with a lower reporting burden, not a larger assessment bureaucracy.

Recognize that research is an ecosystem
The questions in this RFI span researchers, funders, institutions, publishers, repositories, healthcare organizations, government, industry, and the public because modern biomedical research operates across all of them.

Assessment frameworks designed from the perspective of any one participant risk capturing only part of that system.

Digital Science's perspective on these questions has been shaped by more than two decades of working across this research ecosystem—including with researchers, universities and research institutions, publishers, research funders, governments, and commercial organizations, including pharmaceutical and biotechnology companies involved in translating scientific discovery toward application.

That cross-ecosystem perspective informs a central theme of this response: scientific value frequently becomes visible in the connections between systems, organizations, outputs, and stages of the research lifecycle, rather than within any single source of information.

Connected research infrastructure can increasingly make those relationships observable at scale. But infrastructure alone is not an assessment framework. The evidence it provides must be interpreted in the context of scientific purpose, disciplinary differences, timescale, uncertainty, and the intended mission of the research.
From metrics to evidence

The challenge facing research assessment is no longer simply one of measurement. It is increasingly one of interpretation.

As the evidence describing the research ecosystem becomes richer and more connected, NIH should resist replacing one dominant metric with another.

Instead, the opportunity is to develop an assessment framework that asks:
What contribution are we trying to understand?
What evidence would credibly demonstrate that contribution?
Over what timescale should it be observed?
What contextual information is required to interpret it?
What behaviors might measuring it incentivize?
What can quantitative evidence tell us, and what still requires expert scientific judgment?

Across the areas addressed in this RFI, this approach would allow NIH to move from counting isolated outputs toward understanding the pathways through which research creates scientific and public value.

The resulting framework would not eliminate metrics. It would put them in their proper role: as individual pieces of evidence within a broader, scientifically grounded assessment system.

That distinction is essential.

NIH does not need a new definition of scientific success expressed through a different score. It needs an evidence framework capable of recognizing the many ways rigorous, collaborative, exploratory, reusable, translational, and publicly valuable science contributes to its mission, and capable of evolving as science itself changes.

Description: Digital Science response to the NIH Request for Information on Measuring and Rewarding Scientific Impact.

DIGITAL SCIENCE RESPONSE TO NIH REQUEST FOR INFORMATION ON MEASURING AND REWARDING SCIENTIFIC IMPACT

I am responding: On behalf of an organisation

Name: Digital Science

Name of Organisation: Digital Science & Research Solutions Inc.

Type of Organisation: Commercial Entity

Role: Organizational Official

• **Rigor and Reproducibility:** ***Reproducible and replicable biomedical approaches are foundational to rigorous research. New strategies are needed to identify areas ripe for replication and reproducibility efforts, as well as incentives and infrastructure to support the reproduction and replication of existing findings.***

Digital Science Response:

Rigorous and reproducible science is most effectively assessed through observable and documented research practices rather than publication outcomes alone. This directly reflects the priorities set out in Executive Order 14303, Restoring Gold Standard Science, which identifies reproducibility, transparency, communication of uncertainty, and a willingness to subject scientific findings and assumptions to continued scrutiny as foundational tenets of trustworthy federal research.

Successful replication remains one of the strongest indicators of scientific robustness. However, replication is inherently retrospective, resource-intensive and feasible for only a fraction of published research. NIH should therefore complement direct replication with measurable indicators of the research practices and outputs that make findings independently assessable, reproducible, and ultimately replicable.

<u>Use connected research to identify where replication is needed most</u>

Persistent identifiers, interoperable metadata and connected research information have fundamentally changed what can be observed across the research lifecycle. Publications can increasingly be linked to grants, datasets, software, protocols, biological resources, organizations, researchers, and subsequent research outputs. This provides NIH with a substantially broader evidence base for assessing scientific rigor than publication counts and citation metrics alone. These evidence-based indicators reflect transparency, methodological rigor and the stewardship of research outputs.

This same connected evidence base can also help address a critical question: Where would additional replication effort have the greatest scientific value?

Rather than prioritizing replication primarily in response to highly visible failures or individual nominations, NIH could develop an evidence-based framework for identifying research areas where independent verification is most warranted. Such framework could combine multiple signals, including:

- availability and accessibility of quality underlying datasets and analytical code;
- availability of sufficiently detailed protocols and methods;
- use of trusted repositories and persistent identifiers;
- preregistration where scientifically appropriate;
- transparent reporting of methods, including negative and confirmatory findings;
- citation and demonstrated reuse of datasets, software and research resources; and
- independent validation or replication of published results.

Natural language processing and structured metadata applied to the full text of published research can now detect the presence or absence of specific transparency markers at scale, including disclosed funding, stated ethical approval, data and code availability, declared competing interests, validated across multiple fields to avoid disciplinary bias. This allows NIH to move from a largely reactive and subjective model of replication toward a more systematic, evidence-informed model: identifying consequential findings or research areas that have limited independent verification, weaker reproducibility signals, or substantial downstream scientific dependence. NIH could use such evidence to help prioritize replication investments, including expansion of existing efforts to independently replicate significant lines of NIH-supported research.

Reward the work required to make science reliable

Identifying where replication is needed does not resolve why so little of it happens. Academic incentive structures are built almost entirely around individual achievement, including first or last authorship, novel-discovery outputs, principal investigator status, publication volume, grant funding, and citation-based indicators. These measures can undervalue the collaborative and often less glamorous and less visible work required to verify, reproduce, challenge, or strengthen existing findings. Researchers undertaking rigorous replication largely absorb the professional cost of that work personally, while the resulting benefit of a more reliable scientific evidence base accrues broadly to the field as a whole.

NIH can help change this incentive structure by making contributions to reproducibility and replication visible, attributable, and creditable. When replication studies are linked to the original finding through persistent identifiers a contributor's specific role in it, replication design, execution, data verification, methodology, software, resource development, and experimental execution are captured through structured contributor taxonomies such as CRediT, those contributions can become part of an investigator’s

documented scientific record independent of authorship position high citation counts.

NIH could extend this further by formally recognizing verification and replication contributions in biosketches, progress reports, grant review criteria, and other assessment processes and by continuing to explore dedicated funding and recognition mechanisms for high-value replication research.

Measure practices and outcomes, not compliance alone

These indicators should prioritize evidence of accessibility, reuse, verification and scientific utility, rather than simple compliance with reporting requirements. A dataset that is discoverable, interoperable and reused by multiple research communities provides considerably stronger evidence of scientific value than one that is merely deposited.

Potential measurable indicators could include:

- proportion of applicable research outputs with accessible underlying datasets;
- proportion with accessible analytical code or computational workflows;
- availability and completeness of protocols and methodological documentation;
- use of trusted repositories and persistent identifiers;
- preregistration where scientifically appropriate;
- transparent reporting of methods, limitations, negative findings, and confirmatory findings;
- demonstrated reuse of datasets, software, protocols, and research resources;
- successful computational or methodological reproduction by independent researchers;
- documented independent validation or replication;
- links between original findings and subsequent replication or validation studies; and
- continued accessibility of research outputs over time.

Create infrastructure for negative and confirmatory findings

Transparent reporting of negative and null findings, named explicitly above as an indicator, and named directly among the Gold Standard Science tenets as a marker of trustworthy research culture, depends on more than researcher willingness. It requires infrastructure through which these outputs can be persistently identified, discovered, cited, connected to the original research, and recognized as legitimate scientific contributions regardless of journal publication.

Repository infrastructure capable of assigning persistent identifiers to diverse research outputs can provide a durable mechanism for making negative confirmatory findings part of the scientific record. Connecting these outputs to grants, investigators, datasets, protocols and origination studies would also allow NIH to evaluate their subsequent attention, reuse, and scientific influence.

This is important because an incentive to report negative findings will have limited effect if those findings remain effectively invisible within research assessment systems.

Minimize reporting burden through interoperability

Implementation should build upon existing community standards, including DOIs, ORCID iDs, ROR identifiers, RRIDs and grant identifiers, and structured contributor roles. Wherever possible, NIH should derive indicators from existing research infrastructure rather than requiring investigators to repeatedly report on information already available elsewhere.

The objective should be to create a connected evidence layer around NIH-supported research, not another administrative reporting layer.

Protect the independence of replication review

Replication also presents distinct review-integrity considerations. A proposal to replicate an influential finding may be reviewed by researchers who collaborated with, trained with, competed with, or have other significant scientific relationships to investigators associated with the original work.

For replication-focused funding, NIH could therefore consider conflict-of-interest screening that examines relevant relationships to both the replication applicant and the research being replicated. Connected publication, funding, institutional, and collaboration information could assist NIH in identifying relationships requiring additional review while preserving appropriate scientific expertise on review panels.

Distinguish transparency, reproducibility, and replication

Finally, NIH should avoid collapsing transparency, reproducibility, and replication into a single composite measure.

They represent related but distinct dimensions of scientific quality:

Transparency asks whether the evidence, methods, materials, assumptions, and limitations necessary to evaluate the research are available.

Reproducibility asks whether the reported result can be obtained using the original data, methods, or analytical procedures, as appropriate to the research domain.

Replication asks whether a finding can be independently tested and supported using new data, experiments, samples, or other appropriate independent approaches.

Each provides different information about the reliability of a scientific claim. NIH assessment frameworks should preserve these distinctions while recognizing their

complementary value.

Research assessment itself should also be treated as an evidence-based scientific endeavor. Any indicators NIH adopts should be evaluated for construct validity, disciplinary and methodological bias, susceptibility to gaming, administrative burden, and unintended behavioral consequences, and should evolve as evidence accumulates.

The opportunity for NIH is therefore broader than developing another set of research metrics. By connecting information already generated throughout the research lifecycle, NIH can build an evidence-informed system that helps determine which findings most warrant independent replication, which practices make research more reproducible, and which researchers and teams are contributing to the collective reliability of biomedical science. Such a framework would allow NIH to direct replication investment based on evidence rather than visibility while creating meaningful incentives for researchers to produce science that can be independently evaluated, reproduced, and trusted.

• **Data, Software, and Model Sharing:** ***Sharing scientific data and tools accelerates biomedical research discovery, in part, by enabling validation of research results, providing accessibility to high-value datasets, and promoting data reuse for future research studies. NIH seeks to incentivize and reward these activities to maximize the value of research investments, catalyze collaborations, and accelerate scientific impact.***

Digital Science Response:

Scientific publications are increasingly one component of a much broader ecosystem of research objects. The publication should be viewed as an entry point into the research record, rather than the research record itself. Contemporary biomedical discovery depends upon interconnected datasets, software, computational models, protocols, workflows and other digital research assets that enable verification, reuse and cumulative knowledge generation.

NIH assessment frameworks should recognize these outputs as first-class scientific contributions whose value extends well beyond their role in supporting individual publications.

The central objective should not simply be to incentivize sharing, but to incentivize useful and reusable sharing. A binary measure of whether a dataset, software package, or model was deposited provides limited information about whether the resource can be discovered, understood, accessed, reused, and built upon by other researchers.

The more meaningful question is:

Did the shared research asset continue to generate scientific value after the originating project ended?

This distinction is important for maximizing the return on NIH's research investment.

Move from measuring deposition to measuring reuse

Persistent identifiers, interoperable metadata, repositories, and connected research information increasingly make it possible to observe how research objects move through the research ecosystem, from creation and deposit to discovery, citation, integration, reuse, and subsequent scientific outcomes.

NIH therefore has an opportunity to evolve from measuring whether sharing occurred toward measuring whether shared assets are findable, accessible,understandable, reusable, and demonstrably used by others.

Potential measurable indicators could include:

- deposition in appropriate trusted repositories;
- assignment and continued resolution of persistent identifiers;
- completeness and quality of metadata;
- linkage to originating grants, publications, investigators, and institutions;
- adherence to relevant FAIR principles and community standards;
- availability of documentation sufficient to understand and reuse the resource;
- software versioning, documentation, dependency information, and maintenance;
- model documentation, including relevant assumptions, parameters, provenance, limitations, and versioning;
- use of appropriate licenses or terms that clearly communicate conditions of reuse;
- citation or formal acknowledgment of datasets, software, models, protocols, and other research assets;
- evidence of reuse in subsequent publications or research projects;
- reuse by investigators or institutions independent of the originating research team;
- integration into subsequent datasets, software, models, clinical research, public resources, or other research infrastructure;
- evidence of continued maintenance and accessibility over time; and
- breadth and diversity of downstream reuse across research communities.

These indicators should not necessarily be combined into a single score. Different research objects and disciplines have different reuse patterns, and assessment should account for those differences.

Reward stewardship, not compliance alone

NIH should distinguish deposit, stewardship, and reuse.

Deposit establishes that an output has been made available.

Stewardship establishes that the output remains accessible, documented, interpretable, interoperable, and usable.

Reuse demonstrates that the output has generated value beyond the originating research project.

These are related but distinct dimensions of responsible research sharing.

A dataset deposited to satisfy a policy requirement but lacking sufficient metadata or documentation to permit meaningful reuse should not be treated as equivalent to a well-curated dataset that is independently reused across multiple research projects. Similarly, software that is deposited but cannot be executed because dependencies, documentation, or version information are absent provides different scientific value from software that remains maintained, documented, and adopted by other research teams.

NIH incentives should recognize this continuum.

Give researchers credit for creating reusable research assets

Researchers continue to receive substantially more professional recognition for publications than for the creation and stewardship of reusable research resources. This creates a structural incentive problem: producing high-quality datasets, maintaining software, documenting models, curating metadata, and supporting reusable resources require significant scientific effort, yet those contributions may remain largely invisible in traditional research assessment.

NIH can help change this by making these contributions visible and creditable.

Dataset, software, model, and resource contributions could be incorporated more explicitly into NIH biosketches, progress reporting, grant review, and other assessment processes. Where contributor roles can be reliably attributed, NIH could recognize activities such as data curation, software development, validation, visualization, methodology development, and resource stewardship alongside more traditional publication-based evidence of contribution.

Importantly, credit should not depend solely upon citation counts. Dataset and software citation practices remain inconsistent across disciplines. NIH should therefore consider multiple forms of evidence, including formal citation, persistent-identifier linkages, documented reuse, integration into downstream research, and other appropriate indicators of adoption.

Treat software and computational models as scientific methodology

Software and computational models warrant particular attention because they are increasingly integral to biomedical methodology.

Where software materially contributes to scientific findings, its documentation, versioning, provenance, dependencies, accessibility, and maintenance directly affect the ability of other researchers to evaluate or reproduce the work. Similarly, computational and AI/ML models may require documentation not only of the model itself but also of relevant training or validation data, versioning, parameters, assumptions, limitations, and appropriate conditions of use.

Assessment frameworks should therefore recognize software and model stewardship as part of scientific rigor rather than treating these outputs as secondary technical products.

NIH should also recognize that maintenance itself is a scientific contribution. A widely used software package or research resource can continue enabling NIH-funded science for many years after its original grant has concluded. Traditional assessment approaches may substantially underestimate this continuing return on federal investment.

Use connected evidence to understand downstream value

A major opportunity is the ability to connect shared research assets to subsequent scientific activity.

Persistent identifiers and connected metadata can increasingly link a dataset or software resource to its originating grant and publication and then trace subsequent citations, publications, grants, investigators, institutions, clinical research, or other outputs that make use of it.

This creates the possibility of measuring research asset lineage: not simply whether an asset exists, but where it came from, who subsequently used it, and what additional scientific activity it helped enable.

For NIH, this could provide a new way to understand return on research investment. A dataset generated through one NIH award may subsequently support research conducted by dozens of investigators, across multiple institutions and funding programs. Those downstream uses represent scientific value created by the original investment but are largely invisible in publication-centered assessment.

NIH could therefore consider indicators such as:

Reuse rate: whether and how often a resource is independently reused.

Reuse breadth: the number and diversity of investigators, institutions, disciplines, or projects using it.

Reuse longevity: whether the resource continues to generate research activity over time.

Research lineage: the subsequent publications, grants, clinical studies, resources, software, or other outputs connected to the original asset.

Independent reuse: whether reuse extends beyond the originating investigators or institution.

Together, these measures would provide a substantially richer view of scientific impact than deposit counts alone.

Build upon NIH's work on measuring data sharing

NIH has already explored this challenge through efforts such as the Data Sharing Index (S-Index) Challenge, which examined approaches for moving beyond a binary determination of whether data were shared toward more scalable measures of data sharing and reuse.

Experience from that effort demonstrates both the importance and feasibility of connecting repository information, persistent identifiers, research metadata, and downstream scholarly activity to better understand the lifecycle of shared data.

Digital Science's participation in NIH's S-Index Challenge demonstrated the practical feasibility of this approach. Our submission combined repository infrastructure supporting persistent identification and FAIR-aligned metadata with connected research information capable of tracing relationships among datasets, publications, grants, researchers, institutions, and subsequent research activity. Importantly, these capabilities were based on established infrastructure already operating at scale rather than systems created solely for the Challenge. That experience suggests that many of the indicators described above can be derived from existing infrastructure and metadata, rather than requiring NIH to create new reporting systems or impose additional reporting requirements on researchers.

Existing research infrastructure already indexes datasets distributed across many repositories and connects research objects with publications, grants, researchers, organizations, and other outputs. This provides a practical foundation for evaluating not only whether data have been deposited, but whether those assets are subsequently discovered, cited, reused, and connected to additional scientific activity.

NIH can therefore build upon existing community and commercial infrastructure, standards, persistent identifiers, and metadata to develop and validate indicators before introducing additional reporting requirements.

Reduce burden through interoperability

Implementation should prioritize interoperability and automation.

DOIs, ORCID iDs, ROR identifiers, grant identifiers, software identifiers, repository metadata, and other established standards can provide much of the connective infrastructure required to understand research asset creation and reuse.

Where information can be derived reliably from existing systems, researchers should not be required to report it again.

This principle is particularly important if NIH expands assessment beyond publications. The goal should be to recognize a broader range of scientific contributions without creating a correspondingly broader administrative burden.

NIH should also recognize that no single indicator will adequately capture the value of all data, software, or models. Indicators should be validated for disciplinary differences, field maturity, resource type, susceptibility to gaming, and unintended

incentives. Measures of reuse should complement, rather than replace, qualitative scientific judgment.

Ultimately, NIH has an opportunity to shift the incentive structure from "Did you share it?" to "Did you make it reusable, and did it continue to create value?"

That shift would better recognize the researchers who create and steward high-value scientific resources, provide NIH with a more complete picture of the return generated by federal research investments, and encourage a research ecosystem in which data, software, and models remain active scientific assets long after the projects that created them have ended.

• **Training and Mentorship:** ***NIH recognizes that advancing its mission requires promoting the growth and stability of the biomedical research workforce. While NIH supports training and protects time through existing policies and programs, additional indicators are needed to assess and quantify the impact of these efforts.***

Digital Science Response:

The continued strength of the biomedical research ecosystem depends not only on generating new knowledge but on developing the people, skills and research practices, and cultures that make future discovery possible. Training and mentorship should therefore be assessed not simply as activities that occurred, but by the scientific capacity they create over time.

Traditional indicators such as the number of trainees supported, fellowships completed, or training activities delivered provide important administrative information but only a partial measure of impact. They establish that training occurred; they do not establish what that training produced.

NIH has an opportunity to shift from measuring training activity toward measuring researcher development, mentorship effectiveness, and sustained scientific capacity.

Follow outcomes beyond the training period

The impact of NIH-supported training frequently becomes apparent years after an award or fellowship ends. Assessment should therefore follow researcher trajectories over longer periods rather than relying predominantly on outcomes observable within a single grant cycle.

Potential longitudinal indicators could include:

- progression to subsequent career stages;
- time to research independence, where independence is an appropriate career objective;
- subsequent participation or leadership in funded research;
- movement into scientific leadership positions;
- continued participation in biomedical research across academia, healthcare, government, industry, nonprofit organizations, and other sectors;
- participation in interdisciplinary and multi-institutional research;
- development of sustained collaborative research networks;
- subsequent contributions to data, software, methods, protocols, and shared research resources;
- adoption and leadership of rigorous and reproducible research practices;
- subsequent mentoring and supervision of other researchers; and
- continued contribution to the biomedical research ecosystem over time.

Importantly, successful training should not be defined solely as progression toward a tenure-track faculty position or principal investigator status. NIH-supported researchers contribute to biomedical science through many pathways, including industry, clinical research, regulatory science, public health, government, research infrastructure, data science, software engineering, and other technical and collaborative roles.

An assessment framework that defines success too narrowly risks categorizing valuable scientific careers as attrition when they may instead represent substantial returns on NIH's training investment.

Measure mentorship by what it enables

Mentorship itself should be recognized as a scientific contribution.

Effective mentors do more than supervise research activity. They help researchers develop scientific judgment, methodological rigor, professional networks, collaborative skills, responsible research practices, and the ability to mentor others.

NIH could therefore consider indicators of mentorship effectiveness that examine the subsequent development of trainees over time. These might include trainee progression, continued participation in biomedical research, transition into appropriate leadership or independent roles, development of collaborative networks, contributions to rigorous and reproducible research, and evidence that former trainees subsequently become effective

mentors themselves.

This creates an important potential indicator of long-term impact: mentorship propagation.

Rather than viewing the completion of an NIH-supported fellowship or training award as the endpoint of measurement, NIH could examine the longer arc of the investment:

NIH-supported training ➜ mentorship ➜ researcher development ➜ continued contribution to the biomedical research ecosystem ➜ creation of new research, data, software, methods, or other scientific resources ➜ subsequent mentorship and development of additional researchers.

Viewed in this way, the impact of NIH-supported training is not limited to the career outcome of a single trainee. It can propagate through subsequent research contributions, collaborations, institutions, sectors, and generations of researchers. A training investment made in one individual may ultimately contribute to the development of an extended scientific network whose collective impact substantially exceeds what can be observed at the conclusion of the original award.

Persistent identifiers and connected research information increasingly make portions of this longitudinal pathway observable. By linking training awards and mentors to subsequent grants, research outputs, affiliations, collaborative networks, contribution roles, and later mentorship relationships, NIH could begin to understand not simply whether an individual completed training, but how that investment propagated through the biomedical research ecosystem over time.

Such evidence should not be reduced to a simplistic mentor ranking or score. Trainee outcomes are influenced by discipline, institution, career goals, economic conditions, personal choices, and many factors beyond an individual mentor's control. Longitudinal evidence should therefore inform qualitative assessment rather than substitute for it.

Use longitudinal research information to understand career trajectories

Advances in research information infrastructure make it increasingly possible to understand researcher development over longer periods.

Persistent researcher identifiers, grant information, publications, affiliations, contribution metadata, and collaborative relationships can help connect an individual's research activity across career stages. With appropriate safeguards and validation, these data can provide NIH with a portfolio-level view of what happens to researchers following NIH-supported training.

For example, connecting persistent researcher information across successive grants, research outputs, affiliations, and sectors can help NIH understand whether trainees subsequently participate in academic research, industry, government, healthcare, public health, regulatory science, or other parts of the biomedical ecosystem; whether they develop sustained research collaborations; and where appropriate, whether they progress

toward independent funding or scientific leadership.

This would allow NIH to ask questions that are difficult to answer from administrative completion data alone:

What kinds of careers do NIH-supported trainees build?

Which training environments consistently produce sustained participation in biomedical research?

Which programs produce researchers who subsequently develop other researchers?

Where does NIH-supported talent remain within the biomedical research ecosystem, and where is scientific capacity being lost?

Which training approaches are associated with stronger long-term outcomes across different career pathways?

The objective should not be to prescribe a preferred career destination, but to understand whether NIH training investments generate durable scientific capability.

Recognize the full range of contributions that sustain research careers

Many activities that underpin high-quality biomedical research, including mentorship, data stewardship, software development, research infrastructure, peer review, methodological support, and collaborative leadership remain less visible within publication and PI-centered assessment frameworks.

This can particularly disadvantage researchers whose scientific contribution occurs through technical, collaborative, or infrastructure leadership rather than through conventional principal investigator roles.

Structured contributor information and recognized contribution taxonomies can help make these roles more visible. Rather than inferring contribution predominantly from authorship position or PI status, NIH could recognize documented roles in areas such as data curation, software development, methodology, validation, project administration, supervision, and other contributions essential to modern team science.

This is relevant to workforce stability because NIH cannot effectively understand retention if its assessment systems recognize only a subset of the careers through which people contribute to biomedical research.

A researcher who moves from an NIH-supported training program into scientific software development, data stewardship, research infrastructure, regulatory science, or another research-enabling role should not automatically disappear from NIH's understanding of the workforce simply because that individual does not subsequently become a PI.

Recognize contributions to training culture

Mentorship also occurs beyond traditional one-to-one supervisory relationships.

Researchers contribute to workforce development by creating openly available training resources, developing interdisciplinary training programs, teaching responsible research practices, supporting reproducibility initiatives, participating in peer review, building research communities, and creating shared technical or methodological resources.

Potential indicators could therefore include:

- development and demonstrated use of openly available educational or training resources;
- contributions to interdisciplinary or cross-institutional training programs;
- leadership in research integrity, responsible conduct of research, and reproducibility initiatives;
- documented mentorship and supervision contributions;
- contributions to shared research methods, infrastructure, data, or software that enable other researchers;
- sustained collaborative relationships involving junior researchers;
- participation in peer review and other forms of scientific community stewardship; and
- evidence that trainees subsequently contribute to mentorship and workforce development themselves.

Where possible, assessment should emphasize evidence of **use and downstream impact,** rather than simply counting activities. For example, an openly available training resource that is adopted across multiple institutions provides stronger evidence of training impact than the existence of the resource alone.

Build on existing information rather than creating new reporting burdens

Much of the information needed to develop these indicators already exists across research systems.

Persistent identifiers and connected research information can increasingly link researchers with grants, publications, affiliations, research outputs, collaborative networks, and documented contribution roles over time. These data can complement NIH administrative information and targeted qualitative evidence to provide a richer understanding of researcher development.

The goal should be to derive longitudinal evidence from existing information wherever it can be done reliably, rather than requiring mentors and trainees to repeatedly report information NIH or the broader research ecosystem already holds.

NIH should also be cautious about the limitations of these indicators. Persistent identifier coverage varies; affiliation and career information can be incomplete; some sectors produce fewer visible scholarly outputs; career trajectories are not linear; and quantitative indicators may systematically underrepresent important forms of scientific contribution.

For these reasons, longitudinal data, structured contribution statements, trainee and mentor perspectives, and narrative evidence should complement one another.

Measure durable scientific capacity

Ultimately, NIH should assess training and mentorship according to the durable scientific capacity created by its investment.

A successful training investment is not simply a completed fellowship. It is a researcher who develops skills, contributes meaningfully to biomedical science, participates in productive scientific networks, and potentially develops the next generation of researchers.

A successful mentor is not simply someone who supervises a large number of trainees. It is someone whose mentorship contributes to the development of capable researchers and strengthens the culture and practice of science.

And a stable biomedical workforce should not be defined solely by the number of researchers who become principal investigators. It should encompass the diverse scientific, technical, clinical, public-sector, and collaborative careers required for modern biomedical research.

By following researcher trajectories over time, recognizing the full range of scientific contributions, and examining how mentorship propagates through subsequent careers and generations, NIH can move from counting training activities to understanding whether its investments are building and sustaining the biomedical research capacity required for its mission.

• **Collaboration:** ***As biomedical research becomes increasingly interdisciplinary and convergent, collaboration is growing in both scale and complexity. NIH seeks new approaches for assessing and recognizing contributions to team-based science.***

Digital Science Response:

Authorship remains one of the dominant mechanisms for recognizing scientific contribution, yet it captures only a fraction of what contemporary team-based science requires. As biomedical research becomes increasingly interdisciplinary, computational, collaborative, and cross-sector, NIH assessment frameworks should recognize collaboration as the integration of complementary expertise and contributions toward a scientific objective, not simply as co-authorship.

This distinction is increasingly important. Scientific teams now depend upon specialized contributions spanning experimental science, clinical expertise, statistics, data science, software development, methodology, research infrastructure, project leadership, community engagement, and other capabilities. Assessment systems that focus predominantly on first or last authorship risk overlooking many of the contributions upon which modern biomedical research depends.

NIH therefore has an opportunity to address two related but distinct questions:

What did each person contribute to the team?

and

Did the collaboration create scientific capability or value that the participants would have been unlikely to achieve independently?

Both should inform the assessment and recognition of team science.

Recognize contribution, not simply authorship position

Author order is an imperfect proxy for scientific contribution and becomes increasingly inadequate as teams grow larger and roles become more specialized.

NIH could place greater emphasis on structured contributor information, including recognized taxonomies such as CRediT, to make individual roles within collaborative research more visible. Contributions such as methodology development, software, data curation, validation, statistical analysis, visualization, supervision, project administration, resource development, and other activities should be recognizable as scientific contributions in their own right where appropriate.

This would be particularly valuable for researchers whose contributions are essential to multiple projects but who may rarely appear as first or last author or principal investigator.

The objective should not be to replace authorship, but to supplement it with evidence that better reflects who contributed what.

Over time, structured contribution information could enable NIH to recognize patterns of scientific contribution across multiple projects. A researcher who repeatedly provides essential methodological, computational, clinical, data, or infrastructure expertise across collaborative programs may be making an important contribution to NIH's mission even if traditional publication metrics systematically understate that role.

Distinguish collaboration from scientific integration

NIH should also distinguish between the size of a collaboration and the quality or depth of scientific integration.

More investigators, institutions, disciplines, or sectors do not necessarily indicate more effective collaboration. Indicators that simply reward larger teams could unintentionally encourage collaboration for its own sake.

More meaningful evidence would examine whether collaborators combine complementary expertise, share research resources, create sustained intellectual or technical relationships, and produce outputs or capabilities that cross traditional disciplinary or organizational boundaries.

Potential indicators could include:

- diversity and complementarity of documented contributor roles;
- interdisciplinary participation appropriate to the scientific question;
- sustained collaboration across projects or funding periods;
- cross-institutional or cross-sector research relationships;
- shared datasets, software, methods, protocols, infrastructure, or other scientific resources;
- joint development of community research resources;
- evidence of knowledge exchange across disciplines or sectors;
- subsequent reuse or adoption of collaborative outputs;
- development of new collaborations or research communities arising from the original team;
- translation of research across scientific, clinical, public-sector, or commercial environments where appropriate; and
- evidence that the collaboration creates capabilities or outputs beyond those attributable to a single participating group.

These indicators should complement expert assessment rather than be combined Mechanically into a collaboration score.

Understand collaboration as a network, not an event

Collaboration should also be assessed longitudinally.

A co-authored publication provides evidence that researchers worked together on the output. It provides considerably less information about whether the relationship developed into a sustained and productive scientific partnership.

Persistent identifiers and connected research information increasingly make it possible to examine collaborative relationships across grants, publications, datasets, software, clinical studies, organizations and other research activity over time.

This allows collaboration to be understood as a network that develops and evolves, rather than a characteristic of an individual publication.

For example, NIH could examine whether a funded interdisciplinary collaboration:

NIH investment ➔ brings together complementary expertise ➔ produces shared research and resources ➔ develops sustained collaborative relationships ➔ generates additional research or capabilities ➔ expands into new institutions, disciplines, or sectors ➔ produces downstream scientific or translational value.

This provides a richer conception of collaborative impact than counting co-authored publications or participating institutions.

It also allows NIH to distinguish between first-order and downstream effects of collaborative investments. The immediate output may be a publication, dataset, software resource, or clinical finding. The longer-term return may include a durable interdisciplinary network, shared infrastructure, subsequent jointly funded research, movement of methods between fields, or new collaborations that continue after the original award ends.

Evaluate whether funded collaborations become genuinely integrated

Connected research evidence could also help NIH evaluate collaborative programs, centers, and consortia at the portfolio level.

Relationships among funding, researchers, organizations, publications, datasets, software, research resources, and documented contributor roles can provide evidence about whether collaborations develop scientific connections beyond the administrative structure of the original award.

For example, NIH could examine whether participating groups subsequently produce joint outputs, share or reuse research resources, establish new cross-institutional relationships, develop interconnected research programs, or continue collaborating after the initial funding period.

This would not by itself determine whether a collaboration is scientifically successful; expert judgment remains essential. It could, however, help NIH distinguish between collaborations showing evidence of deep and sustained scientific integration and those showing comparatively limited evidence of interaction.

For large collaborative investments, this could provide valuable evidence for program evaluation and future funding decisions.

Recognize cross-sector collaboration

Team science increasingly extends beyond academic institutions.

Biomedical research may bring together academic researchers, healthcare organizations, government laboratories, industry, nonprofit organizations, patient or community groups, data and technology organizations, and other participants.

Assessment frameworks should recognize the value of these collaborations without assuming that all sectors produce the same kinds of outputs.

A successful academic-industry collaboration, for example, may generate software, data resources, methods, technologies, patents, clinical applications, or other outputs that are not adequately represented by publication counts. Similarly, collaborations involving healthcare or public-sector organizations may produce implementation, policy, clinical, or population-health effects that require different forms of evidence.

NIH should therefore assess collaboration according to the scientific objective and intended contribution of the participants rather than imposing a single publication-centered definition of collaborative success.

Use connected information to help form teams as well as assess them

The same research information that supports assessment can also help NIH facilitate future collaboration.

Disambiguated researcher profiles connected to publications, grants, research topics, methods, datasets, affiliations, and previous collaborations can help identify relevant expertise beyond established professional networks.

This creates an opportunity for NIH not simply to measure collaboration after it occurs, but to help identify complementary expertise before teams are formed.

At a portfolio level, such approaches could help identify researchers or institutions working on related problems from different disciplinary perspectives, reveal capabilities that are missing from existing research networks, and identify opportunities to connect investigators who might not otherwise encounter one another.

Similar information could assist with identifying potential reviewers with appropriate expertise while supporting conflict-of-interest screening, although such systems should augment rather than replace established NIH review procedures.

Minimize burden and avoid unintended incentives

Implementation should build upon persistent identifiers, structured contributor roles, existing grant and publication information, and interoperable research infrastructure

wherever possible.

Researchers should not be required to produce extensive new collaboration reporting when relevant evidence can be derived reliably from information already generated through the research process.

NIH should also be cautious about creating incentives that reward collaboration numerically. Number of collaborators, institutions, disciplines, or countries may describe a research team but should not automatically be interpreted as evidence of quality.

Network-based measures should likewise be used carefully. Highly connected researchers are not necessarily the most valuable collaborators, and important specialists may contribute deeply to relatively small numbers of projects.

Quantitative evidence should therefore support expert assessment of contribution, complementarity, integration, durability, and scientific value, rather than become an end in itself.

Recognize collaboration as a scientific capability

Ultimately, NIH should move from treating collaboration primarily as an authorship pattern toward recognizing it as a scientific capability.

The relevant questions are not simply how many researchers participated or how many institutions appeared on an award. They are:

Were complementary capabilities brought together?

Can the contributions of individual team members be recognized?

Did participants genuinely integrate their expertise and resources?

Did the collaboration create something that would have been difficult to achieve independently?

Did the relationships, resources, or capabilities created through the collaboration continue to generate value?

A funding agency that cannot distinguish integrated collaboration from a shared cover page cannot reliably reward the former or understand the return generated by its collaborative investments.

By combining structured contribution information, persistent identifiers, longitudinal research information, network evidence, and expert scientific assessment, NIH can develop a more defensible framework for recognizing the individuals who make team science possible while also identifying the collaborative structures that produce genuine

scientific integration and sustained biomedical value.

• **Entrepreneurship and Translation:** ***To advance the translation of discoveries into products for people, NIH fosters the maturation of discoveries from bench to bedside and promotes innovation across sectors. More can be done to incentivize, assess, and integrate the impact of innovation and entrepreneurial efforts as critical to the NIH mission.***

Digital Science Response:

Patents, licenses, company formation, and commercialization are among the most visible and readily measurable outcomes of biomedical innovation. They are important indicators, but they capture only a portion of the process through which NIH-supported discoveries ultimately improve human health.

NIH should therefore assess not only translational outcomes, but also contributions to translational pathways: the cumulative, often non-linear process through which knowledge moves from fundamental discovery toward clinical, commercial, public-health, policy, or other forms of application.

This distinction matters because biomedical translation rarely results from a single publication, investigator, institution, or funding award. It frequently develops through successive contributions from researchers, organizations, funding programs, healthcare systems, government, industry, and other participants over extended periods.

A framework that recognizes those contributions would better reflect how biomedical innovation actually occurs and allow NIH to understand more fully how its investments contribute to downstream health, economic, and societal value.

Measure pathways, not simply endpoints

Traditional translational indicators tend to emphasize observable endpoints: patents, licenses, spinouts, products, or clinical applications.

NIH should retain these measures while also examining the intermediate steps through which research progresses toward application.

Potential indicators could include:

- progression of NIH-supported research into subsequent translational or development funding;
- patent applications and granted patents linked to NIH-supported research;
- licensing activity and technology transfer, where appropriate;
- formation of companies or other commercialization vehicles;
- industry partnerships and cross-sector research relationships;
- progression into clinical studies or clinical trials;
- incorporation into clinical guidelines or standards of care;

- citations or incorporation into regulatory documents;
- incorporation into public policy or public-health guidance;
- development and adoption of diagnostic tools;
- development and adoption of research or clinical software;
- development of standards, methods, protocols, or shared research resources;
- use within healthcare systems or clinical practice;
- development of public-health interventions;
- subsequent investment or funding that builds upon the original research; and
- demonstrated adoption or use by organizations beyond the originating research team.

These indicators should be interpreted according to the scientific field and intended pathway to impact. Not all valuable NIH-funded research should result in a patent, company, clinical trial, or commercial product.

Understand translation as a connected pathway

Advances in connected research information increasingly make it possible to observe translational pathways empirically.

Persistent identifiers and linked research information can connect publications with grants, patents, clinical trials, datasets, software, researchers, organizations, policy documents, clinical guidelines, and other downstream activity.

Rather than viewing these outputs independently, NIH could increasingly examine the pathways connecting them:

NIH investment → fundamental discovery → subsequent research and validation → translational development → cross-sector engagement → clinical testing or other application → adoption → health, economic, or societal value.

Importantly, these pathways will not always be linear.

A fundamental discovery may contribute to multiple subsequent research programs. A dataset may enable a diagnostic technology. Software may move directly into clinical research without generating a patent. A methodological advance may be incorporated into clinical guidelines. An NIH-supported discovery may contribute to a commercial product years later through research conducted by investigators and organizations that were not part of the original award.

Understanding these connections provides a more realistic model of translation than attempting to attribute an eventual societal outcome to a single publication or investigator.

Distinguish contribution from attribution

NIH should be cautious about attempting to assign exclusive credit for downstream impact.

Translation is cumulative. A successful therapeutic, diagnostic, clinical practice, or public-health intervention may depend upon decades of foundational research funded through multiple programs and performed across numerous institutions.

The appropriate question is often not: **“**Which investigator caused this outcome?” but rather: “What NIH-supported research contributed to the pathway that made this outcome possible?”

Connected evidence can help identify these contributions without implying simplistic causality.

This approach would also allow NIH to recognize foundational research that creates important translational value even when the originating investigators never participate directly in commercialization.

Identify translational inflection points earlier

The same evidence used to evaluate translation retrospectively could potentially help NIH identify emerging translational opportunities prospectively.

Today, important translational signals may appear across disconnected systems. A body of NIH-supported research may begin generating patent activity, follow-on funding, industry collaboration, clinical investigation, new software or diagnostic applications, or increasing attention from organizations outside the originating research community.

Individually, these signals provide incomplete information. Considered together, they may indicate that a line of research is approaching a translational inflection point.

NIH could explore whether combinations of signals such as: “research maturation + independent validation + follow-on funding + patent activity + cross-sector engagement + clinical activity” can help identify research areas where targeted translational support, expertise, partnership, or additional funding might accelerate progress.

This would move the assessment beyond asking “What translated?” toward also asking “What may be ready to translate next?”

Such approaches should be validated carefully and used to support, rather than automate, scientific and programmatic judgment. Translational potential is inherently uncertain, and

indicators should not create pressure to commercialize research prematurely.

Recognize the people who enable translation

Entrepreneurial and translational activity should also be recognized as a legitimate scientific contribution.

Researchers may contribute to translation through invention, company formation, technology development, industry collaboration, clinical development, standards development, software creation, regulatory science, implementation, or other activities that move knowledge toward use.

These contributions can be difficult to see in publication-centered assessment.

NIH could recognize documented translational contributions within biosketches, progress reports, portfolio assessment, and other appropriate review processes. Structured contributor information and connected evidence could help make these activities more visible.

Prior entrepreneurial and translational experience may also provide useful contextual evidence, for example, previous involvement in technology transfer, industry collaboration, clinical development, licensing, or company formation. However, such experience should not become a prerequisite or simplistic score for evaluating future potential.

Researchers at institutions with mature technology-transfer ecosystems have substantially different opportunities from researchers at smaller or less-resourced institutions. Similarly, some biomedical fields offer clearer commercial pathways than others. Assessment should recognize entrepreneurial contribution without creating a structural advantage for investigators who already have access to established commercialization networks.

Recognize multiple routes to impact

Commercialization is one route through which NIH-supported research creates value, but it is not the only one.

Translation may occur through clinical practice, healthcare delivery, public-health interventions, regulatory science, government policy, clinical guidelines, standards, open-source software, shared research infrastructure, diagnostic methods, or widespread adoption of a new research technique.

NIH should therefore avoid equating entrepreneurship exclusively with company formation or translation exclusively with commercialization.

Different types of research should be assessed against pathways appropriate to their intended contribution.

This is particularly important for foundational research. Basic science may have enormous long-term translational significance despite having little immediate commercial potential. An assessment framework overly weighted toward near-term translation could inadvertently discourage the fundamental discovery upon which future biomedical innovation depends.

Measure time to translation carefully

Translation also operates across very different timescales.

Some computational tools or methods can move rapidly into use. Therapeutic development may take many years. Foundational discoveries may generate little visible translational activity for decades before becoming critical to a new technology or treatment.

NIH should therefore consider time-to-translation and translational persistence as contextual rather than purely performance indicators.

Longitudinal analysis can help NIH understand how different types of research move toward application, where pathways commonly stall, and which interventions are associated with successful progression.

This could help answer important portfolio-level questions:

- Where do promising NIH-supported discoveries most commonly stall?
- Which types of support are associated with successful movement between translational stages?
- Where are collaborations with industry, healthcare, or other sectors accelerating translation?
- Which foundational investments ultimately contribute to multiple downstream innovations?
- Which NIH programs are generating translational value that conventional publication metrics fail to capture?

Use connected evidence for portfolio intelligence

At sufficient scale, these indicators could provide NIH with more than an assessment framework. They could provide portfolio intelligence.

Connected evidence across grants, publications, patents, clinical trials, organizations, researchers, and downstream outputs could help program officers and institute leadership identify emerging areas of translational activity across an entire portfolio rather than relying exclusively on individual investigators or technology-transfer offices to surface opportunities.

This could help NIH identify clusters of related discoveries, emerging cross-sector engagement, technologies progressing toward clinical investigation, and areas where additional translational support may be warranted.

It could also help NIH understand the comparative pathways through which different institutes, programs, fields, or funding mechanisms generate downstream value.

The objective should not be to predict commercial success. It should be to provide decision-makers with additional evidence about where translation appears to be occurring, where it may be emerging, and where potentially valuable research is encountering barriers.

Build upon existing research information infrastructure

Many of the relationships required for this type of assessment can already be observed through existing research information infrastructure.

Large-scale connected research databases link publications with grants, patents, clinical trials, researchers, institutions, and other research outputs, making it increasingly possible to examine translational relationships across entire research portfolios rather than reconstructing them manually one project at a time.

Digital Science's experience connecting grants, publications, patents, clinical trials, researchers, and organizations demonstrates the practical feasibility of examining these pathways at research-system scale. Dimensions, for example, links research activity across these different stages, allowing relationships between foundational funding, subsequent research, patent activity, and clinical investigation to be examined within a common evidence environment. This type of existing commercial infrastructure provides NIH with an opportunity to test and validate translational indicators using evidence already available today, rather than first constructing an entirely new reporting or tracking system.

This infrastructure provides a practical starting point for NIH to test translational indicators, examine research pathways retrospectively, and evaluate whether combinations of signals can reliably inform prospective portfolio analysis.

Implementation should build upon existing identifiers, standards, and data sources wherever possible, supplementing these with NIH administrative information and expert assessment rather than creating additional investigator reporting requirements.

Assess contribution while preserving discovery

Ultimately, NIH should expand its assessment of entrepreneurship and translation from counting visible endpoints toward understanding the pathways through which federally

funded knowledge becomes useful.

The relevant questions are not simply:

- Was there a patent?
- Was a company formed?
- Was a product commercialized?

They also include:

- What research made the eventual application possible?
- Who contributed to moving that research toward use?
- What intermediate steps indicate meaningful translational progress?
- Where are promising discoveries encountering barriers?
- Can NIH recognize emerging translational opportunities early enough to help accelerate them?

A discovery that becomes visible as translational only when it reaches a technology-transfer office may already have traveled a substantial portion of its translational pathway.

By connecting evidence across the research lifecycle, NIH can develop a more complete understanding of how its investments contribute to innovation, identify translational momentum earlier, recognize the researchers and teams who enable it, and support pathways that deliver sustained health, economic, and societal value, while continuing to protect the foundational science upon which future translation depends.

• **Foundational Scientific Exploration:** ***Basic research and high-risk, high-reward initiatives represent foundational scientific exploration with an inherent risk of failure but the potential for paradigm-shifting breakthroughs. Further embedding these approaches within the academic enterprise is essential to ensuring continued support for bold and innovative research directions.***

Digital Science Response:

Any indicator built around short-term productivity will systematically penalize the research most likely to produce paradigm-shifting results. NIH's challenge is therefore not to predict which individual foundational or high-risk research project will ultimately transform a field, but to protect sufficient space for exploration within a research portfolio that also rewards more predictable scientific progress.

Transformative advances frequently arise from fundamental research, enabling technologies, methodological innovation, exploratory investigation, unexpected findings, and new combinations of ideas that may initially appear incremental, uncertain, or disconnected from immediate application.

These contributions expand the scientific landscape by creating new questions, methods, resources, and capabilities rather than necessarily producing immediate translational outcomes.

Assessment of foundational scientific exploration should therefore recognize both the contributions created by exploratory research and NIH's broader success in maintaining a portfolio in which scientific risk and uncertainty can be sustained.

Do not require exploratory research to predict its own impact

One of the fundamental difficulties in assessing foundational research is that its eventual importance may be unknowable when the research is proposed or even when the original award concludes.

A discovery, method, dataset, biological resource, or enabling technology may acquire significance only years later, when another scientific development makes it newly useful. Research initially regarded as highly specialized may become foundational to an emerging field. A negative result may eliminate an unproductive direction and redirect subsequent research. A tool created for one purpose may eventually enable discoveries its creators never anticipated.

NIH should therefore avoid assessment frameworks that require foundational research to demonstrate short-term downstream impact as evidence of success.

Instead, potential indicators could include:

- development of novel methodologies, computational approaches, or instrumentation;
- creation of foundational datasets, biological resources, software, or other enabling infrastructure;
- introduction of new concepts, hypotheses, or research questions;
- development of novel combinations of methods or disciplines;
- establishment of new interdisciplinary research directions;
- production and dissemination of negative or null findings that meaningfully refine scientific understanding;
- subsequent adoption of methods, resources, or concepts by researchers outside the originating team;
- diffusion of methods or resources across disciplines;
- emergence of new research communities building upon foundational work; and
- evidence, over longer timescales, that exploratory work enabled subsequent scientific advances.

These indicators should describe contribution and influence without implying that every exploratory project must ultimately generate a transformative outcome.

Evaluate foundational contribution over longer timescales

Foundational research frequently operates on timescales poorly aligned with conventional research assessment.

By the time the importance of a foundational contribution is apparent through citation counts, clinical applications, patents, or other downstream indicators, the funding decisions that enabled it may have occurred many years earlier.

Longitudinal research information provides an opportunity to examine these contributions differently.

Persistent identifiers and connected evidence can increasingly link grants, publications, methods, datasets, software, patents, clinical studies, researchers, institutions, and other outputs over extended periods. This can help reveal how an initially exploratory investment subsequently contributes to scientific capability.

For example:

NIH exploratory investment ➜ new concept, method, resource, or capability ➜ adoption by other researchers ➜ diffusion across research communities ➜ new questions and combinations ➜ subsequent discoveries ➜ potentially transformative scientific or translational impact.

The important point is that the original project's value should not be judged solely by whether it reaches the end of this pathway.

Creating a method or resource that opens new scientific possibilities may itself represent a valuable outcome of foundational research.

Identify emerging science before conventional metrics can see it

Connected research evidence also creates an opportunity to move beyond retrospective assessment.

Citation-based measures are inherently lagging indicators. By the time an emerging research area accumulates substantial citation activity, its importance may already be widely recognized.

NIH could complement conventional assessment with horizon-scanning approaches designed to identify nascent scientific directions while they are still forming.

Potential signals could include:

- emergence of new concepts or terminology;
- rapid development or adoption of new methods;
- unusual combinations of previously separate research areas;
- growth of new interdisciplinary research networks;

- migration of methods or technologies between fields;
- increasing creation or reuse of specialized datasets, software, or research resources;
- formation of new clusters of investigators around emerging questions; and
- changes in funding, publication, or collaboration patterns that suggest the development of a new research direction.

Natural language processing, topic analysis, network analysis, and connected research information can help identify such patterns across large bodies of scientific activity.

These signals should not be interpreted as automatic indicators of scientific quality or future breakthrough potential. Emergence is not synonymous with importance, and novelty is not synonymous with scientific merit. Expert scientific judgment remains essential.

Their value is instead in helping NIH see where the scientific landscape may be changing early enough to investigate further.

Use horizon scanning to inform funding strategy

Applied prospectively, these approaches could provide NIH with a form of scientific horizon scanning.

Rather than waiting until an emerging field has accumulated years of conventional evidence, program officers and institute leadership could receive evidence about where new concepts, methods, technologies, interdisciplinary combinations, and research communities appear to be forming.

This could help NIH ask:

- Which potentially important scientific directions are emerging?
- Which established fields are being disrupted by new methods or technologies?
- Where are previously separate disciplines beginning to converge?
- Which enabling technologies are beginning to diffuse across biomedical research?
- Where is scientific activity emerging faster than NIH investment?
- Are there potentially important areas of exploration that fall between existing programmatic structures?

The objective should not be to automate funding decisions or predict the next breakthrough. It should be to expand the evidence available to scientific leaders deciding where additional exploration may be warranted.

Assess NIH's portfolio risk, not just investigator risk

Perhaps the more important opportunity is to apply these approaches to NIH's own funding portfolio.

High-risk, high-reward research is inherently uncertain at the individual-project level. Some projects will fail to produce their intended results. That is a characteristic of genuine scientific risk, not necessarily evidence of poor funding decisions.

Assessment is therefore more meaningful at the portfolio level.

NIH could examine the distribution of investment across established, developing, and emerging research directions and how that distribution changes over time.

Potential portfolio-level indicators could include:

- concentration of funding within established research areas;
- proportion of funding supporting emerging or exploratory areas;
- entry of new investigators or disciplines into established research fields;
- funding for novel combinations of methods or disciplines;
- diversity of scientific approaches supported within a portfolio;
- changes in the distribution of funding as scientific fields mature;
- persistence of support for exploratory areas during periods of uncertainty;
- subsequent development of research communities around previously exploratory investments; and
- evidence that earlier exploratory investments created methods, resources, or capabilities subsequently used across NIH-supported science.

These measures could help NIH evaluate an important question that cannot be answered by examining individual grant productivity:

Is NIH maintaining a research portfolio with sufficient capacity for scientific exploration and responsible risk-taking?

Detect portfolio drift toward predictability

Portfolio analysis could also help identify risk drift.

Funding systems can gradually become more concentrated around established investigators, methods, topics, or scientific approaches even without an explicit decision to become more conservative.

Each individual funding decision may be scientifically defensible while the cumulative portfolio nevertheless becomes increasingly concentrated around areas with established evidence, established communities, and predictable outputs.

NIH could therefore examine changes in portfolio concentration and scientific novelty longitudinally.

For example: Portfolio at time 1 ➔ distribution across established and emerging areas ➔ subsequent funding decisions ➔ changing concentration of investment ➔ portfolio at time 2.

This would allow NIH to examine whether the agency, an institute, or a program is maintaining its intended balance between exploitation of established scientific opportunity and exploration of less certain directions.

Importantly, such analysis should not assume that a particular percentage of funding to emerging areas is inherently optimal. Appropriate risk tolerance will vary across institutes, programs, scientific opportunities, and public-health needs.

The objective is to make the portfolio's risk characteristics visible enough to be managed intentionally.

Learn from unsuccessful high-risk research

NIH should also distinguish between scientific failure and unproductive investment.

A high-risk project that does not confirm its original hypothesis may nevertheless produce important negative findings, eliminate an unproductive scientific direction, generate a useful method or dataset, reveal methodological limitations, or create knowledge that informs subsequent research.

If high-risk programs are assessed primarily according to whether projects achieve their original anticipated outcomes, researchers will have a rational incentive to propose projects whose outcomes are more predictable.

NIH should therefore recognize informative failure as a legitimate potential outcome of exploratory research, provided the work was rigorous and the resulting knowledge is made available to the scientific community.

This is also why transparent reporting of negative and null results, addressed elsewhere in this RFI, is particularly important for high-risk research.

Protect unconventional combinations of expertise

Transformative research may also arise at the boundaries between established disciplines.

Connected research information can help identify unusual combinations of expertise, methods, concepts, or research communities that differ from established collaboration patterns.

NIH could examine whether funding mechanisms intended to support innovation are actually enabling these unconventional combinations or predominantly supporting teams whose structures resemble already successful research networks.

Again, unusual combinations should not automatically be rewarded. Novelty without scientific rationale has little value.

But the ability to observe disciplinary and methodological combinations provides NIH with another way to assess whether programs intended to encourage convergence and exploration are actually broadening the scientific landscape.

Build on existing evidence infrastructure

Many of the signals required for this type of analysis already exist within research information systems.

Large-scale connected evidence across grants, publications, researchers, organizations, datasets, software, methods, patents, clinical research, and other outputs can support longitudinal analysis of emerging fields, knowledge diffusion, interdisciplinary convergence, and funding concentration.

Natural language processing and network analysis can further help identify changes in concepts and relationships that are difficult to detect through traditional publication and citation measures alone.

NIH could use this existing evidence base to test and validate horizon-scanning and portfolio-risk indicators retrospectively before applying them prospectively.

For example, NIH could examine historical research areas now recognized as transformative and ask: **Would the proposed indicators have detected their emergence before conventional metrics did?**

Similarly, NIH could examine previous high-risk funding portfolios to determine whether proposed measures meaningfully distinguish exploratory investment from established research.

This type of retrospective validation would be important before incorporating new indicators into funding strategy.

Protect the conditions for discovery

Ultimately, foundational scientific exploration presents a different assessment problem from research intended to produce predictable near-term outcomes.

The objective should not be to develop a metric that predicts which high-risk project will succeed. Doing so would risk eliminating the uncertainty that makes the research high-risk in the first place.

Instead, NIH should ask:

- Is exploratory research creating new scientific possibilities?
- Can NIH identify emerging directions early enough to investigate them?

- Is the agency maintaining sufficient diversity of scientific approaches?
- Are programs intended to support high-risk research actually funding research that differs meaningfully from established patterns?
- Is NIH's portfolio gradually becoming more conservative without intending to do so?
- Does the system recognize rigorous, informative failure as part of scientific exploration?

A portfolio that cannot see its own risk profile cannot knowingly protect it.

By combining longitudinal research information, horizon scanning, portfolio analysis, and expert scientific judgment, NIH can make the conditions for exploration more visible without attempting to make uncertain science artificially predictable. This would help preserve the scientific risk, curiosity, and methodological innovation from which future paradigm-shifting discoveries are most likely to emerge.

• **Public Impact:** ***NIH seeks approaches for assessing and recognizing the broader public impact of biomedical research, including contributions to health outcomes, economic growth, clinical practice, public trust, accessibility, and societal benefit.***

Digital Science Response:

Public impact is too often measured by visibility rather than uptake. Media attention is not the same as influence on clinical practice or policy. NIH's assessment framework should draw that distinction explicitly.

Scientific knowledge creates public value through diverse and interconnected pathways, including clinical practice, public health, regulatory science, public policy, education, industrial innovation, healthcare delivery, accessibility of knowledge, and public engagement. These pathways often interact, reinforce one another, and develop over extended periods.

NIH should therefore assess public impact as a pathway from attention to uptake, application, and ultimately societal benefit, rather than attempting to represent it through a single impact metric.

Distinguish attention, uptake, application, and outcome

Different indicators provide evidence of fundamentally different things.

Attention indicates that research has been noticed or discussed.

Uptake indicates that research has been incorporated into a professional, scientific, policy, clinical, educational, or other decision-making context.

Application indicates that knowledge has influenced a practice, intervention, technology, policy, guideline, or other activity.

Outcome indicates evidence of resulting health, economic, accessibility, or broader societal benefit.

These should not be treated as equivalent.

For example: NIH-supported research → publication → clinical guideline citation → adoption in clinical practice → change in patient care → improved health outcome.

Similarly: NIH-supported research → evidence base → public-health guidance → implementation → population-level intervention → measurable health benefit.

Or: NIH-supported research → enabling discovery → technology development → commercial adoption → economic activity → broader health or societal benefit.

A media mention may provide evidence of public attention. A citation in a clinical guideline provides stronger evidence that research has entered professional decision-making. Demonstrated implementation of that guideline represents a further stage of impact. Evidence that implementation contributed to improved outcomes represents something different again.

NIH should preserve these distinctions rather than collapsing them into a single measure of "impact."

Measure multiple pathways to public value

Because NIH supports an extraordinarily diverse biomedical research portfolio, no single pathway will adequately describe public impact.

Potential measurable indicators could include:

Clinical impact

- incorporation of NIH-supported research into clinical guidelines or standards of care;
- citations in clinical decision-support resources;
- progression of research into clinical studies or trials;
- adoption of evidence-based interventions within healthcare systems;
- development or adoption of diagnostics, therapeutics, devices, software, or other clinical tools;
- changes in clinical practice associated with research findings; and
- where evidence permits, contribution to improved patient outcomes.

Public-health and policy impact

- incorporation into public-health guidance;
- citation or use in federal, state, local, or international policy documents;
- incorporation into regulatory science or regulatory decision-making;
- contribution to standards or technical guidance;

- adoption within public-health programs or interventions; and
- evidence of changes in population-health practice associated with the research.

Economic and innovation impact

- patents and licensing associated with NIH-supported research;
- company formation and entrepreneurial activity;
- industrial research partnerships;
- subsequent private-sector investment;
- development of products, technologies, services, or research tools;
- employment or economic activity associated with NIH-supported innovation; and
- downstream commercial use of NIH-supported knowledge or resources.

Accessibility and knowledge diffusion

- public accessibility of NIH-supported research outputs;
- availability and reuse of datasets, software, protocols, models, and other research resources;
- use of research in educational or professional training materials;
- adoption of research resources by communities beyond the originating investigators;
- accessibility of findings to patients, practitioners, policymakers, and other intended audiences; and
- sustained availability of publicly funded research resources.

Public engagement and trust

- evidence of responsible communication of scientific findings, including uncertainty and limitations;
- engagement with patients, communities, and relevant public stakeholders;
- use of NIH-supported evidence in trusted public-information resources;
- transparent correction or updating of scientific findings as evidence changes; and
- where methodologically defensible, changes in understanding or confidence associated with sustained engagement.

These categories should remain distinct. A research project should not be expected to demonstrate impact across all of them.

Measure contribution, not simplistic attribution

NIH should distinguish between attribution and contribution when assessing public impact.

Most improvements in health and society cannot credibly be attributed to a single publication, investigator, grant, or institution. A change in clinical practice may depend upon decades of fundamental research, validation studies, clinical trials, systematic reviews, professional guidelines, healthcare implementation, and public-health activity.

The appropriate question is therefore often not: "Did this NIH award cause this societal outcome?" but: "What role did NIH-supported research play in the pathway that contributed to this outcome?"

Connected research evidence can help reconstruct these pathways without implying causality that the evidence cannot support.

For example: multiple NIH investments ➜ body of evidence ➜ clinical synthesis ➜ professional guideline ➜ healthcare implementation ➜ patient benefit.

This provides a more scientifically defensible account of public impact while recognizing the cumulative nature of biomedical progress.

Trace public impact longitudinally

Public impact frequently occurs years or decades after the original research is funded.

Assessment should therefore connect evidence across longer timescales rather than requiring investigators to demonstrate societal impact within the period of an individual award.

Persistent identifiers and connected research information increasingly make it possible to link grants, publications, datasets, software, patents, clinical trials, policy documents, clinical guidelines, researchers, and organizations over time.

This creates an opportunity for NIH to examine impact pathways across its portfolio.

Rather than relying predominantly on individual success stories, NIH could ask:

- Which NIH-supported research contributes to clinical guidelines?
- Which research areas are subsequently reflected in public-health or regulatory decision-making?
- Which NIH investments contribute to technologies or industries?
- Which datasets, software, and research resources continue to create public value after the originating grant concludes?
- How long does it typically take different forms of NIH-supported research to move from discovery to uptake and application?
- Where does research appear to reach an uptake stage but fail to progress toward implementation?

This would provide a more systematic understanding of the return generated by NIH investment.

Assess impact at the portfolio level

Portfolio-level assessment is particularly important for public impact.

A single project may contribute only one component of a much larger pathway. At the level of an institute, disease area, program, or NIH as a whole, however, the cumulative relationship between federal investment and downstream activity becomes more visible.

NIH could therefore develop public-impact profiles for different portfolios rather than attempting to reduce all impact to one score.

For example, one portfolio may demonstrate substantial influence on clinical practice. Another may primarily create foundational resources used throughout biomedical research. Another may generate significant economic and industrial activity. Another may contribute heavily to public-health policy.

These are different forms of mission value, not necessarily different levels of value.

This approach would also enable NIH to demonstrate impact consistently across Institutes and Centers and research areas rather than depending primarily on highly visible individual examples.

Treat public trust as an outcome requiring particular care

Public trust warrants special treatment because it is both central to NIH's mission and particularly difficult to measure.

NIH has explicitly connected rigor and reproducibility with strengthening confidence and trust in biomedical research.

However, public trust should not be reduced to popularity, positive sentiment, media volume, or social-media engagement.

Trustworthy science and popular science are not necessarily the same thing.

More defensible indicators may include evidence of:

- transparent communication of methods, limitations, and uncertainty;
- accessibility of underlying research and supporting evidence;
- correction of the scientific record when findings change;
- responsible communication of negative or conflicting findings;
- meaningful engagement with affected communities;
- accessibility of research findings to intended audiences; and
- demonstrable use of NIH-supported evidence by trusted clinical, public-health, and professional institutions.

Where surveys or public-opinion measures are used, they should be interpreted carefully and should not create incentives for researchers or NIH to optimize scientific communication for popularity rather than accuracy.

NIH's own current replication and reproducibility efforts recognize that rigorous, transparent, reliable science is foundational to public confidence. Public-impact assessment should reinforce that relationship.

Distinguish public communication from public impact

Media, news, online attention, and other public-facing sources can provide useful evidence, but they should be interpreted according to what they actually measure.

Media attention can identify research entering public discourse.

It does not establish that the research changed policy, clinical practice, health outcomes, or public understanding.

NIH could therefore use public-attention indicators as pathway signals rather than endpoint measures.

For example: “research ➜ public attention ➜ stakeholder engagement ➜ policy consideration ➜ policy adoption” may represent a legitimate pathway worth examining.

But attention alone should not be rewarded as equivalent to demonstrated uptake.

This distinction would also reduce incentives for sensationalism and help ensure that responsible communication of uncertainty remains compatible with NIH's impact framework.

Identify where evidence fails to become impact

One of the most valuable applications of a connected public-impact framework may be identifying translation and implementation gaps.

NIH traditionally asks whether research generated important knowledge. Connected evidence could increasingly help it ask what happened next.

For example:

- strong scientific evidence ➜ no guideline uptake
- guideline incorporation ➜ limited clinical adoption
- effective intervention ➜ limited accessibility
- valuable public-health evidence ➜ inconsistent implementation

These gaps matter because generating knowledge is only one part of delivering value to the American public.

NIH could use portfolio-level analysis to identify areas where strong research evidence exists but downstream uptake appears limited, providing an evidence base for considering whether additional implementation research, dissemination, partnerships, accessibility efforts, or other interventions may be warranted.

This would transform public-impact assessment from a retrospective reporting exercise into a tool for identifying where additional NIH action could help research generate greater public value.

Build upon existing evidence infrastructure

Many components required for this framework can already be observed through existing research information infrastructure.

Research can increasingly be connected across grants, publications, clinical trials, patents, policy documents, clinical guidelines, researchers, institutions, and public-facing sources. Combining these evidence streams provides a practical starting point for reconstructing pathways from federal investment toward downstream uptake.

Digital Science's experience working with research funders and institutions demonstrates the feasibility of this type of cross-source analysis at portfolio scale. Connected research information can link funding and scholarly outputs with downstream evidence such as patents, clinical activity, policy references, and public attention, helping organizations move beyond individual impact anecdotes toward systematic evidence of where research is being taken up and used.

This type of infrastructure could provide NIH with an existing evidence base for testing and validating public-impact indicators across different Institutes, Centers, disease areas, disciplines, and timescales rather than requiring a new reporting system to be created before assessment can begin.

Avoid creating an "impact burden"

NIH should be cautious about requiring every investigator to produce an extensive narrative demonstrating public impact.

Such an approach could create substantial administrative burden, advantage investigators with access to professional communications or research-impact staff, and encourage overstatement of downstream effects.

Where possible, NIH should derive evidence from existing research information, persistent identifiers, administrative systems, and downstream sources and allow investigators to

provide contextual or qualitative evidence where automated information is incomplete.

Assessment should also recognize differences among disciplines, institution types, career stages, and research objectives. Early-career researchers and investigators conducting foundational science should not be disadvantaged because the societal effects of their work may not become visible for many years.

Measure value to the public, not simply visibility

Ultimately, public impact assessment should help NIH answer a straightforward but difficult question: What happened because the knowledge NIH supported entered the world?

Answering that question requires more than counting publications, citations, patents, news stories, or social-media mentions.

NIH should examine whether research was noticed, taken up, applied, and ultimately associated with meaningful health, economic, clinical, accessibility, or societal benefit, while recognizing that different forms of research travel through different pathways and on different timescales.

Public trust in NIH-funded science also depends upon NIH being able to demonstrate these contributions consistently, not only through a small number of highly visible success stories, but across the breadth of its research portfolio.

By connecting evidence from funding, scholarship, clinical practice, policy, innovation, public health, and public engagement, NIH can develop a more rigorous account of the value generated by federal research investment: one that distinguishes attention from impact, contribution from attribution, and anecdote from systematic evidence.

• **Other Areas:**

Digital Science Response:

One overarching opportunity cuts across each of the areas addressed in this RFI: the need to shift from metric-based assessment toward evidence-based assessment.

For many decades, research evaluation has relied heavily on a relatively small number of publication- and citation-based indicators because these represented some of the most consistently available evidence of scientific activity. The research landscape has changed fundamentally.

Contemporary biomedical research now generates rich, interconnected evidence spanning grants, publications, datasets, software, protocols, methods, clinical trials, patents, policy documents, clinical guidelines, contributor roles, researchers,

organizations, and collaborative relationships.

The opportunity for NIH is therefore not to identify a new metric to replace publication counts or citations. It is to integrate complementary evidence streams to develop a more complete understanding of how scientific knowledge is generated, validated, shared, reused, extended, translated, and ultimately contributes to public benefit.

Move from counting outputs to understanding pathways

Across the topics addressed in this RFI, a common principle emerges: individual outputs provide only a partial view of scientific contribution.

NIH increasingly has the opportunity to understand the pathways connecting its investments to subsequent scientific activity and value.

For example:

Rigor and reproducibility: research → transparency → reproducibility → independent verification → replication → more reliable knowledge

Data, software, and models: creation → sharing → stewardship → discovery → reuse → new research and scientific value

Training and mentorship: training investment → mentorship → researcher development → continued scientific contribution → development of subsequent researchers

Collaboration: investment → complementary expertise → scientific integration → shared outputs and capabilities → durable research networks → downstream value

Entrepreneurship and translation: fundamental discovery → validation → translational development → cross-sector engagement → application → adoption

Foundational scientific exploration: exploratory investment → new concept, method, resource, or capability → diffusion → new scientific directions → subsequent discovery

Public impact: research → attention → uptake → application → health, economic, clinical, or societal benefit

These pathways are neither universal nor linear, and they should not become rigid models against which every research project is evaluated. Their value is conceptual: they illustrate why assessment focused predominantly on individual outputs can miss much of the value created by federal research investment.

NIH should increasingly ask not only "What was produced?" but "What did it enable?"

Assess contribution without overstating attribution

A second principle running across these topics is the importance of distinguishing contribution from attribution.

Biomedical progress is cumulative. Important discoveries frequently depend upon decades of foundational research, multiple investigators and institutions, shared datasets and infrastructure, methodological advances, validation studies, collaborations, funding programs, and subsequent translational activity.

Assessment systems should resist the temptation to attribute complex outcomes to individual publications, grants, or investigators simply because those relationships are easiest to measure.

Connected evidence instead provides an opportunity to identify credible contributions to longer scientific pathways.

This distinction is particularly important when assessing societal impact. NIH should be able to demonstrate that federally funded research contributed to advances in health, clinical practice, innovation, policy, and economic activity without implying causal attribution where the available evidence cannot support it.

Recognize the scientific contributions that conventional metrics miss

Scientific progress emerges through the interaction of people, infrastructure, methods, data, software, organizations, and institutions over extended periods.

Many activities that make this system function remain poorly represented in conventional assessment, including:

- stewardship of shared datasets and research resources;
- development and maintenance of scientific software;
- methodological and statistical contributions;
- creation and maintenance of research infrastructure;
- mentorship and supervision;
- peer review;
- replication and validation;
- development of standards and protocols;
- technical and collaborative leadership; and
- community building and scientific stewardship.

These activities should not automatically receive credit simply because they can be documented. Rather, NIH should develop mechanisms for recognizing when they make meaningful contributions to research quality, capability, efficiency, reliability, or impact.

Persistent identifiers, structured contributor roles, interoperable metadata, and connected research information increasingly make these contributions observable.

The challenge is to convert that increased visibility into responsible evidence for assessment, rather than simply creating additional things to count.

Treat research assessment as a scientific endeavor

NIH should also treat research assessment itself as an object of scientific investigation.

Any indicator creates incentives. Poorly designed indicators can change researcher behavior in ways that undermine the objective the indicator was intended to support.

New assessment approaches should therefore be treated as hypotheses to be tested rather than metrics to be institutionalized immediately.

Candidate indicators should be evaluated for:

- construct validity: whether the indicator actually measures the contribution it is intended to represent;
- robustness across disciplines, research types, institutions, and career stages;
- sensitivity to differences in scientific timescale;
- completeness and quality of the underlying data;
- susceptibility to gaming or strategic behavior;
- potential inequities or structural biases;
- administrative burden;
- unintended behavioral consequences; and
- incremental value beyond information already available to expert reviewers and program staff.

Where possible, NIH should test proposed indicators retrospectively before using them prospectively.

For example, NIH could ask whether proposed indicators of emerging science would have identified historically important research directions before conventional metrics did; whether proposed translational indicators reliably distinguish meaningful progression from incidental activity; or whether proposed mentorship indicators accurately reflect successful researcher development across different career pathways.

This would allow NIH to validate the assessment system before attaching significant incentives to it.

Use indicators as evidence, not answers

No quantitative indicator should substitute for scientific judgment.

Connected evidence, natural language processing, network analysis, persistent identifiers,

and other analytical approaches can make patterns visible that would be impossible for an individual reviewer or program officer to observe across an entire research system.

Their purpose should be to improve the evidence available to decision-makers, not to automate decisions that require scientific judgment.

This distinction is particularly important as the volume and sophistication of research information increase.

The appropriate model is: data ➜ evidence ➜ interpretation ➜ expert judgment ➜ decision rather than: data ➜ score ➜ decision.

NIH should be cautious about composite scores that collapse fundamentally different dimensions of scientific contribution into a single ranking.

A researcher, project, program, or portfolio can be strong in one dimension and intentionally different in another. Foundational research should not be penalized because it lacks immediate translational impact. A high-value dataset should not be judged as though it were a publication. A collaborative specialist should not be assessed according to PI-oriented measures. A high-risk research portfolio should not be expected to produce the same success pattern as a program designed around predictable deliverables.

Evidence-based assessment should preserve those distinctions.

Evaluate portfolios as well as people

Many of the questions raised by this RFI cannot be answered adequately at the level of an individual investigator or award.

NIH should therefore complement researcher- and project-level assessment with portfolio-level assessment.

At portfolio scale, NIH can examine questions such as:

- Are investments producing reusable research resources?
- Are training programs generating durable scientific capacity?
- Are collaborative programs producing genuinely integrated research networks?
- Where are translational pathways progressing or stalling?
- Is strong scientific evidence reaching clinical practice and public-health application?
- Are emerging scientific areas receiving appropriate attention?
- Is the balance between established and exploratory research changing over time?
- Which NIH investments continue generating value long after the originating awards have ended?

This changes assessment from an exercise focused primarily on evaluating researchers into a capability NIH can also use to evaluate and improve its own funding strategy.

That distinction is important. Responsible research assessment should not only ask whether researchers are producing the right behaviors and outcomes. It should also allow the funding agency to ask whether its own policies, programs, incentives, and portfolio decisions are producing the research ecosystem it intends to create.

Build upon shared infrastructure and community standards

Continued investment in open scholarly infrastructure, persistent identifiers, trusted repositories, and community standards remains essential.

Digital Science has participated in this work directly, including through NIH's Generalist Repository Ecosystem Initiative (GREI). Initiatives of this kind demonstrate the value of interoperable infrastructure that enables research outputs to remain discoverable, accessible, connected, and reusable beyond the systems or projects in which they originated.

Shared standards such as DOIs, ORCID iDs, ROR identifiers, RRIDs, grant identifiers, structured contributor roles, and interoperable metadata improve not only assessment but also reproducibility, transparency, collaboration, data stewardship, and research efficiency.

NIH should continue supporting this foundational infrastructure while taking advantage of the broader public, community, institutional, and commercial research-information ecosystem that has developed around it.

Where evidence can be obtained reliably from existing infrastructure, researchers should not be required to report it again.

The goal should be a richer evidence base with a lower reporting burden, not a larger assessment bureaucracy.

Recognize that research is an ecosystem

The questions in this RFI span researchers, funders, institutions, publishers, repositories, healthcare organizations, government, industry, and the public because modern biomedical research operates across all of them.

Assessment frameworks designed from the perspective of any one participant risk capturing only part of that system.

Digital Science's perspective on these questions has been shaped by more than two decades of working across this research ecosystem—including with researchers, universities and research institutions, publishers, research funders, governments, and commercial organizations, including pharmaceutical and biotechnology companies involved in translating scientific discovery toward application.

That cross-ecosystem perspective informs a central theme of this response: scientific

value frequently becomes visible in the connections between systems, organizations, outputs, and stages of the research lifecycle, rather than within any single source of information.

Connected research infrastructure can increasingly make those relationships observable at scale. But infrastructure alone is not an assessment framework. The evidence it provides must be interpreted in the context of scientific purpose, disciplinary differences, timescale, uncertainty, and the intended mission of the research.

From metrics to evidence

The challenge facing research assessment is no longer simply one of measurement. It is increasingly one of interpretation.

As the evidence describing the research ecosystem becomes richer and more connected, NIH should resist replacing one dominant metric with another.

Instead, the opportunity is to develop an assessment framework that asks:

- What contribution are we trying to understand?
- What evidence would credibly demonstrate that contribution?
- Over what timescale should it be observed?
- What contextual information is required to interpret it?
- What behaviors might measuring it incentivize?

What can quantitative evidence tell us, and what still requires expert scientific judgment?

Across the areas addressed in this RFI, this approach would allow NIH to move from counting isolated outputs toward understanding the pathways through which research creates scientific and public value.

The resulting framework would not eliminate metrics. It would put them in their proper role: as individual pieces of evidence within a broader, scientifically grounded assessment system.

That distinction is essential.

NIH does not need a new definition of scientific success expressed through a different score. It needs an evidence framework capable of recognizing the many ways rigorous, collaborative, exploratory, reusable, translational, and publicly valuable science contributes to its mission, and capable of evolving as science itself changes.

186. STM (The International Association

I am responding: On behalf of an organization

Name: Caroline Sutton

Name of Organization: STM (The International Association

Type of Organization: Professional Organization/Association

Role: Organizational Official

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: STM welcomes NIH's efforts to strengthen rigor, reproducibility, and replication across the biomedical research enterprise. These goals are central to public trust in science and to NIH's mission of generating knowledge that enhances health, lengthens life, and reduces illness and disability. NIH's Replication and Reproducibility Initiative recognizes the need to elevate replication and reproducibility studies as foundational to "gold standard science" and identifies data standardization, public availability of research findings, independent replication research, and sustained infrastructure as part of NIH's approach.

These goals also mirror concrete efforts and contributions by STM and its member publishers across the research ecosystem. For example, STM's research integrity work supports editorial standards, integrity checks, stewardship of the Version of Record, post-publication corrections and retractions, and transparent communication when concerns arise. STM's Integrity Hub provides a shared infrastructure to help publishers detect paper-mill activity, duplicate submissions, references to retracted work, and other research-integrity risks and ensure this material does not enter the scientific record. STM's research data initiatives catalyze action to advance FAIR data practices by promoting data availability policies, links between articles and datasets, persistent identifiers, community metadata standards, repository workflows, and best practices for data citation and reuse. These publisher-led activities are complemented by third-party frameworks such as COPE guidance on publication ethics and stewardship of the scholarly record, the Center for Open Science TOP Guidelines on transparency and verifiability, and responsible research-assessment initiatives such as DORA and CoARA. Together, these efforts demonstrate that reproducibility depends not only on actions by individual researchers, but also on the shared systems, standards, editorial practices, and infrastructure that make research findings reliable, discoverable, correctable, reusable, and trustworthy. They also demonstrate that publications are a key part of this system.

STM encourages NIH to adopt a broad, evidence-based framework for recognizing and supporting activities that improve the reliability, transparency, and trustworthiness of biomedical research. Potential indicators include:

• Publication of replication studies, negative results, null findings, and confirmatory research. Many publishers provide options to support the communication of such reports.

• Use of preregistration, registered reports, reporting guidelines, and other transparency-enhancing practices. Such practices are increasingly supported and enabled by publishers.

• Availability of underlying data, code, protocols, and materials, where appropriate. STM, in coordination with others in the research community, have provided best practices for supporting code and data

sharing.
• Adherence to field-specific reporting standards and methodological best practices. These are often communicated and stewarded by journal communities sustained by publishers.
• Reliance on the integrity-enhancing practices of publishers, including peer review, editorial assessment, research integrity screening, corrections, retractions, and post-publication stewardship of the scientific record.
• Documented efforts to reproduce, validate, or extend prior research findings, which could be included in journal articles or elsewhere.

NIH should be careful not to replace one narrow assessment framework with another, nor should NIH ignore the importance of publications in achieving NIH's core mission of supporting high-quality research and ensuring its impact. While overreliance on publication counts, citation metrics, or other individual-level indicators can distort incentives, under reliance on the scholarly record as an integral contributor to the impact of research would be inappropriate.

With both traditional and alternative metrics, care must be taken to ensure that any metric is not overly rigid or treated as compliance targets rather than contextual evidence of scientific contribution. As noted in DORA's guidance on responsible use of quantitative indicators, indicators are inherently reductive and require careful contextualization when used in research assessment. CoARA similarly seeks to reform assessment systems, promoting a broader understanding of research quality and contribution, but not ignoring the importance of publications as expressions of research quality and impact.

Integrity depends on coordinated action across the research ecosystem, with publishers, funders, institutions, policymakers, and researchers fulfilling distinct but interconnected responsibilities. Accordingly, NIH should recognize not only researchers who produce reproducible findings, but also contributions that strengthen the systems through which reproducible science is evaluated, communicated, corrected, preserved, and reused. This is particularly important because replication and reproducibility depend on access to reliable, well-documented, and discoverable research outputs. Research cannot be reproduced or validated if findings, methods, data, and related materials are not effectively communicated and maintained. This again emphasizes the importance of publication to achieving NIH's core goals.

NIH should also account for disciplinary variation. Replication may look different in clinical research, laboratory science, computational biology, population health, epidemiology, and translational research. A flexible framework that recognizes field-specific norms and methodological constraints will be more effective than a uniform checklist.

STM and its members would welcome opportunities to collaborate with NIH on incentives and infrastructure that achieve our shared goals of advancing trusted research.

2. Data, Software, and Model Sharing: STM supports NIH's efforts to incentivize and reward responsible sharing of data, software, models, and related research objects. Effective sharing can accelerate discovery, enable validation, promote reuse, and increase the return on public investment in biomedical research. NIH's Public Access materials state that access to NIH-supported research can accelerate research, generate higher quality scientific results, encourage greater scientific integrity, and enable future inquiry, discovery, and translation. STM agrees, and this is a key focus of STM's research data initiatives and many of our members' commitments to support data sharing, linking, citation, and use. As NIH seeks to incentivize and reward these activities, it should again take a comprehensive approach, incentivizing not just sharing but appropriate sharing, citation, linking, and use. The STM, DataCite, and Crossref's "12 Best Practices for Research Data Sharing" provides a roadmap for assessment of whether data is shared in ways that make them findable, accessible, interoperable, reusable, and appropriately stewarded. Potential indicators include:

- Deposition of datasets, software, models, protocols, and related materials in trusted repositories and linking to the primary literature.
- Use of persistent identifiers, metadata, and community standards to improve findability and reuse.
- Evidence that shared resources have been accessed, reused, cited, and incorporated into downstream research.
- Clear documentation, versioning, licensing, and maintenance practices.
- Use of appropriate safeguards for privacy, confidentiality, security, intellectual property, and ethical obligations.
- Contributions to infrastructure, standards, tools, and workflows that make data, software, and model sharing more reliable and useful.

NIH should avoid incentives that reward superficial compliance. For example, measuring only the number of datasets deposited could encourage quantity over quality. A dataset that is incomplete, poorly documented, difficult to access, unconnected from scholarly literature, or not maintained may do little to advance scientific impact. NIH should instead encourage meaningful sharing that supports validation, reuse, and long-term stewardship.
NIH should also recognize that not all data, models, or software can or should be shared in the same manner. Legal, ethical, privacy, security, proprietary, and participant-protection considerations may limit what can be made publicly available. Researchers should not be penalized when they apply appropriate protections or when responsible sharing requires controlled access rather than unrestricted access.
Scholarly publishers increasingly support these goals through data availability policies, repository integrations, links between articles and datasets, persistent identifiers, metadata improvement, software citation practices, reporting standards, and editorial checks. These practices help connect publications to the broader research objects that underlie them, making research more transparent, reproducible, and reusable.
STM's Research Data Program (started in 2020) helped some publishers implement these practices and still provides guidance to promote the sharing, linking, and citation of research data alongside scholarly articles. STM and its members heavily contributed to the development of the Scholix framework for linking publications with datasets by the Research Data Alliance (RDA) and continues to champion data linking and citation to ensure findability and utilization of research data. STM and its members are also

coordinating with related initiatives, such as the State of Open Data project, which tracks the evolution of open science practices globally.

As it considers changes to assessing research, NIH should consider how its assessment framework and policies align with its public access and metadata initiatives. NIH has stated that its efforts to increase public access are intended to make it easier for researchers, clinicians, students, and the public to find and use research results, including through metadata and persistent identifiers (PIDs). Publishers are critical to ensuring that articles and data related to NIH research are reliable, usable, findable, and preserved, including through peer review, editorial assessment, research integrity checks, transparency standards, corrections and retractions, metadata enhancement, PIDs, preservation, and maintenance of the Version of Record. It is therefore critical that NIH policy continue to ensure support for the publishing enterprise as well as assessment of data, software, and model sharing: impact depends not only on availability, but on usability, discoverability, integrity, and stewardship.

STM is developing voluntary recommendations to help journals and publishers clarify data sharing guidance for medical and health science researchers, where generic data sharing policies may be insufficient because of privacy, regulation, and ethics considerations. These recommendations are expected to be released later this year. STM and its members would welcome additional discussion on how we can support NIH's efforts to incentivize and reward these activities in line with our shared commitment to increase the impact of NIH-funded research on public health and improve the return on investments, particularly in the health and medical space.

7. Public Impact: STM agrees that public impact is a critical dimension of scientific success. NIH-funded research generates public value when it contributes to better health outcomes, improved clinical practice, innovation, economic growth, public trust, workforce development, and broader societal benefit. However, public impact should be assessed carefully, over appropriate time horizons, and with recognition that many important discoveries produce benefits only after years of cumulative research, validation, dissemination, and translation.

NIH should explicitly recognize the role of trusted scholarly communication in enabling public impact. Scientific discoveries produce public benefit only when they can be found, evaluated, trusted, corrected when necessary, and reused. Peer-reviewed publication provides an essential mechanism for making biomedical knowledge visible, scrutinized, structured, preserved, and connected to the broader scientific record.

NIH's own public access policies strongly support this point. In its Public Access Policy, NIH states that

increasing access to publications resulting from NIH funding offers benefits to the scientific community and the public, including patients, families, healthcare providers, researchers, students, and members of the public. NIH's Office of Science Policy adds that public access can accelerate research, generate higher quality scientific results, encourage greater scientific integrity, and enable future inquiry, discovery, and translation. These statements reflect NIH's longstanding recognition that publication and dissemination are not peripheral to impact; they are core pathways through which research investments generate public benefit.

The peer-reviewed Version of Record is especially important for public impact. It provides a stable, curated, and citable record of research findings; links findings to underlying evidence; supports metadata and indexing; enables discovery through trusted databases; and provides mechanisms for correction, expression of concern, and retraction when needed. These functions are essential to public trust and to the responsible use of biomedical research in clinical, policy, and innovation contexts.

Public impact should therefore be measured not only by immediate translational outcomes, commercial products, or media attention, but also by contributions to the trusted knowledge infrastructure that makes later public benefits possible. Articles reporting on basic research, replication studies, negative results, data resources, methods papers, standards development, and editorial or peer-review contributions may all generate significant public value even when their effects are indirect or long-term.

NIH should be particularly cautious about short-term indicators of public impact. Measures such as media coverage, downloads, social media attention, or public engagement may provide useful signals in some contexts, but they should not be treated as proxies for scientific quality, reliability, or health benefit. Public impact should be assessed through a portfolio of evidence that recognizes both immediate and long-term contributions.

Finally, NIH should recognize that the public benefits described above depend on sustained and appropriate support for the publishing enterprise. Peer review management, editorial assessment, research-integrity screening, metadata creation, indexing, preservation, data and article linking, public access workflows, corrections, retractions, and long-term stewardship of the Version of Record all require ongoing investment. Publication charges, subscriptions, and other sustainable publishing models are mechanisms through which the research ecosystem supports these services and infrastructure. If NIH wishes to maximize the public impact of NIH-funded research, it should avoid policies or assessment frameworks that inadvertently undermine the financial sustainability of trusted scholarly communication and should instead recognize reasonable publishing costs as part of the infrastructure required to make biomedical knowledge reliable, discoverable, reusable, and beneficial to the public.

8. Other Areas: STM encourages NIH to ensure that any future framework for measuring scientific impact explicitly recognizes publication and dissemination as fundamental components of the research process and as essential pathways for achieving NIH's mission. Fundamentally, NIH's mission is not accomplished when an experiment is completed. It is advanced when knowledge generated through

NIH-supported research can be evaluated, trusted, disseminated, replicated, translated, and ultimately used to improve health. Publication is one of the central mechanisms through which that process occurs. STM therefore urges NIH to recognize that the Version of Record, robust peer review, and ongoing integrity maintenance are essential to NIH's research priorities and to maximizing the return on NIH's scientific investments and to explicitly affirm that dissemination through trusted scholarly communication channels advances NIH's core mission, and provide appropriate support for those activities.

Several recent NIH statements and RFIs, including this one, appear to distinguish between conducting research and communicating research outcomes. STM believes that distinction should be approached with caution. While publication is a private sector activity that is not directly funded through core research activities, biomedical research does not achieve its full value at the point of discovery alone. It achieves value when findings are evaluated, communicated, preserved, disseminated, made discoverable, corrected when necessary, and used by others to advance science, clinical practice, innovation, and public health.

Publication is therefore not merely an administrative byproduct of research or a narrow productivity measure. It is one of the principal mechanisms through which scientific knowledge enters the research ecosystem. Research findings that are not effectively communicated cannot be scrutinized, replicated, synthesized, incorporated into guidelines, translated into products or practices, used by clinicians, or accessed by the public.

NIH's own policies support this conclusion. NIH's Public Access Policy ensures that the public has access to published results of NIH-funded research in PubMed Central. NIH's public access materials state that access to publications resulting from NIH-funded research benefits the scientific community and the public and supports patients, families, healthcare providers, researchers, students, and members of the public. NIH's Office of Science Policy further states that public access can accelerate research, generate higher quality scientific results, encourage greater scientific integrity, and enable future inquiry, discovery, and translation.

NIH's Replication and Reproducibility Initiative also recognizes the importance of making research findings freely and quickly available to the public as part of NIH's ongoing efforts to strengthen rigorous and reproducible science. This is because replication, validation, reuse, correction, and translation all depend on effective communication and preservation of research findings.

Accordingly, STM urges NIH not to interpret responsible research assessment reform as a reason to diminish the role of publication. Initiatives such as DORA and CoARA rightly caution against overreliance on publication counts, journal impact factors, and citation-based proxies. But these efforts do not imply that publication itself is unimportant. Rather, they support a more nuanced approach that assesses research and researchers based on the substance, reliability, transparency, openness, integrity, and societal value of their contributions. The appropriate conclusion is that assessment should recognize what high-quality publication and scholarly communication actually do: support peer review, editorial assessment, research integrity, discoverability, public access, metadata creation, preservation, correction, reuse, and long-term stewardship of the scientific record.

This point is also consistent with STM's recent submissions on federal research policy. STM has emphasized that research is not complete at the point of discovery; it achieves value only when findings are validated, communicated, and made accessible. In comments on NIH's strategic plan, STM has urged NIH to recognize that the Version of Record, robust peer review, and ongoing integrity maintenance are essential to NIH's research priorities and to maximizing the return on NIH's scientific investments.

STM is concerned that any policy framework suggesting publication does not advance NIH's core mission is inconsistent with NIH's own public access, reproducibility, metadata, and stewardship policies. Publication and dissemination are not separate from NIH's mission of improving health. They are among the principal mechanisms through which NIH-supported research becomes useful, trustworthy, accessible, and actionable.
In addition to recognizing the importance of publication to NIH's core mission, NIH should also ensure that policies related to allowable costs, research assessment, public access, and reproducibility are aligned. Specifically, NIH should continue to ensure that appropriate and sustained funding continues to be available for publishing costs and subscriptions as part of NIH grants. More information on these issues can be found in STM's previous submissions on these topics, which are linked below.

187. Medical Research Support

I am responding: On behalf of an organization

Name: EMİNE ARZU KANIK

Name of Organization: Medical Research Support

Type of Organization: Professional Organization/Association

Role: Institutional Review Oversight Committee Member

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: Rigor and Reproducibility — Proposed Response

Biomedical research needs a system in which rigor and reproducibility are assessed not only through what investigators plan to do, but through verifiable evidence generated across the entire research lifecycle. We therefore recommend that NIH explore a lifecycle-based framework that complements existing grant and publication assessment with structured, transparent, and time-bounded scientific evaluation.

One component of such a framework could be a Time-Bounded Open Scientific Review model. For appropriate studies, before data collection or analysis begins, a registered protocol could enter a defined 30–60 day review period. Qualified reviewers would provide structured assessments of the scientific rationale, study design, causal assumptions, potential sources of bias, sample-size justification, outcome definitions, confounding, missing-data strategies, statistical analysis plans, ethical considerations, feasibility, and plans for data, code, model, and metadata sharing.

Importantly, this process should not become a popularity-based voting system. Reviewers should provide structured scores accompanied by methodological justification, disclose relevant expertise and conflicts of interest, and remain accountable for the quality of their assessments. Investigators should have an opportunity to respond to the reviews, and the protocol should be revised through a transparent, time-stamped version history. The original protocol, reviewer comments, author responses, revisions, and documented reasons for accepting or declining substantive recommendations should become part of the scientific record.

This approach could create a measurable distinction between a research plan that merely states that rigorous methods will be used and a research project for which methodological rigor has been independently examined and improved before the study is conducted.

A second review point could occur when the study is completed and the manuscript is prepared. A time-bounded open review of the resulting research output could evaluate not only the findings but also adherence to the original protocol, deviations and their justification, analytical reproducibility, interpretation of uncertainty, completeness of reporting, and readiness for independent replication.

A particularly useful indicator would be registry-to-publication concordance. Where a study has a registered protocol, NIH could evaluate whether primary and secondary outcomes, sample-size targets, and major elements of the analysis plan correspond to the final publication, while recognizing and documenting legitimate amendments. This would provide a transparent measure of selective reporting and protocol adherence without assuming that every deviation represents misconduct.

NIH could also promote machine-readable implementation of established reporting frameworks such as CONSORT, STROBE, PRISMA, and ARRIVE, adapted to the relevant study design. Such structured checks could identify missing methodological information with relatively low administrative burden while leaving substantive scientific judgment to human experts.

Prioritizing Replication and Reproducibility

Not every published finding requires the same level of replication effort. NIH could develop a risk- and impact-informed framework for prioritizing replication and reproducibility studies.

Priority could be given to findings that:

have potentially substantial implications for clinical practice, public health, or policy;
depend heavily on a single study, laboratory, dataset, software pipeline, model, or population;
have conflicting results or substantial between-study heterogeneity;
have limited statistical power, imprecise effect estimates, or substantial analytical flexibility;
lack accessible data, code, software, models, metadata, or sufficient methodological documentation;
have not undergone independent computational reproduction or external validation;
show substantial unexplained deviations from prospectively specified protocols;
have achieved extensive citation or use despite limited independent validation; or
could cause substantial research waste or public harm if incorrect.

Replication should therefore be viewed not as a universal requirement applied identically to every study, but as a strategic allocation of scientific resources toward findings for which independent confirmation would provide the greatest value.

What Should Be Measured?

Potential indicators of rigor and reproducibility could include:

Documentation of the research protocol and statistical analysis plan before data collection or analysis, where appropriate.
Concordance between registered protocols and published outcomes and analyses.
Methodological completeness according to study-design-appropriate reporting standards.
Number, nature, and justification of substantive protocol deviations.
Quality of investigator responses to methodological review.
Documented improvements resulting from scientific review.
Availability and usability of data, metadata, analysis code, software, and models, subject to ethical and

legal constraints.
Successful independent computational reproduction.
Independent replication or external validation.
Transparent reporting of negative, inconclusive, and conflicting findings.
Correction and updating of the scientific record when errors are identified.
Reuse of research outputs by independent investigators.

These indicators should support scientific judgment rather than automatically determine scientific value. A single numerical score should not replace expert assessment, nor should researchers be incentivized to optimize metrics rather than improve science.

Incentives and Infrastructure

NIH could recognize rigorous research practices through citable records for protocols, methodological reviews, datasets, software, models, and replication studies. Contributions to independent replication, methodological review, research infrastructure, and correction of the scientific record should be visible in investigators' scientific portfolios and considered in progress reports and future funding decisions.

Incentives could also include protected time for replication, dedicated funding mechanisms, and infrastructure supporting version control, persistent identifiers, data and code sharing, computational environments, and transparent scientific review.

At the same time, safeguards are essential. The system should monitor reviewer burden, inter-reviewer agreement, conflicts of interest, retaliation or inappropriate review behavior, disadvantages affecting early-career researchers or smaller institutions, administrative burden, and potential gaming of the metrics.

A Practical Pilot

We recommend that NIH initially test such a framework through a voluntary, independently evaluated pilot involving a defined cohort of researchers across different NIH Institutes, disciplines, career stages, and institution types.

The pilot could compare conventional research workflows with a lifecycle-based framework incorporating protocol review, structured methodological assessment, transparent revision, reproducibility checks, and prioritized replication. Outcomes could include methodological quality, errors detected before publication, reporting completeness, researcher burden, reviewer burden, inter-reviewer agreement, time to scientific output, computational reproducibility, and subsequent independent validation.

MedicReS would be willing to contribute to such a pilot. For nearly two decades, MedicReS has worked on research methodology, biostatistics, research integrity, scientific reporting, and researcher development. Our experience with Good Medical Researcher training and the development of connected research-support environments such as EPICOSAI provides practical experience across

multiple stages of the research lifecycle.

We would be particularly interested in supporting a one-year pilot cohort at no commercial financial obligation to NIH or participating researchers, subject to mutually agreed governance, data protection, interoperability, and independent evaluation requirements. EPICOSAI should not be viewed as a proprietary requirement for such a system; rather, it could serve as one practical environment through which the proposed workflow could be tested.

We would welcome the opportunity to discuss the design of such a pilot with NIH in a scientific meeting or Zoom discussion, including cohort selection, evaluation metrics, governance, interoperability, and independent assessment of outcomes.

The ultimate objective should not be to create another publication metric. It should be to create a research environment in which rigor is visible, methodological improvement is documented, reproducibility is rewarded, replication is strategically supported, and the scientific record can continuously improve.

2. Data, Software, and Model Sharing: Data, Software, and Model Sharing — Proposed Response

NIH should broaden the concept of data, software, and model sharing from making research objects available to demonstrating that they are understandable, verifiable, reproducible, and reusable.

A dataset deposited in a repository, a software package made available on a public platform, or a model accompanied by a download link should not automatically be considered a successful scientific contribution. The more meaningful question is whether another research team can understand the research object, determine how it was generated, verify its intended use, reproduce relevant analyses, and build upon it.

We therefore recommend that NIH develop a Research Object Impact Framework that evaluates data, software, and models throughout their lifecycle.

1. From “Shared” to “Usable”

For appropriate NIH-funded projects, investigators could be encouraged to create a version-controlled research object containing, as applicable:

the dataset or an appropriate controlled-access representation;
data dictionaries and comprehensive metadata;
analysis code;
software and package versions;
computational dependencies;
model versions and model documentation;
information about model development and validation;
performance and uncertainty measures;
known limitations and intended-use conditions;

provenance and version history;
instructions for reproducing key analyses; and
documentation describing how the resource can appropriately be reused.

The objective should not be to impose identical technical requirements on every project. Requirements should be proportionate to the research design, data sensitivity, computational complexity, and scientific purpose.

2. FAIR Should Be Operational, Not Merely Declarative

The FAIR principles — Findable, Accessible, Interoperable, and Reusable — provide a useful foundation. However, compliance should not be reduced to checking whether a file has been deposited in a repository.

NIH could develop measurable indicators for the functional usability of shared research objects.

For example:

Can an independent researcher locate the resource?
Can its contents and structure be understood?
Are the metadata sufficient to interpret the data correctly?
Can the researcher determine which version was used in the original analysis?
Can the published analysis be rerun?
Can the software environment and dependencies be reconstructed?
Can a model's performance and limitations be independently assessed?
Can another research group appropriately reuse the resource?
Has independent reuse actually occurred?

This distinction is important because availability is an input, whereas successful independent reuse is evidence of scientific impact.

3. Reproducibility of Computational Research

For computationally intensive research, NIH could encourage preservation not only of source code but also of the computational environment required to reproduce key analyses.

Where appropriate, this could include:

software and package versions;
dependency specifications;
version-controlled code;
computational workflows;
containerized environments;
model versions;

randomization or seed information where relevant;
documentation of preprocessing and analytical pipelines; and
machine-readable descriptions of the workflow.

The objective should be to make the computational pathway from data to reported result sufficiently transparent that an independent researcher can evaluate and reproduce it.

Importantly, reproducibility should not require identical hardware or an identical computational environment in every circumstance. The appropriate standard should be scientifically meaningful reproducibility, with deviations or technical limitations documented transparently.

4. Model Sharing Requires More Than Sharing Model Files

The rapid expansion of AI and computational models makes this particularly important.

A model should not be evaluated solely on whether its weights or source code are publicly accessible. For meaningful scientific reuse, researchers need information about:

the purpose and intended use of the model;
development and validation datasets or their relevant characteristics;
inclusion and exclusion criteria;
preprocessing procedures;
model version;
performance measures;
uncertainty and calibration;
external validation;
known limitations;
population and setting in which the model was evaluated;
potential sources of bias; and
appropriate and inappropriate uses.

For biomedical AI, model documentation should therefore become part of the scientific contribution itself.

5. Measure Reuse, Not Download Counts

NIH should avoid relying heavily on easily manipulated indicators such as download counts, repository views, or the number of files deposited.

More meaningful indicators could include:

Independent computational reproduction.
Independent reuse of a dataset or research resource.
New publications based on the resource.

Independent validation studies.
Replication or extension of the original findings.
Reuse across institutions or scientific disciplines.
Development of new methods, tools, or models based on the resource.
Identification and correction of errors through independent reuse.
Documented contribution to clinical, translational, or public-health research.
Long-term maintenance and continued usability of the resource.

A resource that is downloaded thousands of times but cannot be understood or reproduced may have less scientific value than a smaller resource that is successfully reused and independently validated.

6. Recognize the People Who Build Research Infrastructure

Data curation, software engineering, statistical programming, model documentation, computational validation, database development, and long-term maintenance are scientific contributions.

NIH should make these contributions visible in investigators' scientific portfolios and in grant evaluation.

Researchers who create and maintain high-value datasets, software packages, computational pipelines, registries, biobanks, harmonized protocols, or reusable models should not be disadvantaged simply because these contributions produce fewer conventional journal articles.

Persistent identifiers and structured contributor attribution could allow these contributions to become citable and independently verifiable scientific outputs.

This would also support recognition of technical and methodological contributors who are often essential to research but remain invisible in conventional publication-based assessment.

7. Controlled Access Should Be Considered a Successful Form of Sharing

Not all biomedical data can or should be openly downloadable.

Patient-level data, genomic data, sensitive health information, and other protected datasets may require controlled access. NIH should therefore distinguish between open accessibility and responsible accessibility.

A dataset should not be considered scientifically unsuccessful because privacy, consent, security, intellectual-property, or regulatory requirements prevent unrestricted access.

Instead, evaluation should consider whether investigators have provided an appropriate access pathway, sufficient metadata, documentation, governance procedures, and a transparent mechanism through which qualified researchers can request access.

The principle should be:

As open as possible, as restricted as necessary.

8. Reward Reuse and Maintenance

Scientific recognition should continue beyond the initial publication.

NIH could provide explicit recognition for:

independent reuse;
successful replication using shared resources;
software maintenance;
dataset updates;
correction of errors;
model recalibration;
external validation;
development of derived resources; and
sustained infrastructure contributions.

Progress reports and future funding decisions could incorporate evidence that research outputs remained useful beyond the original project.

This would create a powerful incentive to produce durable scientific infrastructure rather than one-time research outputs.

9. Interoperability Should Be a Core Principle

NIH-supported resources should, where feasible, use interoperable standards and machine-readable formats that allow integration across research environments.

This is particularly important for multidisciplinary biomedical research, where datasets, registries, imaging resources, electronic health records, statistical software, AI models, and clinical research platforms increasingly need to interact.

Interoperability should therefore be evaluated as a scientific infrastructure contribution rather than treated solely as a technical specification.

10. A Practical Pilot

We recommend that NIH test these principles through a voluntary pilot involving a diverse cohort of funded research projects.

The pilot could evaluate shared datasets, software, and models using a common but adaptable framework and compare:

Availability → Documentation → Verification → Reproducibility → Independent Reuse → Scientific Impact

The pilot should measure not only whether resources were shared, but whether independent researchers could successfully understand, reproduce, validate, and reuse them.

Outcomes could include:

time required for independent reuse;
number and type of reproducibility barriers identified;
successful computational reproduction;
independent validation;
documented reuse;
new scientific outputs generated from the resource;
maintenance burden;
researcher and infrastructure costs; and
unintended consequences.

The framework should be independently evaluated and remain open, provider-neutral, interoperable, and adaptable to different research domains.

MedicReS Perspective

MedicReS has long approached medical research as a connected lifecycle rather than as a sequence ending with publication. Our experience in research methodology, biostatistics, scientific reporting, and research-support environments such as EPICOSAI has reinforced an important practical principle: the value of a research output depends not only on whether it exists, but on whether its methodological pathway and underlying research objects can be understood and appropriately reused.

EPICOSAI can provide practical experience relevant to this concept, particularly in connecting research questions, study design, statistical planning, analysis, reporting, and reproducibility-oriented workflows. However, we do not propose EPICOSAI as a proprietary NIH requirement. Any NIH framework should be based on open standards and should allow multiple interoperable platforms to participate.

We would be willing to contribute to an NIH pilot and, if useful, provide access to relevant research-support capabilities for a defined cohort during a one-year evaluation period without a commercial financial objective, subject to appropriate governance, privacy, security, interoperability, and independent evaluation requirements.

Conclusion

NIH has an opportunity to move the scientific community from a culture of “share because the policy requires it” toward a culture of “build research objects that others can trust, reproduce, and reuse.”

The most meaningful measure of data, software, and model sharing is therefore not simply:

Was it deposited?

but:

Could another researcher understand it, verify it, reproduce it, reuse it, and create new scientific value from it?

That is where sharing becomes measurable scientific impact.

3. Training and Mentorship: NIH should distinguish between training activity and training impact.

Courses completed, training hours, certificates awarded, number of trainees, or number of mentoring meetings are useful measures of participation, but they do not necessarily demonstrate that training has strengthened the biomedical research workforce.

The more meaningful question is:

What can a researcher demonstrably do after training or mentorship that they could not do independently before?

We therefore recommend that NIH complement existing training indicators with a competency- and independence-based framework that follows researchers across the research lifecycle.

From Participation to Demonstrated Research Competence

For biomedical researchers, measurable competencies could include the ability to:

formulate a meaningful and answerable research question;
distinguish exploratory from confirmatory research;
select an appropriate study design;
develop a scientifically and ethically sound protocol;
define appropriate outcomes and estimands;
justify sample size and statistical power;
develop a prespecified statistical analysis plan;
recognize major sources of bias, confounding, and missing-data problems;
manage research data appropriately;
conduct or supervise reproducible analyses;
interpret effect sizes and confidence intervals rather than relying primarily on statistical significance;
use artificial intelligence responsibly and verify AI-generated outputs;
select and apply appropriate reporting guidelines;
conduct systematic reviews and evidence synthesis when appropriate;
write and critically revise a scientific manuscript;

critically evaluate the work of others through structured peer review;
respond scientifically to peer-review comments; and
communicate scientific evidence accurately to clinicians, patients, policymakers, and the public.

These competencies could be documented through real research outputs rather than course attendance alone.

For example, a researcher could demonstrate competence by producing a protocol, statistical analysis plan, data-management plan, reproducible analysis, systematic review, structured peer-review report, conference abstract, or manuscript.

Measure Progress Toward Scientific Independence

The ultimate objective of research mentorship should not be indefinite dependence on a mentor.

It should be progressive scientific independence.

NIH could therefore evaluate whether trainees become increasingly capable of making and defending their own methodological and scientific decisions.

Potential indicators could include:

Verified change in research competencies before and after training.
Ability to develop a research question and protocol with decreasing levels of supervision.
Completion of a scientifically appropriate statistical analysis plan.
Ability to identify methodological weaknesses in one's own research.
Ability to interpret results in terms of magnitude, uncertainty, and scientific or clinical relevance.
Production of reproducible research outputs.
Successful completion and submission of manuscripts or other meaningful scientific outputs.
Ability to respond independently and appropriately to peer review.
Continued research activity after formal training or mentorship ends.
Transition from trainee to independent investigator, collaborator, or mentor.

This would allow NIH to assess not simply whether training was delivered, but whether research capacity was actually created.

Mentorship Should Be Evaluated by What Happens to the Mentee

Mentorship itself should also be evaluated differently.

The number of individuals mentored is an incomplete indicator of mentorship quality. A mentor supervising 30 researchers should not automatically be considered more effective than one who provides intensive mentorship to 5 researchers who subsequently become scientifically independent.

More meaningful mentorship indicators could include:

development of mentee scientific independence;
improvement in methodological competence;
responsible research and research-integrity practices;
successful progression through research milestones;
transition to independent scientific leadership;
retention in biomedical research;
development of interdisciplinary collaboration skills;
equitable access to opportunities, authorship, and scientific networks;
subsequent mentorship of other researchers; and
sustained scientific activity after the formal mentoring relationship ends.

This creates an important longitudinal concept:

The impact of mentorship is not the number of people a scientist has mentored, but the scientific capacity that remains after the mentorship ends.

Recognize the Mentorship Chain

One particularly informative long-term indicator could be the development of a mentorship chain.

If an investigator trains a researcher who subsequently becomes scientifically independent and then successfully mentors another generation of researchers, the original training investment has generated a multiplier effect.

NIH could therefore explore indicators capturing:

Mentor → Trainee → Independent Researcher → Mentor

Such longitudinal measures would be particularly valuable for assessing programs intended to strengthen the biomedical research workforce over many years.

They could also help identify training environments that create sustainable research capacity rather than short-term academic output.

Research Quality Should Matter More Than Publication Counts

Training programs should not be rewarded primarily because their participants produce more publications.

Publication productivity may be one outcome, but it can create unintended incentives if used without measures of quality.

A training program producing fewer but methodologically rigorous, reproducible, transparent, and clinically meaningful studies may have greater scientific impact than one producing many low-value publications.

NIH could therefore examine the quality of research outputs generated during and after training, including:

protocol quality;
adherence to appropriate reporting standards;
reproducibility practices;
appropriate statistical methodology;
transparent reporting of uncertainty;
responsible data and code sharing;
publication of negative or inconclusive findings when scientifically important;
corrections when errors are discovered; and
subsequent reuse or replication of the research.

The objective should be to reward better researchers, not simply more papers.

Training in Responsible Use of Artificial Intelligence

The rapid adoption of generative AI creates an additional workforce competency that should now be considered.

Researchers increasingly use AI for literature exploration, coding, statistical support, scientific writing, evidence synthesis, and methodological assistance. However, the ability to use AI is not equivalent to the ability to use it scientifically and responsibly.

NIH could therefore recognize competencies in:

verification of AI-generated information;
protection of confidential and sensitive research information;
recognition of hallucination and algorithmic bias;
appropriate disclosure of AI use;
preservation of human scientific accountability;
validation of AI-assisted analyses;
provenance of AI-assisted scientific content; and
understanding when AI should not be used.

Responsible AI literacy is increasingly becoming part of research literacy itself.

Recognize Mentorship as Scientific Work

High-quality mentorship requires substantial intellectual effort and time but is often less visible than

publications and grants.

NIH could recognize mentorship explicitly within scientific contribution portfolios and consider mechanisms such as:

protected mentorship time;
supplemental training support;
recognition of documented mentoring contributions in progress reports and renewals;
support for mentor training;
recognition of methodological and interdisciplinary mentorship; and
credit for developing researchers who subsequently achieve scientific independence.

This is particularly important for methodological disciplines such as biostatistics, epidemiology, bioinformatics, data science, research ethics, and research methodology, where a scientist's contribution may substantially improve dozens of other research projects without necessarily being visible through first- or senior-author publications.

Avoid Creating Another Certificate Economy

Any competency-based framework also requires safeguards.

NIH should avoid replacing publication-counting with certificate-counting.

A proliferation of credentials without demonstrated competence would reproduce the same problem in a different form.

Competency assessments should therefore, where possible, be:

performance-based;
independently verifiable;
linked to authentic research activities;
portable across institutions;
proportionate to career stage;
accessible to researchers from institutions with different levels of resources; and
based on open standards rather than dependence on any single commercial provider.
MedicReS Experience

This recommendation reflects an approach MedicReS has pursued since its early development: good research requires development of the researcher across the entire research lifecycle, not isolated instruction in individual techniques.

Our Good Medical Researcher educational approach has therefore emphasized the interconnected competencies required to move from a research question through methodology, study design, biostatistics, research integrity, interpretation, scientific writing, peer review, and communication.

More recently, experience with structured learning environments such as BeGMRAI has reinforced the potential to move beyond attendance-based education toward demonstrated research competencies and outputs.

We offer this experience not as a proposed proprietary NIH standard, but as practical evidence supporting a broader principle:

Training can be designed and evaluated around demonstrated research capability rather than educational participation alone.

Any NIH implementation should use open competency standards that can be adopted, assessed, and independently validated across institutions.

A Practical NIH Pilot

NIH could test this approach in a longitudinal cohort drawn from existing training, career-development, or early-career investigator programs.

At entry, participants could complete a structured assessment of research competencies.

During the program, competencies could be demonstrated through authentic research outputs rather than examinations alone.

At completion and at subsequent intervals, NIH could assess:

Training → Competence → Independence → Scientific Output → Mentorship of Others

A pilot could compare these measures with traditional indicators such as training hours, certificates, publication counts, and grant success to determine which indicators better predict sustained scientific independence and research quality.

MedicReS would be willing to contribute methodological experience to the design of such a pilot and, if useful, make relevant training and research-support capabilities available to a defined NIH pilot cohort for one year without a commercial financial objective, subject to appropriate governance and independent evaluation.

Conclusion

NIH has already invested substantially in training the biomedical research workforce. The next opportunity is to improve how the impact of that investment is measured.

The central shift we recommend is:

Training hours → Demonstrated competence

Certificates → Authentic research outputs

Number of mentees → Quality of mentorship

Publication counts → Quality of research

Dependence → Scientific independence

One generation trained → The next generation capable of training others

Ultimately, the most meaningful indicator of successful training and mentorship may be simple:

Can the researcher independently ask an important question, design a rigorous study, analyze and interpret the evidence responsibly, communicate it transparently, and eventually enable another researcher to do the same?

If the answer is yes, training has produced more than a credential.

It has created sustainable scientific capacity.

4. Collaboration: NIH should assess collaboration not primarily by the number of coauthors, institutions, disciplines, or countries represented in a project, but by the verifiable scientific value that different contributors add to the research.

As biomedical research becomes increasingly interdisciplinary, the conventional publication model does not adequately capture how knowledge is produced. A large collaborative study may depend on investigators who formulate the research question, clinicians who define its relevance, biostatisticians who shape the design and analysis, data scientists who build computational infrastructure, software developers who create analytical tools, methodologists who identify sources of bias, patient representatives who help define meaningful outcomes, and researchers who validate or replicate the findings.

All of these contributions can be scientifically important, yet conventional authorship and bibliometric indicators often make them difficult to distinguish.

We therefore recommend that NIH move from measuring collaboration size toward measuring contribution quality, complementarity, and scientific added value.

1. Make Individual Contributions Visible

At the beginning of an NIH-funded collaborative project, major contributor roles could be defined and subsequently updated as the research evolves.

Relevant contributions may include:

conceptualization;
clinical or scientific domain expertise;
methodology;
study design;
biostatistics;
formal analysis;
software development;
data management and curation;
model development and validation;
research ethics;
patient and community engagement;
visualization;
replication and external validation;
scientific writing;
critical methodological review;
project administration;
development of shared research infrastructure; and
scientific communication and dissemination.

Frameworks such as the CRediT Contributor Roles Taxonomy could provide a useful starting structure, while allowing NIH to recognize additional roles important to contemporary biomedical research.

The objective should be to answer:

Who contributed what, at what stage, and how did that contribution improve the science?

2. Evaluate Scientific Added Value, Not Team Size

Large teams should not automatically be considered more collaborative or more impactful than small teams.

NIH could assess whether collaboration resulted in demonstrable improvements such as:

stronger study design;
better control of bias and confounding;
more appropriate statistical methodology;
improved data quality;
increased population diversity or representativeness;
stronger external validation;
improved reproducibility;
development of reusable research resources;
integration of previously disconnected disciplines;

more clinically meaningful research questions or outcomes; and
increased potential for translation or public benefit.

This would distinguish meaningful interdisciplinarity from nominal interdisciplinarity.

A project involving many disciplines should be rewarded because those disciplines changed or strengthened the research—not simply because their names appear on the application or publication.

3. Recognize Methodological and Statistical Collaboration

NIH should pay particular attention to scientific contributions that are essential but can become invisible under conventional authorship-based assessment.

Biostatisticians, epidemiologists, research methodologists, bioinformaticians, data scientists, software engineers, research-data specialists, and other methodological collaborators may contribute across numerous projects without consistently occupying first- or senior-author positions.

Their impact may be reflected instead in:

preventing inappropriate study designs;
improving sample-size planning;
defining appropriate estimands and outcomes;
developing statistical analysis plans;
identifying bias;
improving reproducibility;
validating analytical methods;
preventing overinterpretation;
developing reusable analytical tools; and
improving the methodological quality of multiple research programs.

These contributions should be explicitly recognized as scientific contributions, not merely as technical support.

This distinction is important for interdisciplinary biomedical science.

4. Recognize Those Who Build the Infrastructure That Makes Collaboration Possible

Some of the most important collaborative contributions do not result immediately in a conventional publication.

Researchers may create:

biobanks;
registries;

shared data platforms;
harmonized protocols;
common data models;
research networks;
multicenter infrastructures;
statistical or computational platforms;
standardized outcome sets; or
shared methodological resources.

Such infrastructure may enable hundreds of subsequent studies.

NIH should therefore recognize the creation, validation, governance, maintenance, and scientific reuse of research infrastructure as collaborative scientific impact.

The contribution of the scientist who creates the system enabling research should not disappear behind the publications subsequently produced through that system.

5. Peer Review and Methodological Review Are Forms of Scientific Collaboration

Scientific collaboration should not necessarily end when a manuscript is written.

Researchers who provide substantive methodological criticism, identify errors, improve protocols, evaluate analytical approaches, or contribute to replication are also contributing to the scientific process.

Under appropriate transparent review models, high-quality scientific reviews could become citable scholarly contributions.

This could include structured methodological assessments of protocols and manuscripts, particularly when the review produces documented improvements in the research.

Recognition should depend on the quality and substance of the review—not merely on the number of manuscripts reviewed.

This would also help address an important imbalance in the current scientific ecosystem: peer review is essential to science but remains largely invisible in conventional measures of scientific contribution.

6. Measure Collaboration Across the Research Lifecycle

Collaboration should be evaluated longitudinally rather than only through the final publication.

NIH could examine contributions at multiple stages:

Research question → Protocol → Study design → Data generation → Analysis → Interpretation → Reporting → Review → Replication → Translation

Different scientists may make their most important contributions at different points in this lifecycle.

A lifecycle-based contribution record would provide a more accurate representation of team science than authorship order alone.

7. Consider Contribution Networks Rather Than Publication Networks Alone

Traditional scientific-network analyses often identify collaboration through coauthorship.

However, coauthorship captures only part of the scientific network.

NIH could explore a broader contribution network in which relationships are based on verified scientific activities such as:

shared protocols;
shared datasets;
methodological contributions;
software development;
validation;
replication;
mentorship;
infrastructure development;
structured scientific review; and
translational implementation.

Such a model could reveal researchers whose influence on biomedical science is substantial but poorly captured by publication counts or authorship position.

8. Recognize Sustainable Collaboration

One important indicator of successful collaboration is whether scientific relationships and infrastructure continue after the original grant ends.

Potential longitudinal indicators could include:

continuation of interdisciplinary research partnerships;
new research questions generated by the collaboration;
subsequent joint projects;
continued reuse of shared infrastructure;
expansion to new institutions or populations;
development of independent investigators within the network;
successful replication or external validation; and
continued sharing of research resources.

The objective should not be to reward networking itself.

It should be to recognize collaboration that creates durable scientific capacity.

9. Patient and Community Contributions Should Be Visible

Contemporary biomedical research increasingly involves patients, caregivers, community representatives, and other stakeholders.

Their contribution should not be treated as symbolic participation.

Where appropriate, NIH could document whether these collaborators meaningfully influenced:

selection of research questions;
outcome selection;
study feasibility;
recruitment strategies;
interpretation of results;
dissemination;
implementation; or
identification of unintended consequences.

Meaningful stakeholder involvement should be distinguishable from nominal inclusion.

10. Safeguards Against Gaming

Any contribution-based system creates potential unintended consequences.

NIH should guard against:

honorary or gift authorship;
inflated contribution claims;
excessive fragmentation of contributor roles;
reciprocal credit arrangements;
artificial expansion of research teams;
dominance of prestigious institutions;
disadvantage to investigators from smaller or less-resourced institutions;
undervaluing individual or small-team science; and
converting contribution metrics into another single ranking system.

Contribution statements should therefore be verifiable where feasible, and NIH should avoid creating a single numerical “collaboration score.”

Instead, collaboration should form one dimension of a broader scientific contribution profile.

11. Potential Indicators

NIH could consider indicators such as:

Clearly defined and verified contributor roles.
Demonstrable influence of interdisciplinary expertise on study design or analysis.
Jointly developed protocols, datasets, methods, software, or models.
Creation and sustained use of shared research infrastructure.
Meaningful methodological and statistical contributions.
Contributions to independent validation and replication.
Substantive peer-review or methodological-review contributions.
Meaningful patient or community participation.
Transparent management of conflicts of interest and contribution changes.
Continued collaboration or infrastructure use after project completion.
Reuse of collaborative outputs by researchers outside the original team.
Development of new investigators or research capacity through collaboration.
Conclusion

The central principle is simple:

Collaboration should be measured by the scientific value created between people, not merely by the number of people connected to a project.

A publication with 50 authors is not necessarily evidence of better collaboration than one with five. Likewise, a scientist who appears infrequently as first or senior author may nevertheless have transformed the quality of dozens of studies through methodology, biostatistics, software, data infrastructure, validation, or scientific review.

NIH has an opportunity to make these previously less-visible contributions visible.

The progression we recommend is:

Number of collaborators → Verified contributions

Authorship position → Scientific role

Institution count → Complementary expertise

Coauthorship network → Contribution network

Project collaboration → Sustainable scientific capacity

Ultimately, team science should be rewarded when collaboration enables biomedical research to become more rigorous, more reproducible, more innovative, more inclusive, and more useful than any individual contributor could have achieved alone.

5. Entrepreneurship and Translation: NIH should distinguish between entrepreneurial activity and translational impact.

Patents filed, licenses executed, companies formed, venture capital raised, or products launched are useful indicators of activity, but they do not necessarily demonstrate that a biomedical discovery has generated meaningful scientific, clinical, or public value.

For the NIH mission, the more important question is:

Did the discovery move from scientific promise to independently validated, safe, effective, accessible, and useful application for people?

We therefore recommend that NIH assess entrepreneurship and translation as a stage-specific pathway from discovery to real-world value, rather than as a count of commercial outputs.

1. Measure the Translational Pathway, Not Only Its Commercial Milestones

A biomedical discovery may progress through several stages:

Discovery → Validation → Prototype → Independent Validation → Regulatory Readiness → Clinical Evaluation → Implementation → Real-World Evidence → Patient/Public Benefit

Different innovations will appropriately reach different points along this pathway.

NIH should therefore recognize progress according to the scientific and developmental stage of the innovation rather than expecting every funded discovery to rapidly generate a patent, company, licensed product, or commercial return.

Potential indicators could include:

successful technical validation;
independent scientific validation;
external clinical validation;
progression from proof-of-concept to prototype;
demonstration of safety and performance;
regulatory readiness or regulatory milestones;
integration into clinical or health-system workflows;
evidence of usability by clinicians, patients, or other intended users;
real-world adoption;
generation of pragmatic or real-world evidence;
contribution to clinical guidelines or health policy;

accessibility and affordability; and
measurable benefit to patients or populations.

The central shift should be:

Commercialization metrics → Translational evidence

2. Independent Validation Should Be a Major Indicator

One of the most important transitions in biomedical innovation occurs when a discovery moves beyond the laboratory, institution, dataset, or team that originally developed it.

NIH should therefore recognize independent validation as a major translational milestone.

For diagnostics, predictive models, digital health tools, AI systems, biomarkers, devices, therapeutic approaches, or research technologies, validation could include evaluation:

by an independent research group;
in an external dataset;
in another clinical institution;
in a different patient population;
under routine clinical conditions; or
through prospective evaluation where appropriate.

An innovation that performs exceptionally in its development environment but fails when independently evaluated should not be considered successfully translated.

Conversely, independent confirmation—even before commercialization—represents substantial translational progress.

3. Distinguish Efficacy From Effectiveness

A particularly important translational question is whether an intervention that works under controlled research conditions also works in routine practice.

NIH could therefore explicitly recognize the transition from:

Efficacy → Effectiveness

as a measurable component of scientific impact.

Pragmatic trials, implementation studies, comparative-effectiveness research, registries, and appropriately designed real-world evidence studies can help determine whether benefits observed in controlled settings persist across:

routine clinical practice;
broader patient populations;
different institutions;
different clinicians;
different socioeconomic settings; and
populations historically underrepresented in research.

The efficacy–effectiveness gap itself can be scientifically informative and should be considered part of translational evaluation.

4. Adoption Is More Meaningful Than Availability

A product becoming technically available does not mean that it has achieved meaningful translation.

NIH should distinguish:

Product exists → Product is available → Product is adopted → Product improves outcomes

Potential indicators of meaningful adoption could include:

integration into routine clinical workflows;
sustained use rather than temporary pilot use;
clinician acceptance;
patient acceptance;
implementation across multiple institutions;
incorporation into guidelines or care pathways;
measurable improvement in clinical processes;
measurable improvement in patient-important outcomes; and
evidence that the innovation reaches its intended population.

This would prevent the existence of a commercial product from being treated automatically as evidence of public benefit.

5. Patient Value Should Remain the Translational Endpoint

For biomedical research, the ultimate translational objective should remain benefit to people.

Where appropriate, NIH could therefore assess:

survival;
morbidity;
symptoms;
functional status;

quality of life;
validated patient-reported outcomes;
diagnostic accuracy;
prevention;
safety;
treatment burden;
access to care;
time to diagnosis or treatment;
health-system efficiency; and
patient experience.

Surrogate or intermediate outcomes may be appropriate at earlier translational stages, but the evaluation framework should distinguish them from demonstrated patient benefit.

6. Accessibility and Health Equity Are Components of Translation

An innovation that works but cannot reach the population that needs it has achieved only partial translation.

NIH should therefore consider:

affordability;
geographic accessibility;
feasibility in lower-resource settings;
usability across different health systems;
representation of relevant populations during validation;
accessibility for underserved populations;
digital-access requirements;
language and cultural barriers; and
potential to reduce or exacerbate existing health disparities.

This is especially important for AI and digital health technologies, where innovation may inadvertently widen disparities if development and validation are concentrated in populations and institutions with greater resources.

Thus:

Translation should include not only whether an innovation works, but also for whom, where, and under what conditions it works.

7. Cost and Value Should Be Considered

A scientifically effective innovation may still have limited translational value if its cost makes implementation unrealistic.

Depending on the stage and type of innovation, NIH could recognize evidence concerning:

cost-effectiveness;
budget impact;
resource utilization;
implementation costs;
scalability;
sustainability; and
opportunity costs.

Economic evaluation should not replace clinical value, but it can help determine whether an innovation can realistically move from research into sustainable practice.

8. Failed Translation Can Still Produce Scientific Value

Not every scientifically promising discovery will become a successful product.

Failure is inherent to innovation.

NIH should avoid creating incentives that encourage researchers or entrepreneurs to hide unsuccessful translational efforts.

A well-designed translational project that demonstrates that an intervention:

does not replicate;
fails external validation;
produces unacceptable adverse effects;
lacks effectiveness in routine practice;
is not cost-effective;
cannot be implemented feasibly; or
performs differently across populations

may generate extremely valuable scientific information.

Such findings can prevent further research waste, unnecessary investment, ineffective clinical implementation, or patient harm.

NIH should therefore recognize transparent, methodologically rigorous translational failure as scientific learning.

9. Entrepreneurship Should Not Move Faster Than the Evidence

Commercial incentives can create pressure to move rapidly from scientific discovery to claims of clinical

benefit.

NIH should maintain a clear distinction between:

commercial success and scientific validation.

Appropriate safeguards should include:

transparent conflict-of-interest disclosure;
independent validation;
clear distinction between exploratory and validated claims;
evidence appropriate to the level of clinical claim;
transparent reporting of negative results;
monitoring of safety and performance after implementation; and
correction of claims when subsequent evidence changes the conclusion.

Commercial success should never substitute for scientific validity.

10. Recognize Different Forms of Innovation

Entrepreneurship should not be interpreted narrowly as company formation.

Biomedical innovation can include:

new therapeutics;
diagnostics;
medical devices;
biomarkers;
AI and predictive models;
digital health technologies;
statistical and methodological tools;
research software;
clinical decision-support systems;
data infrastructures;
new models of care;
public-health interventions;
implementation strategies; and
educational or research-capacity technologies.

Some highly impactful innovations may be open-source, nonprofit, academically maintained, or integrated directly into public infrastructure.

NIH should therefore reward scientific and public value regardless of the business model through which it is delivered.

11. Recognize the People Who Enable Translation

Translation is inherently multidisciplinary.

The pathway from discovery to implementation may involve basic scientists, clinicians, biostatisticians, epidemiologists, engineers, data scientists, regulatory experts, implementation scientists, health economists, patient representatives, entrepreneurs, and health-system leaders.

NIH should recognize these contributions individually rather than attributing translational success only to the inventor, principal investigator, patent holder, or company founder.

Structured contributor frameworks could document who contributed to:

discovery;
validation;
methodology;
product development;
regulatory strategy;
clinical evaluation;
implementation;
economic evaluation;
real-world evidence; and
patient/community engagement.
12. Potential Indicators

NIH could consider a multidimensional translational profile including:

Independent technical validation.
Independent clinical validation.
External validation across populations and settings.
Progression from prototype to real-world use.
Regulatory readiness and appropriate regulatory milestones.
Safety and performance evidence.
Integration into clinical or health-system workflows.
Real-world adoption and sustained use.
Pragmatic research and real-world evidence.
Evidence addressing the efficacy–effectiveness gap.
Patient-important outcomes.
Guideline or policy influence.
Accessibility and affordability.
Health-equity implications.
Cost-effectiveness or implementation value where appropriate.
Transparent reporting of unsuccessful translation.

Sustained benefit after implementation.

These indicators should be interpreted according to the type and maturity of the innovation rather than combined into a universal numerical entrepreneurship score.

13. A Stage-Appropriate NIH Framework

NIH could evaluate translational projects according to their position on the research-to-impact pathway.

For example:

Early stage:
Scientific rationale, reproducibility, technical validation.

Development stage:
Prototype performance, independent validation, safety, usability.

Clinical translation:
Clinical validity, clinical utility, regulatory readiness.

Implementation:
Workflow integration, adoption, effectiveness, accessibility.

Real-world impact:
Patient outcomes, population impact, health equity, sustainability, and value.

This would reduce pressure for premature commercialization while allowing NIH to recognize genuine translational progress before a product reaches the market.

Conclusion

NIH has an opportunity to redefine entrepreneurship in biomedical research around evidence rather than commercial activity alone.

The progression we recommend is:

Patent → Independent validation

Prototype → Demonstrated utility

Company formation → Sustainable implementation

Investment → Evidence generation

Efficacy → Effectiveness

Product launch → Real-world adoption

Commercial success → Patient and public value

The most important question should therefore not be:

“Did this research generate a patent, company, or product?”

but:

“Did this discovery survive independent validation, move responsibly toward real-world use, reach the people who need it, and create demonstrable scientific, clinical, or public value?”

That is the translational impact most closely aligned with the NIH mission.

6. Foundational Scientific Exploration: Foundational science and high-risk, high-reward research require an impact framework fundamentally different from that used for mature translational research.

By definition, exploratory research operates under substantial uncertainty. Some projects will not confirm their hypotheses, generate immediately publishable positive findings, produce patents, or lead rapidly to clinical applications. This should not automatically be interpreted as scientific failure.

The central question should instead be:

Did the research reduce important uncertainty, rigorously test a consequential idea, create new knowledge or capability, or open a scientifically valuable path for others to pursue?

NIH should therefore protect foundational research from evaluation systems that unintentionally reward short-term productivity, predictable positive results, or rapid translation at the expense of scientific exploration.

1. Distinguish Scientific Failure From Research Failure

A negative result is not necessarily a failed research project.

There is an important distinction between:

A hypothesis that fails after rigorous testing

and

Research that fails because it was poorly designed, inadequately conducted, or insufficiently documented.

The first can be scientifically valuable. The second should not be rewarded merely because it is described as high-risk research.

For foundational exploration, NIH should therefore evaluate whether:

the scientific question was important;
the hypothesis or proposition was meaningfully testable;
the study was appropriately designed;
methods were sufficiently rigorous;
uncertainty was honestly characterized;
alternative explanations were considered;
negative or unexpected findings were transparently reported; and
the resulting knowledge can inform subsequent research.

A rigorously demonstrated negative result can eliminate an incorrect hypothesis, prevent duplication of unproductive work, redirect resources, or reveal previously unrecognized biological complexity.

That is scientific progress.

2. Reward Reduction of Scientific Uncertainty

Foundational research often creates value by changing what the scientific community knows not to be true, narrowing the range of plausible explanations, or identifying what must be investigated next.

NIH could therefore recognize reduction of important scientific uncertainty as a legitimate form of impact.

Potential evidence could include:

rejection or refinement of an important hypothesis;
identification of previously unknown mechanisms;
discovery of unexpected relationships;
clarification of conflicting evidence;
identification of boundary conditions;
development of new conceptual models;
generation of new research questions; and
redirection of a scientific field toward more promising hypotheses.

This would allow NIH to recognize knowledge generation without requiring every project to produce a positive or immediately actionable result.

3. Use Longer Time Horizons

Foundational discoveries frequently require years—or decades—before their importance becomes apparent.

A scientific observation that initially has little clinical relevance may later become essential to a therapeutic technology, diagnostic method, computational approach, or entirely new field.

NIH should therefore avoid assessing foundational research primarily through short-term indicators such as:

publications within the grant period;
immediate citation counts;
journal prestige;
patents;
company formation;
licensing activity; or
rapid clinical translation.

These measures may become relevant later, but they are often poor indicators of the value of early scientific exploration.

NIH could instead use longitudinal and portfolio-based evaluation, allowing the influence of foundational discoveries to emerge over appropriate time periods.

4. Measure What Foundational Research Creates

Foundational research can produce many forms of scientific value beyond conventional publications.

Potential indicators could include:

Creation of a new hypothesis or conceptual framework.
Development of a new experimental or analytical method.
Creation of a new measurement instrument or assay.
Generation of a valuable dataset or biological resource.
Development of a model system.
Creation of software or computational methods.
Establishment of shared research infrastructure.
Identification of previously unknown mechanisms.
Resolution of important scientific uncertainty.
Generation of new questions subsequently pursued by independent researchers.
Independent testing or replication of the finding.
Adoption of methods or resources by other laboratories.
Emergence of new interdisciplinary research directions.
Long-term contribution to translational or clinical research.

The emphasis should be on what scientific capability or knowledge became possible because the research was conducted.

5. Protect Negative and Null Results

The current research ecosystem can unintentionally reward positive findings and discourage publication of negative, null, or inconclusive results.

This creates scientific waste and may distort the evidence base.

NIH could explicitly recognize high-quality negative findings when:

the research question was scientifically important;
the study had adequate methodological rigor;
the analysis was appropriate;
uncertainty was reported transparently;
the result meaningfully informs the hypothesis; and
the findings and methods are accessible to other researchers.

This recognition could reduce unnecessary duplication and make failed scientific paths informative to the broader research community.

However, NIH should not create incentives for low-quality negative studies. Methodological rigor must remain the prerequisite for scientific credit.

6. Distinguish Exploratory From Confirmatory Research

Foundational science often requires exploratory analyses.

Exploration should not be discouraged. It should be identified honestly.

NIH could encourage researchers to distinguish clearly between:

Exploratory findings: hypothesis-generating observations requiring further testing.

and

Confirmatory findings: evidence generated through appropriately prespecified testing.

For high-dimensional, omics, imaging, AI, or other data-intensive research, NIH could encourage transparent documentation of:

which analyses were prespecified;
which analyses emerged during exploration;

multiple-comparison procedures where appropriate;
internal validation;
external validation;
sensitivity analyses; and
plans for subsequent confirmatory investigation.

The problem is not exploration.

The problem is presenting exploration as confirmation.

7. Recognize Scientific Risk Properly

NIH should also distinguish genuine scientific risk from poor planning.

A high-risk project should be high-risk because:

the hypothesis is bold;
the scientific uncertainty is substantial;
the mechanism is poorly understood;
the methodology is novel;
existing evidence is limited;
or the potential discovery challenges established assumptions.

It should not be considered high-risk simply because the protocol is underdeveloped or the methods are weak.

A useful principle would therefore be:

High scientific uncertainty should be encouraged; low methodological rigor should not.

This distinction is essential if NIH wants to reward genuinely transformative research.

8. Evaluate Learning Milestones, Not Only Success Milestones

For high-risk projects, investigators could define learning milestones at the beginning of the project.

Instead of asking only:

“Did the intervention work?”

or

“Was the original hypothesis confirmed?”

NIH could also ask:

What uncertainty was resolved?
Which assumptions were supported or rejected?
What unexpected findings emerged?
Which methodological barriers were identified?
What new hypotheses resulted?
What should the next experiment test?
Should this research direction continue, change, or stop?

This would make rigorous learning visible even when the original hypothesis is not confirmed.

9. Reward the Decision to Stop When Evidence Justifies It

Scientific culture strongly rewards continuation: another experiment, another grant, another publication.

But sometimes the scientifically responsible decision is to stop.

If rigorous evidence demonstrates that a research direction is unlikely to succeed, documenting that conclusion may prevent substantial duplication of effort and public expenditure.

NIH could therefore recognize a well-supported “stop decision” as a legitimate scientific outcome when it is based on transparent evidence.

Stopping an unproductive research direction can itself represent responsible stewardship of research resources.

10. Evaluate Research Programs as Portfolios

High-risk/high-reward science is particularly poorly suited to evaluation one project at a time.

If every individual project is expected to succeed, investigators will rationally reduce risk.

NIH could instead consider portfolio-level assessment.

Within a portfolio of well-designed exploratory projects:

some may confirm hypotheses;
some may refute them;
some may create tools;
some may generate unexpected findings;
some may fail technically;
and a small number may transform a field.

The appropriate question is therefore not whether every project succeeded.

It is whether the portfolio created enough new knowledge, capability, and opportunity to justify the scientific risk undertaken.

This is particularly important for genuinely high-risk, high-reward funding programs.

11. Protect Early-Career Investigators

A system that encourages risk but penalizes unsuccessful outcomes creates a contradiction.

This is especially consequential for early-career investigators, who may reasonably avoid ambitious research if a negative result threatens their next grant, publication record, or academic advancement.

NIH could consider mechanisms that recognize rigorous high-risk research independently of whether the initial hypothesis was confirmed.

Evaluation should emphasize:

quality of reasoning;
methodological rigor;
transparency;
learning generated;
resources created;
and subsequent scientific directions.

This would allow investigators to take scientifically justified risks without being rewarded for recklessness or punished for honest negative results.

12. Avoid a Single Foundational-Impact Score

The diversity of foundational science makes a single numerical score inappropriate.

A theoretical contribution, new biological mechanism, assay, dataset, computational method, animal model, or unexpected negative finding creates value in different ways.

NIH should therefore use a multidimensional profile rather than attempting to collapse foundational impact into one ranking.

Relevant dimensions could include:

Novelty

Rigor

Uncertainty reduced

Knowledge generated

Methods/resources created

Independent reuse

New research enabled

Long-term influence

This profile could complement rather than replace expert scientific judgment.

13. Follow the Scientific Genealogy of Discoveries

For long-term evaluation, NIH could also examine the scientific genealogy of foundational discoveries.

Rather than relying solely on citations, NIH could ask whether an early discovery subsequently:

generated new hypotheses;
enabled new methods;
was incorporated into independent research programs;
contributed to new therapeutic or diagnostic approaches;
supported a new field;
enabled interdisciplinary research;
or became part of a later translational pathway.

This would help make visible something traditional metrics often miss:

The scientific impact of foundational research may appear far downstream from the original investigator and many years after the original grant.

14. Potential Indicators

NIH could consider:

Importance and originality of the scientific question.
Testability of the central hypothesis or proposition.
Methodological rigor.
Transparent characterization of uncertainty.
Transparent reporting of negative and unexpected findings.
Creation of new hypotheses or conceptual frameworks.

Creation of methods, tools, datasets, models, or infrastructure.
Independent reuse of these resources.
Independent testing, validation, or replication.
Generation of subsequent research questions.
Emergence of interdisciplinary research directions.
Evidence that negative findings prevented unnecessary duplication.
Progression of exploratory findings to confirmatory studies.
Long-term scientific or translational influence.

These indicators should be interpreted according to scientific context and over an appropriate time horizon.

Conclusion

NIH's support for foundational exploration requires an assessment system that accepts a fundamental property of science:

A scientifically valuable experiment does not have to confirm the hypothesis.

The progression we recommend is:

Positive results → Informative results

Short-term productivity → Long-term scientific value

Publication count → Knowledge created

Citation count → Research enabled

Failure avoidance → Responsible scientific risk

Unexpected result → New scientific direction

Individual project success → Portfolio learning

The most important distinction is therefore not between success and failure.

It is between:

Research that rigorously teaches us something important and research that does not.

A bold hypothesis that is carefully tested and ultimately rejected may advance science further than a predictable hypothesis that produces another positive publication.

If NIH wants to sustain genuinely transformative research, researchers must be able to pursue important uncertainty without fearing that an honest negative answer will be interpreted as scientific failure.

7. Public Impact: NIH should distinguish between public visibility and public impact.

Media coverage, website visits, social-media engagement, news mentions, or public attention can demonstrate dissemination, but they do not necessarily demonstrate that biomedical research has improved health, clinical practice, public policy, accessibility, public trust, or societal well-being.

The more meaningful question is:

What verifiable difference did the research make to people, health systems, communities, policy, or society—and what evidence supports that contribution?

We recommend that NIH assess public impact through a multidimensional and longitudinal framework that recognizes different pathways from scientific discovery to societal benefit.

1. Measure Contribution to Health Outcomes

For biomedical research, one of the most important forms of public impact is improvement in health.

Where appropriate, NIH could recognize evidence of contribution to:

reduced mortality;
reduced morbidity;
improved prevention;
earlier or more accurate diagnosis;
improved treatment effectiveness;
improved treatment safety;
improved functional status;
improved quality of life;
reduced disease burden;
improved access to effective care; and
reduction of avoidable health disparities.

Importantly, impact should not be restricted to statistically significant changes.

The magnitude of benefit, confidence intervals, clinical importance, population reach, durability, and potential harms should also be considered.

This would align public-impact assessment with the fundamental principle that statistical significance is not equivalent to clinical or societal significance.

2. Recognize Patient-Important Outcomes

Research impact should be evaluated partly through outcomes that matter directly to patients.

Depending on the research question, these may include:

survival;
symptoms;
functional ability;
quality of life;
treatment burden;
adverse effects;
ability to work or participate in daily life;
patient experience; and
validated patient-reported outcome measures.

Intermediate biomarkers and surrogate outcomes may be scientifically important, particularly during earlier stages of research, but NIH should distinguish between evidence of biological effect and demonstrated benefit meaningful to patients.

3. Measure Influence on Clinical Practice

A research finding may have substantial public impact when it changes how health care is delivered.

Potential indicators could include:

incorporation into clinical practice guidelines;
changes in standards of care;
adoption of diagnostic or treatment approaches;
discontinuation of ineffective or harmful practices;
incorporation into clinical decision-support systems;
changes in screening or prevention strategies;
adoption across health systems; and
sustained implementation in routine clinical practice.

However, guideline citation alone should not automatically constitute high public impact.

NIH could distinguish:

Evidence cited → Recommendation changed → Practice changed → Patient outcomes changed

These represent progressively stronger evidence of translation into public benefit.

4. Recognize Contributions to Public Health and Policy

Biomedical research can also create impact beyond individual clinical encounters.

NIH could recognize contributions to:

public-health recommendations;
vaccination strategies;
screening programs;
disease-surveillance systems;
prevention policies;
environmental or occupational-health policies;
health-system planning;
emergency preparedness;
regulatory decisions; and
allocation of health resources.

Where feasible, evaluation should document the pathway through which research informed a policy or program rather than assuming that citation in a policy document demonstrates causation.

5. Evaluate Accessibility and Reach

An effective intervention cannot generate broad public benefit if people cannot access it.

NIH should therefore consider:

affordability;
geographic accessibility;
availability across different health systems;
implementation in underserved communities;
language and cultural accessibility;
digital accessibility;
barriers affecting people with disabilities;
scalability;
population reach; and
sustainability.

A scientific innovation that benefits only a narrow, highly resourced population may have important scientific value, but its broader public impact should be distinguished from an intervention that reaches populations with substantial unmet need.

6. Include Health Equity and Representativeness

Public impact assessment should ask:

Who benefited—and who did not?

NIH could evaluate whether study populations appropriately represent the populations expected to use or benefit from the resulting evidence.

Where scientifically appropriate, this could include assessment by:

age;
sex;
race and ethnicity;
socioeconomic circumstances;
geographic setting;
relevant comorbidities; and
other clinically meaningful population characteristics.

Stratified analyses and interaction assessments should be used when justified by the research question and design, rather than applied mechanically to every study.

Researchers should also communicate clearly the populations to which their conclusions can and cannot reasonably be generalized.

This is particularly important for AI, precision medicine, genomic research, and predictive models, where performance may differ substantially across populations.

7. Public Trust Should Be Considered a Scientific Asset

Public trust is essential to biomedical research.

Trust should not be measured merely through favorable public opinion. It is better supported through observable research practices.

Potential indicators could include:

transparent protocols;
appropriate public access to research findings;
transparent disclosure of conflicts of interest;
understandable communication of benefits and risks;
appropriate communication of uncertainty;
accessible explanations of research findings;
transparent corrections;
acknowledgment of errors;
publication of negative or conflicting evidence;
disclosure of important protocol changes;
responsible communication of AI use; and
availability of replication or validation evidence.

Trust is strengthened not by presenting science as infallible, but by demonstrating that science has mechanisms to identify uncertainty, detect errors, correct itself, and update conclusions when evidence changes.

8. Recognize Meaningful Patient and Community Engagement

Patients, caregivers, and communities should not be viewed only as recipients of scientific impact.

They can contribute to defining it.

Where appropriate, NIH could recognize meaningful involvement in:

identifying research priorities;
defining relevant research questions;
selecting patient-important outcomes;
improving recruitment and retention;
assessing study feasibility;
interpreting results;
designing dissemination strategies; and
supporting implementation.

The key word is meaningful.

Participation should be assessed according to whether stakeholder input actually influenced research decisions, rather than simply whether a patient or community representative attended meetings.

9. Economic Impact Should Be Broader Than Commercial Revenue

Biomedical research can generate economic value without necessarily creating a commercial product.

NIH could recognize contributions to:

reduced hospitalization;
prevention of avoidable disease;
reduced treatment burden;
improved health-system efficiency;
improved diagnostic efficiency;
reduced use of ineffective interventions;
improved workforce participation;
reduced caregiver burden;
development of research infrastructure;
creation of skilled scientific employment; and
development of technologies or industries based on publicly funded science.

Where appropriate, cost-effectiveness, budget impact, and resource-utilization analyses can provide useful evidence.

However, economic return should remain one dimension of public impact, not its dominant definition.

10. Recognize the Public Value of Preventing Harm and Research Waste

Research can create societal benefit not only by introducing something new but also by showing that something should not be done.

A rigorous study demonstrating that an intervention is ineffective, harmful, unnecessarily expensive, or unsupported by evidence may create substantial public value.

Similarly, replication or reproducibility work that prevents widespread reliance on an unreliable finding may save research resources and protect patients.

NIH should therefore recognize:

Evidence supporting adoption

and

Evidence supporting de-adoption

as legitimate forms of public impact.

This is especially important because current incentive structures often make positive innovation more visible than the scientific work that prevents ineffective or harmful practices.

11. Distinguish Contribution From Attribution

A major methodological challenge in measuring public impact is attribution.

Changes in population health, clinical practice, or policy rarely result from a single paper, grant, laboratory, or investigator.

They often emerge through cumulative evidence produced by many researchers over years.

NIH should therefore be cautious about asking:

“Did this researcher cause this societal outcome?”

A more scientifically defensible question is:

“What documented contribution did this research make to the pathway that produced the outcome?”

Evidence could include:

Research finding → Evidence synthesis → Guideline → Implementation → Practice change → Health outcome

An individual project may contribute importantly at one or more points along this pathway without being solely responsible for the final outcome.

This contribution-based approach would reduce exaggerated impact claims while still recognizing meaningful scientific influence.

12. Public Impact Requires Time

Some research influences practice within months.

Other discoveries require decades.

NIH should therefore avoid imposing a single time horizon for public impact.

A multidimensional scientific-impact record could distinguish:

Immediate impact — dissemination, public access, stakeholder engagement.

Intermediate impact — replication, evidence synthesis, guideline consideration, implementation research.

Long-term impact — clinical adoption, population-health effects, policy influence, economic value, or establishment of new standards of care.

This would prevent foundational research from being disadvantaged simply because its societal impact has not yet matured.

13. Potential Indicators

NIH could consider indicators including:

Contribution to clinical guidelines or standards of care.
Use in public-health programs or policy.
Adoption of diagnostic, therapeutic, preventive, or care approaches.
Demonstrable contribution to patient-important outcomes.
Use of validated patient-reported outcomes where appropriate.
Contribution to accessibility and health equity.

Meaningful patient, caregiver, or community involvement.
Population reach and representativeness.
Transparent communication of uncertainty.
Appropriate public access to findings.
Transparent correction of scientific errors.
Replication or validation supporting public use.
Evidence supporting de-adoption of ineffective or harmful practices.
Economic or health-system value.
Reuse of publicly funded research resources.
Documented contribution to a broader pathway from evidence to societal outcome.

These indicators should not be collapsed into a universal “public impact score.”

Different forms of biomedical research produce public value through different pathways and over different periods.

14. Avoid Rewarding Visibility Instead of Value

Any public-impact framework should include safeguards against metric gaming.

NIH should avoid creating incentives for researchers to:

exaggerate the implications of preliminary findings;
equate media coverage with scientific importance;
pursue social-media attention;
overstate causality;
overstate clinical relevance;
selectively communicate positive findings;
minimize uncertainty; or
choose highly visible research questions over scientifically important but less publicly attractive ones.

Altmetrics and media indicators may document dissemination, but they should remain contextual indicators rather than primary evidence of societal impact.

15. A Public Impact Pathway

NIH could organize public impact around a transparent pathway:

Discovery

↓

Validation

↓

Evidence Synthesis

↓

Guideline / Policy Consideration

↓

Implementation

↓

Adoption

↓

Patient / Population Outcome

↓

Societal Value

At each stage, researchers could document their contribution and the evidence supporting it.

This would create a far more defensible measure of public impact than attempting to infer societal benefit directly from publication or citation metrics.

MedicReS Perspective

For nearly two decades, MedicReS has approached good medical research as a lifecycle extending from the research question through methodology, biostatistics, interpretation, scientific communication, and ultimately the responsible use of evidence.

This experience has reinforced a central principle relevant to the NIH RFI:

Research is not valuable merely because it is published. Its ultimate value depends on whether trustworthy evidence can contribute to better decisions.

Transparency is essential to this process. Protocols, methodological evaluation, author responses, corrections, replication findings, and appropriately accessible research outputs can strengthen not only reproducibility but also public confidence in how scientific knowledge is produced and corrected.

Our broader recommendation is therefore that public impact be connected to the same lifecycle-based framework proposed across the other NIH domains.

Conclusion

NIH has an opportunity to move public-impact assessment beyond visibility metrics toward verifiable societal contribution.

The progression we recommend is:

Media attention → Evidence of use

Citation → Contribution to decisions

Statistical significance → Clinically meaningful benefit

Guideline citation → Practice change

Availability → Accessibility

Innovation → Population benefit

Publicity → Public trust

Claimed impact → Documented contribution

And perhaps most importantly:

“Who saw the research?” → “What changed because trustworthy evidence became available?”

The goal should not be to reward scientists for making the largest claims about their impact.

It should be to recognize research that can demonstrate a credible pathway from scientific evidence to better health, better decisions, greater accessibility, stronger public trust, and meaningful societal benefit.

8. Other Areas: Building Better Researchers Before Measuring Their Impact

In addition to the areas identified in this RFI, we recommend that NIH consider a fundamental upstream question:

Before measuring the scientific impact of researchers, are we systematically ensuring that researchers have the competencies required to produce rigorous, reproducible, ethical, and impactful research?

Many problems that later emerge as failures of reproducibility, inappropriate study design or statistical

analysis, selective reporting, inefficient use of research resources, or inappropriate interpretation originate much earlier in the research lifecycle.

NIH already invests substantially in research projects, research infrastructure, training, and protected time. We suggest complementing these investments with a structured researcher competency pathway that can be evaluated through demonstrated research performance rather than course attendance or certificates alone.

A Good Medical Researcher Pilot

MedicReS has supported the development of the Good Medical Researcher (GMR) Online Training Program, developed under the editorship of Prof. E. Arzu Kanık.

The program can be completed online and is designed around the complete biomedical research lifecycle, integrating competencies in research ethics and integrity, research question formulation, study design, protocol development, population and sampling, sample-size planning, biostatistical reasoning, interpretation of effect sizes and confidence intervals, evidence synthesis, scientific reporting, peer review, and responsible use of artificial intelligence.

We propose that NIH consider testing this existing educational approach in a defined cohort of NIH-supported investigators.

MedicReS would be willing to provide NIH-selected participants with free access to the online Good Medical Researcher training program for a one-year pilot period, without a commercial financial objective.

The purpose would not be to promote or evaluate a training product. It would be to test a scientific hypothesis:

Does structured, lifecycle-based researcher education measurably improve the rigor, reproducibility, methodological competence, and scientific independence of NIH-supported investigators?

Baseline and follow-up indicators could include research-methodology competence, protocol quality, appropriateness of study design, sample-size justification, statistical analysis planning, interpretation of effect sizes and uncertainty, recognition of bias and confounding, reproducibility practices, research integrity, responsible AI use, reporting quality, manuscript quality, and progression toward independent research capability.

Where feasible, outcomes could be compared with an appropriate comparison group or baseline, and the evaluation methodology could be defined prospectively with NIH.

Measure the Researcher, Not the Certificate

Completion of the program itself should not be considered evidence of impact.

The relevant outcome is whether the researcher subsequently demonstrates improved scientific competence and produces better research.

In other words:

Course completion → Activity

Certificate → Credential

Demonstrated research competence → Outcome

Improved research quality → Impact

This distinction is essential. We do not propose replacing publication counting with certificate counting.

From Pilot to Evidence-Based Policy

If independent evaluation demonstrates meaningful improvements in research quality, reproducibility, or researcher independence, NIH could then consider whether demonstrated lifecycle-based research competency should become a recommended component of researcher development for appropriate categories of NIH-supported investigators.

Any future NIH framework should remain open and provider-neutral, allowing equivalent programs developed by universities, scientific organizations, or other qualified providers to participate if they satisfy transparent and independently assessable competency standards.

MedicReS offers its program as a pilot environment in which the concept can be tested, not as a proprietary requirement.

Why This May Have Long-Term Impact

The return on researcher development may extend far beyond an individual grant.

A research project has a defined duration. A scientifically well-trained independent investigator may conduct rigorous research for decades, develop research teams, mentor future investigators, build infrastructure, and transmit good scientific practices to subsequent generations.

The potential pathway is:

NIH investment

→ Researcher competency

→ Better-designed research

→ More rigorous and reproducible evidence

→ Greater scientific impact

→ Independent research leadership

→ Future mentorship

→ Sustainable scientific capacity

This also connects the seven areas described in this RFI. Rigor, reproducibility, responsible data sharing, collaboration, translation, foundational exploration, and public impact ultimately depend, at least in part, on the competencies of the researchers responsible for producing and interpreting the science.

Our Proposal

Rather than assuming that researcher education improves research quality, we propose testing it as a scientific intervention.

NIH could identify the cohort. MedicReS could provide the existing online Good Medical Researcher educational environment without charge during the pilot. Outcomes could be prospectively defined and independently evaluated.

If it works, the evidence would support expansion.

If it does not, the results would still provide valuable information about how researcher development should be redesigned.

This approach reflects the principle underlying the broader recommendations in our response:

Do not only measure better research. Build better researchers—and measure whether better research follows.

Description: Supplementary report presenting a lifecycle-based framework for measuring scientific impact, the rationale and proposed indicators across all NIH RFI domains, and proposed NIH pilots for time-bounded open scientific review and lifecycle-based researcher competency development.

188. Xiaoxin Wang

I am responding: On behalf of myself

Name: Xiaoxin Wang

Name of Organization: Georgetown University

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: Nature published a paper a decade ago demonstrating that nearly 90% of tested landmark studies were not reproducible. By extension, a vast portion of grant funding could be supporting non-reproducible research. The frustrating reality is that the scientific community seems to have grown comfortable with this baseline.

With new administration, this issue must be brought back to the forefront. Our current peer-review system and study sections fail to prevent non-reproducibility—and may actively reward it. Without a dramatic overhaul of how grants are evaluated, I propose the following targeted changes:

Timing & PI Justification: Every grant application should explicitly answer two questions: What recent scientific or technological advance makes this proposed experiment viable right now rather than years ago? and Why is this specific PI, rather than their peers, uniquely qualified to execute it?

Verifiable & Standardized Data: Key data in grant and progress reports should prioritize publicly verifiable approaches (e.g., RNA-seq) deposited in public repositories where data manipulation is difficult. Alternatively, core samples should be submitted to NIH-designated facilities to generate independent validation. Easily manipulated, qualitative figures from traditional assays should no longer serve as primary proof.

Panel Anonymity & Annual Rotation: To eliminate cronyism and implicit bias, study section panels should rotate fully on an annual basis, and reviewer identities must remain undisclosed prior to review.

Fraud Flags & Accountability: Unreproducible findings should be treated as an explicit fraud flag rather than a harmless error, triggering closer administrative scrutiny. Furthermore, a paper's stated limitations must directly downgrade its claimed impact, preventing authors from making overblown claims while burying critical caveats in the fine print.

2. Data, Software, and Model Sharing: To accelerate scientific discovery through crowdsourced effort, I propose a fast-reaction funding mechanism dedicated to reproducible, novel observations. Because these early discoveries are initially unfunded, applicants should not be expected to provide complex preliminary experiments. Instead, funding should focus on validating the core observation, and the

originating Principal Investigator (PI) should have the option to delegate or assign specific follow-up studies to other qualified research groups.

3. Training and Mentorship: When the most experienced research workforce relies almost entirely on soft money, scientists face immediate displacement the moment a supporting grant ends. Without a viable solution to retain this veteran workforce, the rationale and necessity for continually training a young workforce become nearly impossible to justify.

4. Collaboration: Productive scientific collaboration relies on a fair system for awarding credit. To encourage this, I propose a funding mechanism where a PI with a novel finding is awarded a grant designed to bring in external collaborators to address secondary or complementary questions. Under this framework, the PI who generated the original finding receives a controlling 51% majority credit, while the remaining 49% is distributed among collaborating partners who address the necessary secondary questions to collectively advance the science.

Name:

Name of Organization:

Type of Organization: Academic Institution

Role: Investigator/Researcher

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: Direct reproducibility studies are typically only good at finding that labs do things differently or use slightly different materials. Under close scrutiny the 'replication crisis' does not hold up in many fields. If a finding or idea is significant and impactful, then it is used as a foundation to build upon as others try to advance the finding. It is at this stage that reproducibility matters. If the idea can't be confirmed, then science moves on. I would oppose using funds to support experiments with the goal of simply testing if a finding can be reproduced in another lab. Funding impactful science as determined by peer-review that is free of political influence is the best way to address rigor and reproducibility.

2. Data, Software, and Model Sharing: The current sharing of data through publications and open-source databases and data warehouses is an important way that has advanced research. It is working well, as demonstrated by a study from Holst et al. published in Nature 2026 that disruptive science and technology have remained steady since the 1960s despite a significant reduction in government investment in science and technology when adjusted for inflation. If the NIH reduces or limits the support for paying publication charges occurs, this will significantly hamper the goal of sharing. Another important way of sharing data, software, and models is through conferences and collaborations (many of which start at a conference). Scientific communities have meetings that support real-time sharing that help advance research and technological development. Conferences allow scientists from small and large private companies, non-profits, governments, academia, and more to engage in sharing. Moreover, students, trainees, researchers, scientists, and lead investigators are involved, allowing the best ideas to flow from several places. Removing support for attending conferences and meetings will further harm the sharing necessary for breakthroughs.

3. Training and Mentorship: Mentoring and training the next generation of creative researchers must happen to build healthier communities and strong economies within the US. The NIH should be proud of its strong history in funding F, T, and K awards that have contributed to innovative breakthroughs and supplied a critical workforce that has strengthened the US economy. Funding research and training at universities through direct and indirect costs has made the NIH an amazing partner in mentoring, training, and supporting the clinicians who address our pressing medical needs and the scientific workforce that stimulates our economy. Peer review of these applications should remain. The NIH should create additional paths for F or T awardees to apply for transitional awards to help retain the initial investment in people. The timelines on K awards should be re-examined and extended to be more inclusive since some research takes longer than others (i.e., developing a truly innovative project related

to aging is likely to take more time than a project on a rapidly growing cancer). Importantly, NIH should focus on a decentralized approach in partnerships with states and universities to best fit the state and local communities' needs. NIH should provide a supporting role, not a regulatory role. Moreover, NIH investment in training and mentorship should help recruit the best and brightest in the world to come to the USA for training. We should also retain them to make the US's biomedical research and health systems the envy of the world. Restricting access would be counterproductive.

4. Collaboration: I agree that collaborations are essential for pushing our boundaries of knowledge and technology and am encouraged that the NIH may start to improve its support for collaborative research. Collaborations have become a bedrock of modern science. However, some NIH changes threaten to harm collaborations. For example, capping grant submissions to 6 has discouraged MPI projects. Some potential NIH changes further threaten collaborations. For example, capping a PI at 2, 3, or 4 grants. NIH should encourage and grow collaborations. One simple way to stimulate collaboration is to exclude collaborative grants from the aforementioned caps. Funding new collaborative projects would also help. The NIH could do this immediately by reducing the number of forward-funded and multiyear-funded NIH projects. Additionally, the NIH could create new initiatives to support interdisciplinary research without drawing resources away from institutes that have already faced multiple cuts.

5. Entrepreneurship and Translation: Entrepreneurship and translation should be an important aspect of NIH's responsibility to taxpayers. Support for startup entrepreneurship projects should be continued and should be done in partnership with non-profits, academic institutions, and private startups. However, it should not come at the cost of foundational (i.e., basic) research that all translational, innovation, and entrepreneurial effort is based on. Support for foundational research must remain a priority.

6. Foundational Scientific Exploration: I agree that we need to support innovative ideas. It is important to remember that paradigm-shifting breakthroughs can come from high-reward, well-justified, and feasible projects that are currently funded through peer review of investigator-initiated R01 projects. Recognizing the importance of high-risk, high-reward projects is easy, but supporting them is challenging. One easy step the NIH could take today is to exclude applications to high-risk funding mechanisms from the 6-application-per-PI cap and the potential 2-4 funded-projects-per-PI cap the NIH is considering. Additionally, the NIH could create new initiatives to support a high-risk, high-reward project on existing R01s (i.e., a new 3rd or 4th aim). This could be a separate, funded 5th and 6th year for a project that has led to an innovative, novel idea that is too high-risk for an R01 renewal.

7. Public Impact: It is important that the NIH helps educate taxpayers, politicians, and the public at large that research is a long game. Today's discoveries do not translate to tomorrow's cures. The process takes years, and it is important that the public understands the process and the importance of this timeline to public health and safety. Moreover, the NIH must continue to recognize that the impact of a project is best assessed by a strengthened peer review process. Politically appointed personnel that lack the true expertise that is provided by peer review should not override identification of the most meritorious research when making funding decisions. AI cannot assess impact and should not be used to make funding decisions. If the NIH uses politically appointed individuals or AI to override peer review, trust from taxpayers and stakeholders in the NIH will be further eroded. Finally, the NIH needs to invest in research that will impact policy making. The public needs to feel the impact as they have enjoyed with clean water, safe food, and clear air to breathe that we enjoyed prior to 2025.

8. Other Areas: The NIH must restore trust from taxpayers and stakeholders, not be leading the charge to further erode it. Trust in the NIH is falling more rapidly now than at any point in my career. Currently, policy decisions are made without scientific foundations or unbiased data. Attacks on scientists, including previous government officials, are further harming progress that the NIH can make at this time. Changes outlined in “Strengthening Replication and Reproducibility of NIH-funded Research” and “Leading in Gold Standard Science” will be with skepticism because of the attacks on the CDC and NIH. The NIH should not move forward with the recently proposed changes. Instead of focusing on changing the way science is done, it would be better if we had an NIH administration that was focused on supporting research.

I am responding: On behalf of myself

Name: Maryam Al-Mujtaba

Name of Organization: Avarynth Group

Type of Organization: Not Applicable

Role: Investigator/Researcher

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: Research assessment should explicitly distinguish the quality of research from its reception. Publication counts, journal prestige, and citation metrics may capture aspects of visibility or reach, but they do not directly measure whether research was conducted rigorously or whether its findings can be reproduced. Future assessment systems should therefore explicitly reward methodological rigor, transparency, scientific integrity, and reproducibility.

I recommend that research assessment treat quality and reach as two distinct, separately measured dimensions rather than combining them into a single score. Quality—including contribution to knowledge, methodological rigor, and reproducibility, should be evaluated through structured expert judgment, similar to the way grant reviewers evaluate proposals: a reviewer examines the work in depth and translates that judgment into a structured assessment. Reach, by contrast, should be measured separately and quantitatively, with appropriate adjustments for factors such as accessibility and career stage so that these measures are not systematically distorted by them.

This mixed-methods approach is reflected in my Ten Triple R Principles for Guiding the Development of Future Research Assessment Metrics, which call for expert judgment for dimensions that cannot be meaningfully reduced to counts, alongside appropriately adjusted quantitative measures for dimensions that can be measured quantitatively, within a transparent and multidimensional assessment system. I am currently developing a working framework built from these principles and expect to share it as it matures.

2. Data, Software, and Model Sharing: N/A

3. Training and Mentorship: Research assessment should recognize that scientific contribution extends beyond publications and citations. Training and mentorship are essential mechanisms through which knowledge, skills, and scientific standards are transmitted across generations of researchers.

Specific measurable indicators could include: mentoring activities; trainee completion and progression; development of trainees into independent researchers; contributions to methodological or professional development; and evidence of sustained mentorship relationships. Quantitative indicators should be interpreted alongside qualitative evidence because trainee outcomes are influenced by discipline, career stage, institutional resources, and other contextual factors.

Implementation approach: NIH could allow investigators to document mentorship contributions and outcomes as a distinct category of scientific contribution, supported by structured narrative evidence and selected indicators.

Potential benefit: This would reward researchers for investing in the scientific workforce rather than creating incentives that prioritize individual productivity at the expense of mentorship.

Feasibility consideration: Assessment should avoid comparing early-career and senior investigators using identical cumulative indicators. Career-stage adjustment is essential because opportunities and accumulated outcomes differ substantially across stages.

4. Collaboration: N/A

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: N/A

7. Public Impact: Scientific impact extends beyond citations and academic attention. Research can influence clinical practice, policy, education, public understanding, innovation, accessibility, and societal well-being. Future assessment systems should therefore distinguish attention from actual contribution. A paper may receive substantial media or social-media attention without producing meaningful impact, while research with limited academic visibility may substantially influence policy or practice.

I recommend assessment approaches that explicitly separate volume of attention from demonstrated translation into clinical practice, policy, education, industry, innovation, or other forms of meaningful use. Public impact should be credited where genuine application or use of research can be demonstrated, rather than inferred solely from mentions, media coverage, social-media attention, or other indicators of visibility.

My The Ten Triple R Principles for Guiding the Development of Research Assessment Metrics identify societal impact and knowledge translation as core dimensions of research assessment, alongside the production of knowledge itself. The principles also call for measures of research reach to account for factors such as accessibility and career stage, so that equally rigorous and valuable work is not systematically undercounted because of unequal access to the infrastructure through which visibility and citations accumulate.

I am currently developing a working framework built from these principles and expect to share it as it matures.

8. Other Areas: A principles-based approach to the development of future research assessment metrics

I propose that NIH consider not only which individual indicators should be added to existing systems, but also the principles that should guide the development, governance, and implementation of future research assessment metrics.

I have developed the Ten Triple R Principles for Guiding the Development of Research Assessment

Metrics, organized into three domains: foundational principles, assessment principles, and system design principles.

Foundational Principles

1. Understand the Philosophical Divide: Research assessment is not purely a technical exercise. The metrics used to evaluate science operate within scientific, economic, and political systems. Those developing future assessment systems should consider how incentives, ownership, and governance shape what research is rewarded.

2. Researchers Must Author and Ratify the Standards: The research community should play a central role in developing and collectively validating the standards by which scientific contributions are assessed.

Assessment Principles

3. Measure Contribution, Not Prestige: Research should be assessed according to what it contributes to knowledge rather than the prestige of the journal in which it appears.

4. Reward Methodological Rigor: Assessment should explicitly recognize methodological quality, transparency, scientific integrity, and trustworthy evidence.

5. Value Reproducibility: Research should be rewarded for being sufficiently transparent and robust to permit testing, reproduction, replication, and cumulative scientific progress.

6. Adjust for Accessibility: Measures of reach should account for differences in access to research because accessibility affects visibility and the opportunity for knowledge to be used.

7. Adjust for Career Stage: Cumulative indicators such as citation counts should not systematically advantage researchers simply because they have had more years to accumulate them.

8. Recognize Societal Impact and Knowledge Translation: Research assessment should recognize meaningful contributions to policy, clinical practice, education, innovation, industry, and public engagement.

System Design Principles

9. Assess Through Mixed Methods: Research assessment should combine structured quantitative indicators with expert human judgment rather than assuming that either approach alone can adequately capture scientific contribution.

10. Transparency in Assessment Methods: Researchers should be able to understand how assessment systems operate, how indicators are calculated, who governs them, and how they evolve.

Together, these principles suggest that future research assessment should be multidimensional. No

single metric can adequately capture the quality, rigor, reproducibility, reach, accessibility, translation, and broader contribution of scientific research. NIH could support the development and empirical testing of assessment approaches that combine multiple dimensions rather than seeking a single replacement for publication counts or citation metrics.

Finally, I recommend that any future assessment system developed in response to this initiative be created through meaningful engagement with researchers across career stages, disciplines, institution types, and sectors. The people who produce and validate scientific knowledge should play a central role in defining how scientific contribution is measured and rewarded.

Description: The Ten Triple R Principles for Guiding the Development of Research Assessment Metrics," developed by Maryam Al-Mujtaba. The document outlines a principles-based approach to the development, governance, and implementation of fair, comprehensive, and multidimensional research assessment systems.

I propose the Ten Triple R Principles for Guiding the Development of Research Assessment Metrics, organized in three parts: the foundations on which assessment should rest, what assessment should measure, and how the assessment system itself should be designed (see Figure 1).

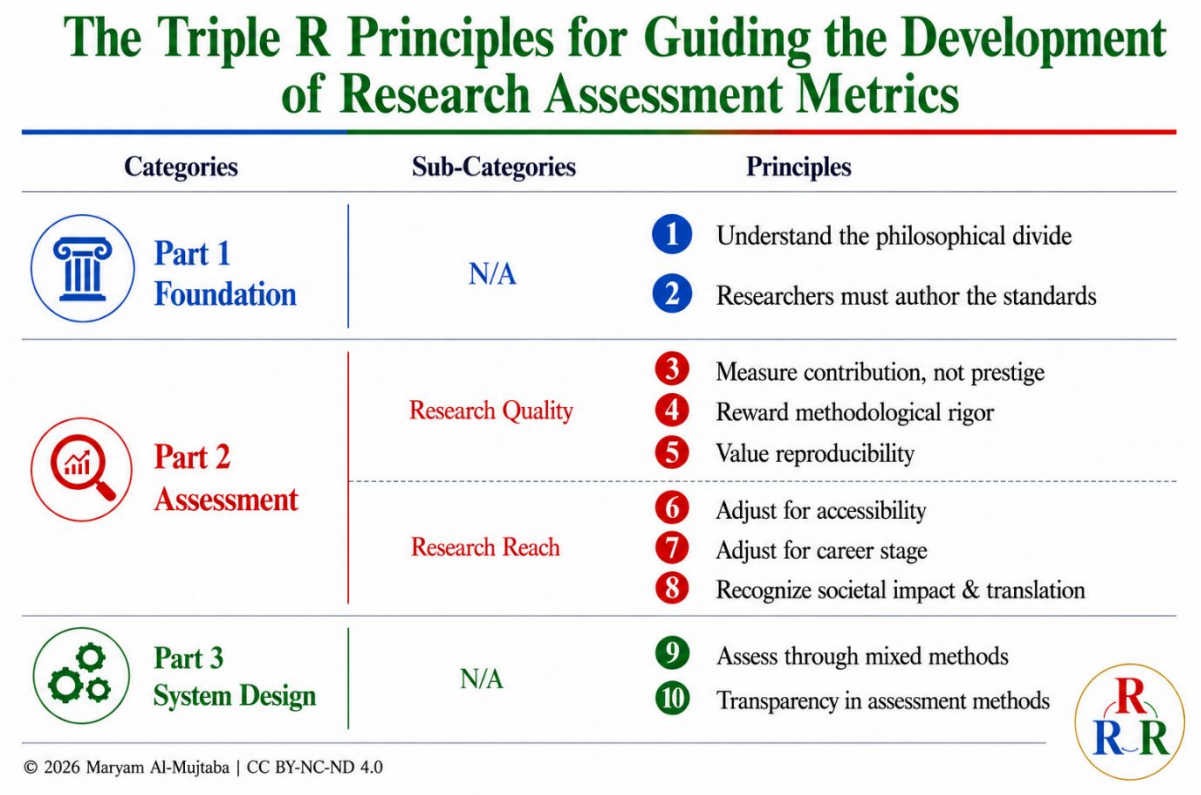

Figure 1: The Triple R Principles for Guiding the Development of Research Assessment Metrics

Part I: Foundational Principles *Why we assess, and who should hold the authority to define it.*

Principle 1, Understand the Philosophical Divide: Academic publishing has three dimensions: the scientific, the economic, and the political. For decades, our philosophical perspective as researchers has confined us to the first. We have seen science as our contribution to society and peer review as our service to it, and in doing so we left the economic and political dimensions uncontested. Publishers saw the same things differently: not as contribution and service, but as free content and free labor to be monetized. That is *The Philosophical Divide*, and it is how an equitable bargain, in which researchers created knowledge and the system served them, was quietly broken. Anyone building a new system of research assessment, and it should be researchers who build it, must understand this divide, because it determines what they build. A researcher who does not see the economic and

© 2026 Maryam Al-Mujtaba | Licensed under a Creative Commons Attribution-NonCommercial-NoDerivatives 4.0 International License (CC BY-NC-ND 4.0)

political forces at work could, however unintentionally, produce another metric that feeds the current inequitable business model.

Principle 2, Researchers Must Author and Ratify the Standards: The authority to define good science should rest with those who produce and validate it. Researchers should not only author the criteria by which research is assessed but also collectively ratify them. This is precisely what never happened with the impact factor. It was devised by the information scientist Eugene Garfield as a commercial tool to help libraries choose which journals to subscribe to, not as a measure of research quality. No consensus was reached, no policy was agreed; it simply drifted into use, repurposed until the journal you published in came to define how good a scientist you were. A standard that governs hiring, promotion, and funding should never be adopted by default.

Part II: Assessment Principles *What good research assessment should measure.* These principles fall into two groups. The first concerns the quality of the research itself, what it contributes and how soundly it was done. The second concerns its reach, how far, and how fairly, that knowledge travels into the world. *Today's metrics largely measure reach (citation count) and call it quality.* A fair assessment must measure both and keep them distinct.

Research Quality

Principle 3, Measure Contribution, Not Prestige: The reputation of a journal is not the same as the value of a piece of research. Neither journal prestige nor citation counts alone should determine scientific quality. Research should be evaluated according to what it contributes to knowledge.

Principle 4, Reward Methodological Rigor: Scientific progress depends not only on novel ideas but on trustworthy evidence. Research assessment should explicitly value methodological rigor, transparency, and scientific integrity, the qualities that make evidence trustworthy.

Principle 5, Value Reproducibility: A finding that cannot be reproduced cannot be relied upon. Research assessment should reward work transparent enough to be tested, replicated, and built upon by others, because reproducibility is the foundation of cumulative science, not a bureaucratic checkbox.

Research Reach

Principle 6, Adjust for Accessibility: Knowledge cannot create impact if it cannot be accessed, and citation-based measures quietly punish work that is harder to reach. Open-access research is systematically more visible, and therefore more cited, than work behind a paywall, independent of its quality. Any assessment that uses citations as a measure of reach must correct for this, so that a paper is not judged less influential simply because fewer people could access it.

Principle 7, Adjust for Career Stage: Citation counts accumulate over time, so they inevitably favor established researchers over early-career ones. An early-career researcher has had fewer years for their work to be read and cited, not because it is less valuable, but because it is more recent. Where citation-based measures are used, they must be calibrated

© 2026 Maryam Al-Mujtaba | Licensed under a Creative Commons Attribution-NonCommercial-NoDerivatives 4.0 International License (CC BY-NC-ND 4.0)

for career stage, so that two equally strong researchers are not ranked differently simply because one has had twenty years and the other three.

Principle 8, Recognize Societal Impact and Knowledge Translation: Research exists to improve the world beyond academia. Helping knowledge reach and be used by others, through translation into policy, clinical practice, education, industry, innovation, and public engagement, matters just as much as creating it in the first place. Scientific influence extends well beyond citations.

Part III: System Design Principles *How the assessment system itself should operate.*

Principle 9, Assess Through Mixed Methods: The two halves of assessment call for two different methods. The dimensions of quality, contribution, rigor, and reproducibility cannot be reduced to citation counts; they require expert human judgment. However, that judgment is not a vague verdict. Just as grant reviewers read a proposal in depth and then assign it a score, expert assessors evaluate a work's quality and express that evaluation as a structured number. The dimensions of reach, by contrast, are quantitative from the start, captured through numbers corrected for the conditions that distort them. Research assessment should therefore be mixed-methods, reflecting the methodological pluralism that already characterizes good research. Both halves are expressed as scores and combined into a single, structured assessment, so that expert judgment and measured reach carry transparent, comparable weight. Neither the reviewer's judgment nor the raw number is sufficient by itself.

Principle 10, Transparency in Assessment Methods: A metric that cannot be understood cannot be trusted. If researchers do not know how an assessment is calculated, who controls it, or how it changes over time, the door reopens to the very capture these principles resist. Future research assessment must be transparent in its methods, its governance, and its evolution, open to scrutiny by the community it serves.

How to Apply These Principles: A single system or metric may not comprehensively address every principle across all three categories, and that is to be expected. But all three categories matter; assessment must be multidimensional, and a legitimate system must reflect that:

1. **Foundational Minimum:** The two foundational principles (*Understand the Philosophical Divide* and *Researchers Must Author and Ratify the Standards*) are non-negotiable and must be fulfilled.
2. **Assessment Minimum:** Within the assessment category, a system must address at least one of the three principles in the research quality subcategory and at least one of the three in the research reach subcategory, so that it captures different dimensions of a work's value and produces a more rounded assessment, rather than mistaking reception for contribution.
3. **System Design Minimum:** It must satisfy at least one of the two system design principles, so that the way it operates is itself sound.

Why Principles Matter: For decades, we have debated which metric should replace the impact factor. Perhaps we have been asking the wrong question. Instead of asking which metric, we should first ask which principles should guide the development of those metrics.

© 2026 Maryam Al-Mujtaba | Licensed under a Creative Commons Attribution-NonCommercial-NoDerivatives 4.0 International License (CC BY-NC-ND 4.0)

Consider where we are now. As one recent review notes, the scientific community has developed more than sixty indices to evaluate researchers (Bihari et al., 2023). Beyond the impact factor, the h-index, SCImago Journal Rank, Field-Weighted Citation Impact, and Altmetrics that I discussed in Issue 9, there is the g-index, the w-index, the Ψ-index, and dozens more. But look closely, and nearly all of them are measuring the same thing. They are citation-based, differing mainly in the formula applied to the same underlying data: some count an author's citations, some a journal's, some weight highly-cited papers more heavily. The few that reach beyond citations do not go far. Altmetrics, for instance, tries to capture societal reach by tracking how often a work is mentioned in the news, on social media, in policy documents, or online. But it counts attention, not impact. It records that a paper was mentioned, not why. A work might be mentioned because it informed a policy or improved practice, or because it is controversial and people are citing it to say it is wrong. The metric cannot tell the difference. Attention is not the same as contribution.

I am not the first to propose principles for research assessment: Over the past decade, these are the four documented that I came across:

1. *The DORA* (2013) urged us to stop treating the Journal Impact Factor as a measure of individual quality.
2. *The Leiden Manifesto* (2015) offered ten principles for the responsible use of metrics, insisting that quantitative indicators support rather than replace expert judgment.
3. *The Metric Tide* (2015) set out five dimensions of responsible metrics: robustness, humility, transparency, diversity, and reflexivity.
4. *The Hong Kong Principles* (2019) focused on rewarding research integrity.

These four principles, for all their value of telling evaluators how to use metrics responsibly; they share three limits:

1. They do not tell us how to design the metrics in the first place. They are principles for behavior, not blueprints for building. Second, none confronts the economic and political capture of research assessment.
2. The Philosophical Divide is absent from all of them.
3. None of them was ever operationalized into a working assessment instrument. They are declarations and guidelines.

A decade on, we still evaluate research with the very metrics they criticize, because principles alone change nothing until someone builds the tool that embodies them.

I developed the Triple R Principles independently, from my own analysis of the economic and political dimensions of academic publishing. Yet several of my principles converge with theirs: mixed-methods assessment, transparency, and fairness appear in their work as well as in mine. I take that convergence as a strength. When people reasoning from different starting points arrive at the same conclusions, those conclusions are more likely to be sound. However, the Triple R Principles go further. Where the others guide how to *use* metrics responsibly, mine are designed to guide the *development* of research assessment metrics that are fair, comprehensive, and multidimensional, and that can be operationalized into a working framework (See Figure 2).

The Ten Triple R Principles in Relation to Existing Principles

Category	Triple R Principle	Annotation (What This Principle Does)	Explanation (Why It Matters)	Relation to Existing Principles
Foundation Why we assess, and who should hold the authority to define it.	1 **Understand the Philosophical Divide**	• Clarifies the philosophical differences in research values that shape assessment.	• Makes explicit the value divide behind assessment systems.	**New** — no existing principle explicitly states either of these two principles.
	2 **Researchers Must Author & Ratify the Standards**	• Ensures researchers are the authors and approvers of the standards that assess them.	• Returns authority and accountability to the research community.	
Assessment: Quality The quality of the research itself — what it contributes and how soundly it was done.	3 **Measure Contribution, Not Prestige**	• Evaluates what researchers achieve, not where they publish.	• Shifts focus from journal prestige to real research contribution.	**Convergent** — central to DORA; echoed in the Leiden Manifesto.
	4 **Reward Methodological Rigor**	• Values robust, transparent, and reproducible methods.	• Rewards the rigor of how research is designed and conducted.	**Convergent** — central to the Hong Kong Principles.
	5 **Value Reproducibility**	• Promotes openness and the ability to verify and build on research.	• Encourages transparency and verifiability as core values.	**Convergent** — reflected in the Hong Kong Principles.
Assessment: Reach How far, and how fairly, knowledge travels into the world.	6 **Adjust for Accessibility**	• Ensures research is accessible to all, broadening reach and impact.	• Corrects for barriers that limit dissemination and visibility.	**New** — no existing principle explicitly states this.
	7 **Adjust for Career Stage**	• Addresses structural disadvantages faced by early-career researchers.	• Creates a fairer playing field across career stages.	**Partial** — existing principles recognize this as an issue but do not provide an explicit principle or requirement to address it.
	8 **Recognize Societal Impact & Knowledge Translation**	• Elevates contributions that advance society and translate knowledge beyond academia.	• Values impact in the real world, not just within academia.	
System Design How the assessment system itself should be designed.	9 **Use Quantitative Assessment Measures**	• Balances metrics with expert judgment for a holistic assessment.	• Prevents overreliance on metrics and preserves expert judgment.	**Convergent** — Leiden Manifesto Principle 1 (supporting quantitative data with qualitative, expert judgment).
	10 **Transparency in Assessment Methods**	• Ensures openness, clarity, and accountability in assessment processes.	• Builds trust and enables sccutiny, improvement, and accountability.	**Convergent** — Leiden Manifesto Principle 4 ("Keep data collection and analytical processes open, transparent and simple"); Metric Tide (Transparency).

191. The Massive Analysis and Quality Control (MAQC) Society

I am responding: On behalf of an organization

Name: Wendell Jones

Name of Organization: The Massive Analysis and Quality Control (MAQC) Society

Type of Organization: Professional Organization/Association

Role: Organizational Official

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: The MAQC Society (maqcsociety.org) appreciates this opportunity to respond to the NIH Request for Information on Measuring and Rewarding Scientific Impact. As an organization dedicated to advancing quality control and reproducibility in biomedical research (Shi L et al., Nature Biotechnology 2017, PMID: 29220036), we strongly support NIH's efforts to align its measures of scientific success with its core mission of generating knowledge that enhances health, lengthens life, and reduces illness and disability. We focus our comments on the category of Rigor and Reproducibility, drawing upon our recently accepted position paper, "Ensuring multiomics data reproducibility for artificial intelligence with reference materials as a common calibrator" (Shi L et al., Nature Biotechnology, in press); a proof copy is attached for reference.

The Challenge: A Systemic Root Cause of Irreproducibility
For three decades, the omics field has struggled with batch effects and irreproducibility that fundamentally undermine the rigor of biomedical research. A primary root cause is a deeply flawed practice: treating raw instrument responses (fluorescent intensities, read counts, or peak areas) as direct surrogates for analyte concentration. Because instrument sensitivity varies substantially across batches, laboratories, and platforms, the same underlying concentration can generate dramatically different numerical values under different conditions. This technical variation is often larger than true biological signals of interest and can become amplified by AI/ML models as spurious biological features. Hundreds of batch-effect correction algorithms have been developed. However, without proper calibration or stable reference material, these methods do not directly measure or address the root cause and thus, can induce technical effects as well as remove them.

A Solution: Reference Materials as a Common Calibrator
The MAQC Society proposes a practical, measurement-based solution: the routine co-profiling of community-adopted reference materials alongside study samples, with results reported as sample-to-reference ratios (SRR). When a common reference sample is analyzed in the same batch as study samples, the ratio of the study sample response to the reference response removes the batch-specific sensitivity factor on a feature-by-feature basis. This converts unstable, batch-specific instrument responses into measurements anchored to a common calibrator, making data far more comparable across batches, laboratories, platforms, and time. The Quartet multiomics project has demonstrated the feasibility of this approach across epigenomics, transcriptomics, proteomics, metabolomics, and other platforms (www.nature.com/collections/ibadeahigd). We note that SRR is platform-agnostic and can be

implemented with existing reference materials from NIST, the Quartet project, and other community resources.

Specific Recommendations for NIH
We respectfully urge NIH to consider the following specific, measurable indicators and implementation approaches:

1. Require Reference Material Co-Profiling as a Default Expectation for Funded Omics Studies. The cost of co-profiling with an accessible reference sample is modest compared to the cost of irreproducible research. NIH should establish grant review criteria that evaluate whether applicants have included appropriate reference materials in their experimental design and budget. Pilot programs could support the development of matrix-specific references for underserved areas (e.g., tissues, stool, single-cell, or spatial omics). This requirement would serve as a measurable indicator of rigor that is objective, feasible across institution types, and scalable.

2. Fund the Metrological Characterization of Community-Adopted Reference Materials. NIH should support international consortia in developing additional reference material optimized for different biological specimens (such as specific tissues or blood) and fully characterizing the absolute concentrations of analytes in these additional and currently existing reference materials. This one-time investment would create a shared resource, bypassing the need for individual laboratories to perform costly SI-traceable measurements for every analyte in every study sample. It would also enable a future upgrade from SRR to absolute quantification, maximizing the value of NIH's research investments.

3. Incentivize Data Sharing That Includes Reference Material Raw Data. NIH should require that data deposition for funded omics studies include raw data from reference materials co-profiled with study samples, enabling independent SRR calculation, reanalysis, and quality evaluation. This provides an objective, measurable indicator of data quality and reusability that goes beyond mere publication counts.

4. Support Training in Measurement Science Fundamentals. NIH training programs should ensure that the next generation of biomedical researchers are trained in measurement science fundamentals, including the principles of calibration, reference materials, and quality control. This would create consistency and standards across career stages and institution types.

Potential Benefits
The SRR framework offers transformative benefits: improved reproducibility, enhanced data interoperability for AI/ML applications, reduced false discoveries, and more reliable translation of omics findings to clinical and regulatory settings. It shifts reproducibility from a retrospective validation to a proactive design principle.

The SRR approach is feasible across diverse research settings. For early-career investigators, co-profiling reference materials provides an objective quality control metric that can strengthen grant applications and publications. For resource-limited institutions, reference materials can be shared across laboratories, and the cost of co-profiling a small number of replicates is minimal compared to the total cost of a

typical omics experiment. For large-scale cohort studies, reference material co-profiling should be incorporated from the outset. For emerging technologies such as single-cell and spatial omics, analogous strategies using matrix-matched reference samples or synthetic spike-ins should be actively developed.

We acknowledge potential challenges. No single reference material can perfectly mimic every biological matrix, and matrix mismatch or commutability issues may persist. Analytes absent from a reference cannot be ratio-normalized. However, these are surmountable limitations that should be addressed through continued community investment rather than used as justification for inaction. The MAQC Society is actively working to expand reference materials for additional matrices.

Conclusion
Reproducibility is not a luxury; it is fundamental to the integrity of science. The MAQC Society urges NIH to embrace reference-material co-profiling using established community reference material and ratio-based quantification as a new default expectation for funded omics research. By requiring this practice, funding the characterization of community reference materials, and incentivizing training in measurement science, NIH can lead the biomedical community toward a truly reproducible foundation for discovery in the AI-omics era.

We thank NIH for this opportunity to provide input and stand ready to assist in implementing these recommendations.

Respectfully submitted,

The MAQC Society

Check for updates

Reference materials should be adopted as a common calibrator for multiomics measurement and co-profiled with study samples. Multiomics results should be reported as sample-to-reference ratios so that they are reproducible and suitable for artificial intelligence tools.

The convergence of multiomics, systems biology and artificial intelligence/machine learning (AI/ML) delivers tools such as virtual cells[1] and personalized predictive models[2], but these applications are limited by the quality of their training data[3]. Batch effects, measurement platform differences and other technical variations can become amplified features that AI/ML models learn as 'biological signals', which can then become downstream sources of spurious biological inference. Recent benchmarks show that several state-of-the-art deep-learning perturbation models do not yet consistently outperform simple linear baselines in current evaluation settings, underscoring the need for better data standards[4]. The emerging reproducibility crisis in AI-driven biomedicine will only intensify unless the community redefines multiomics data quality.

Flagship initiatives such as the UK Biobank, All of Us, Fudan Taizhou Longitudinal Cohort and China Kadoorie Biobank are generating vast multiomics datasets across millions of individuals. AI-driven research will use and integrate this data, requiring controls for accuracy and interlaboratory reproducibility. There already exist prespecified data acceptance criteria and well-established guidelines for bioanalytical method validation and study sample analysis for the pharmaceutical industry[5], and multiomics data should also adopt requirements that consider within-laboratory, cross-laboratory and cross-platform reproducibility.

Commercial plasma proteomics platforms (for example, Alamar NULISA, Illumina IPP, Olink Explore HT) rely on their own proprietary references to improve cross-batch reproducibility. However, proprietary references are not community-adopted standards and can limit interoperability across technologies by confining users to vendor-specific ecosystems. A shared, open, physically anchored standard set would support comparable measurements across laboratories, platforms and time, as advocated for blood proteomics[6]. Well-characterized reference-material resources already exist for several important biological and technical uses, including the Quartet multiomics materials[3] for cell-based applications from the Massive Analysis and Quality Control (MAQC) Society[7], materials for plasma metabolomics or proteomics[8] and liver proteomics[9] from the National Institute of Standards and Technology (NIST) of the United States of America, and the Plasmix suite of reference materials[10] developed by MAQC for plasma multiomics. These resources establish reference-material-based harmonization as already practical for parts of the multiomics ecosystem, and it can be expanded through coordinated community efforts.

Here, we propose the use of suitable community-adopted standards so that data generated today remain reproducible, interoperable, interpretable and suitable for future scientific or regulatory decision-making. This requires the development, management and continued use of reference materials[11], harmonized metadata, transparent sample processing and analysis pipelines, and AI-ready data values. Within this framework, reproducibility shifts from a retrospective validation to a proactive design principle. Operationally, this means that high-quality multiomics datasets should include stable reference anchors, harmonized metadata, transparent analytical provenance, and reporting formats that preserve comparability across batches, laboratories and future analytical methods[3].

The root cause of irreproducibility: instrument responses as surrogates of concentration

For single-analyte measurements, the instrument response is related to concentration by establishing a calibration curve using reference standards for that analyte. The concentration of a new sample can then be deduced from its instrument response and the calibration curve[5]. This approach is feasible when the number of analytes is small and standards are available for each analyte. In large 'omics studies, thousands to millions of analytes (genes, transcripts, proteins or metabolites) are measured simultaneously, and establishing a calibration curve for each analyte is practically impossible because of the lack of individual reference standards and prohibitive cost.

The 'omics field has adopted a pragmatic but deeply flawed shortcut since 1996 by treating raw instrument responses as direct surrogates for concentration[12]. The same underlying concentration of an analyte in the same sample can generate substantially different instrument responses when measured under various batch- or platform-specific sensitivity states (Fig. 1a). The consequence is that biological information from sample analytes becomes disguised by unwanted technical variation such as batch effects, directly undermining downstream

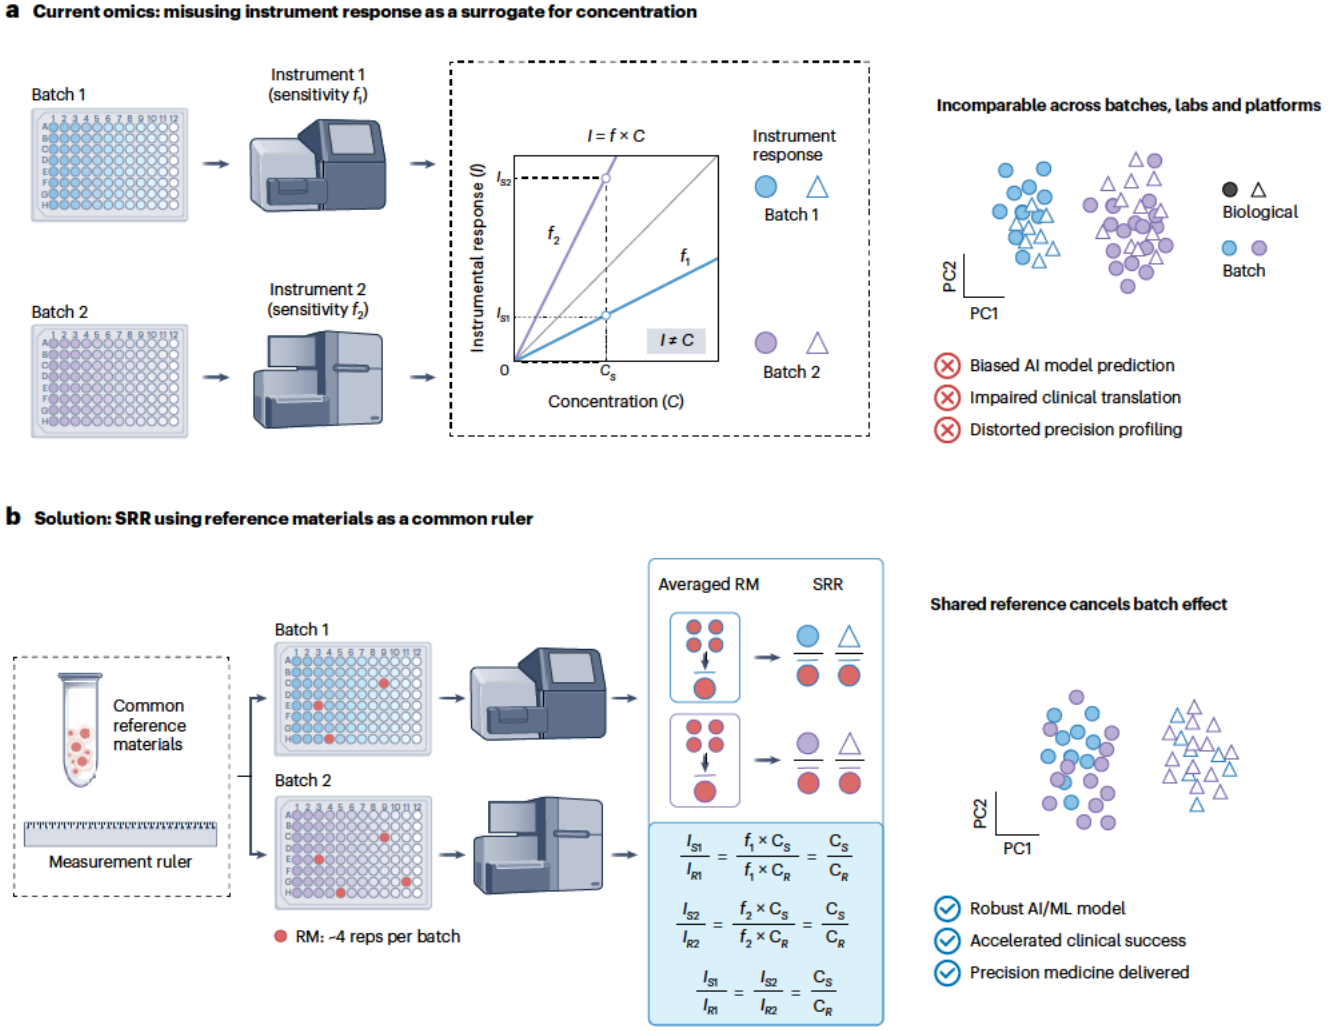

Fig. 1 | Root cause of multiomics data irreproducibility and the role of reference materials as a common calibrator. a, Current practice: raw instrument response is used as a surrogate for concentration. Because instrument sensitivity varies across batches, laboratories and platforms, the same analyte concentration can generate different numeric responses under different conditions (for example, $I = f \times C$ with $f_1 \neq f_2$). As a result, samples may cluster by batch rather than by biology, compromising downstream interpretation, AI/ML modeling, clinical translation and precision-medicine applications. PC, principal component. **b**, Proposed practice: a common reference material is co-profiled with study samples in every batch, typically in randomized technical replicates. Expressing each analyte as a sample-to-reference ratio (SRR; I_S/I_R) reduces the shared batch-specific sensitivity term and anchors measurements to a common calibrator. This makes data far more comparable across batches, laboratories, platforms and time, thereby improving the reliability of multiomics integration and AI-ready analysis.

inference, data integration and future AI/ML model training. The data generated within a single batch may appear 'high quality' when restricted to that batch yet become incomparable across batches. This paradox has misled and mystified the field for three decades.

The magnitude of batch effects is usually much larger than true, often subtle, biological signals of interest, such as the differences between responders and non-responders to a particular stimulus. Furthermore, batch effects are routinely confounded with biological signals, leading to false discoveries when batch differences are misinterpreted as biology, or true signals are attenuated when 'correction' algorithms remove genuine biological signals along with technical noise. Even when not confounded, deep learning models can detect batch effects and interpret them as biologically significant. Hundreds of increasingly complex batch-effect correction algorithms have been published and some of them widely used, yet none can recover information that was never comparable to begin with[13,14] (Fig. 1a).

Unfortunately, the 'omics field has come to accept batch effects as normal and unavoidable, without addressing the underlying and fundamental causes. Instrument responses (fluorescent intensities, read counts or peak areas) are widely used as surrogates of concentration but are often inherently variable as a result of feature-dependent fluctuating sensitivity and background noise. A major driver of

analyte-specific instrument sensitivity drift is platform hybridization dynamics. Microarrays, targeted sequencing capture, antibody-based proteomics and even some single-molecule methods rely on probe–target hybridization or binding. Small variations in temperature, buffer composition or incubation time cause analyte-specific changes in binding efficiency[15]. This is why batch effects are often feature-dependent and cannot be corrected by global scaling alone[13,14].

The solution: reference materials as a common calibrator

Reference materials possess homogeneity, stability, accuracy, traceability, cost-effectiveness and ample supply and are routinely used for measurement system calibration and quality control[3,11]. When a common reference sample R is analyzed alongside study samples S in the same batch, the ratio I_S/I_R eliminates the batch-specific sensitivity factor f on a feature-by-feature basis:

$$\frac{I_{S1}}{I_{R1}} = \frac{f_1 \times C_S}{f_1 \times C_R} = \frac{C_S}{C_R} \quad \frac{I_{S2}}{I_{R2}} = \frac{f_2 \times C_S}{f_2 \times C_R} = \frac{C_S}{C_R} \quad \frac{I_{S1}}{I_{R1}} = \frac{I_{S2}}{I_{R2}} = \frac{C_S}{C_R}$$

where I is the instrument response, C is the true concentration and f is the batch- and analyte-specific sensitivity factor, assuming a linear relationship between I and C[16].

Once a common reference material is measured in each batch, the shared batch effect in sensitivity factor f is captured in both the study sample and reference responses and is therefore reduced through sample-to-reference ratio (SRR) processing (Fig. 1b). This converts unstable, batch-specific instrument-response values into measurements anchored to a common calibrator so that biological structure is more likely to dominate over batch structure in downstream analyses[3]. This shift is important for AI/ML applications, in which technical artifacts can be interpreted as biologically meaningful signals.

The SRR approach produces more harmonized data across diverse sources and can provide an important physical anchor for the large-scale data integration required by AI-based biomedical research. When every dataset is expressed as ratios relative to suitable, common reference materials, data from different laboratories, platforms and time points become far more comparable. This is more than an incremental improvement: it is a practical component of the measurement infrastructure needed for robust AI-era omics. Indeed, recent evidence suggests that deep-learning model performance depends strongly on the calibration of evaluation metrics[17,18].

Physical reference-based harmonization using SRR and computational batch-correction methods are complementary rather than competing strategies: the former can improve measurement comparability at the source whereas the latter can further address residual structure that remains after experimental control[19].

The SRR concept is not limited to affinity-based vendor platforms. The Quartet multi-omics study demonstrated its use in liquid chromatography–tandem mass spectrometry-based proteomics and metabolomics, showing that ratio-based profiling with a concurrently measured common reference sample improves comparability across batches, laboratories, platforms and 'omics types[3,20]. Thus, SRR is a general quantitative strategy for multiomics and is platform agnostic. It can be implemented globally with any suitable reference materials, including those developed by NIST[8,9], the Quartet[3], the Plasmix[10] or future community standards[6,11].

No single reference material can perfectly mimic every biological matrix. The Quartet materials (cell lines) are most appropriate for blood derived or cultured cell studies; Plasmix is suitable for plasma and serum applications. The broad community must create appropriate reference materials for tissues, urine, cerebrospinal fluid, stool and other matrices. In addition, the reference-material-based SRR method is not limited to existing reference materials or technologies. Emerging technologies such as single-cell, spatio-temporal and low-input 'omics should actively pursue analogous strategies by designing matched reference samples or synthetic spike-ins that enable ratio-based calibration within their unique constraints. The underlying principle of co-profiling a common reference to reduce shared batch-specific variation should guide the design of calibration strategies across matrices and assays, even though the specific reference material will need to be adapted to each technology and use case.

The SRR approach has known limitations[3]. Analytes absent from a reference cannot be ratio normalized, matrix mismatch and commutability issues can persist, preanalytical variability (for example, collection or storage) is not corrected unless the reference is processed identically from the start, low-abundance response may be dominated by noise, and non-linear assay responses may violate the multiplicative model. The SRR approach assumes that background signal is low and relatively uniform between study samples and the reference material across analytes. For platforms with high or analyte-specific background, ratio calculation may amplify noise and compress the ratio values. In such cases, additional background correction may be needed, but co-profiling a reference material remains essential for estimating batch-specific parameters.

If the community collectively characterizes the true absolute concentrations of analytes in a commonly used reference material, then, in principle, the absolute concentration of an analyte in a study sample could be estimated by combining its SRR value with the calibrated concentration of the corresponding analyte in the reference material. In practice, this will also require attention to uncertainty budgets, commutability, analyte stability, and transferability across platforms and workflows. This 'one-time' characterization creates a shared resource, bypassing the need for individual laboratories to perform costly International System of Units (SI)-traceable measurements on every analyte in every study sample. We urge international consortia and standards bodies to invest in this collective absolute characterization initiative. By sharing the cost of fully characterizing community-adopted reference materials, practical, low-cost SRR can be achieved today, and a clear upgrade path to absolute concentrations (SI) can be realized in the near future.

Urgent call to action: co-profiling reference materials and reporting SRRs

The omics field has been challenged by batch effects, irreproducibility and data incompatibility for three decades. The SRR framework provides a practical path toward improved harmonization and reproducibility. Certified or well-characterized reference materials are available for several important use cases, additional matrix-specific standards are under development, and the conceptual foundations for broader adoption are in place. What is required is a coordinated implementation across the biomedical community to enable adoption of these practices at scale.

We call upon the following:

Funding agencies should require co-profiling of reference samples as a default expectation for funded 'omics studies. The cost of co-profiling with an accessible reference sample is modest compared to the cost of irreproducible research. Pilot programs could support the development of matrix-specific references for underserved areas

(for example, tissues, stool, single-cell or spatial). Agencies should also fund the development and metrological characterization of community-adopted reference materials (for example, absolute concentration assignment) to enable the future upgrade from SRR to absolute quantification.

Journals should adopt editorial policies that require authors to report whether suitable reference materials were co-profiled with study samples. Manuscripts omitting such controls should provide clear scientific rationale for their absence. Data deposition must include raw data from reference materials co-profiled with study samples, enabling independent SRR calculation, reanalysis and quality evaluation.

Regulators should update guidance documents to recommend, and in appropriate contexts encourage, reference-based calibration for regulatory submissions involving 'omics data, particularly in longitudinal, multi-site, and diagnostic-development settings. The US Food and Drug Administration has played a leading role in MAQC since its inception, and participation should be translated into policy. Regulators should also consider requiring SRR-based reporting for pivotal clinical studies that rely on 'omics endpoints.

Technology vendors should calibrate instruments using shared community reference materials where available and report SRR values as a primary harmonized output alongside raw instrument response and sufficient metadata to enable independent reanalysis. To ensure cross-platform compatibility, vendors should work with third-party reference-material providers to adopt well-characterized common reference materials, rather than perpetuating proprietary silos. Vendors should also adopt the platform- and omics-agnostic signal-to-noise ratio metric as an objective, overall quality measure of their products[3,20]. Vendors should ensure that users are trained to use reference materials appropriately before valuable study samples are analyzed.

Institutions and laboratories should implement SRR reporting as a standard operating procedure for 'omics experiments where appropriate references exist and participate in proficiency testing programs using common reference materials. Laboratory directors should allocate dedicated resources for reference material acquisition and co-profiling. At least three technical replicates of the reference material per batch should be included to estimate intrabatch variability and calculate SRR[20].

For large-scale cohort studies, researchers and consortia should incorporate reference material co-profiling from the outset. Researchers should also demand that vendors demonstrate their products' ability to generate reproducible data with high signal-to-noise ratio across various scenarios.

Training programs should ensure that the next generation of biomedical researchers are trained in measurement science fundamentals. For new 'omics technologies (single-cell, spatial or metagenomics), the community should include matrix-matched reference materials and SRR protocols as an integral part of method development, not an afterthought.

AI-enabled biomedical discovery, large-scale population cohorts and precision medicine initiatives all depend on reliable and interoperable 'omics measurements. The MAQC Society calls upon the entire biomedical community to embrace reference-material co-profiling and ratio-based quantification as a new default practice for 'omics data generation and reporting. Reproducibility is not a luxury: it is fundamental to the integrity of science[7]. Let us move beyond measuring "with rulers of uncertain length" or without rulers at all and build a truly reproducible foundation for the future of biomedical discovery in the AI-omics era with reference materials as a common calibrator.

1. Rigor and Reproducibility: For at least a decade, we have known that reproducibility and replicability in the study of biological and living systems is difficult to achieve in practice. Myriad intrinsic and environmental factors, as well as experimental details and indirect measurements compound to challenge the ability to reproduce.
Several well documented studies have established the challenges one encounters when attempting to reproduce research studies (https://doi.org/10.7554/eLife.67995; https://doi.org/10.1038/s41586-025-09844-9). We propose that multiplying examples of lack of reproducibility by attempting to systematically reproduce more studies would not be particularly productive. Instead, we can learn broadly three things from these published replication initiatives:
1) Incentivize open science practices that facilitate replication attempts
Published replication initiatives have highlighted that a surmountable challenge for replication attempts is the availability of data, code, and methodological details (https://doi.org/10.7554/eLife.67995). Incentivizing the sharing of these outputs alongside study findings, and incentivizing open science practices in general, is a logical step towards facilitating replication attempts when they are deemed necessary. Many resources already exist that the NIH could use and emulate, for example:
The National Academies have published a toolkit to align incentives by raising expectations of open science practice at multiple stages of the research life cycle and researchers' career: grant application, grant report, hiring, tenure and promotion, annual faculty reports, etc (https://doi.org/10.17226/26308).
Publishers and replication experts have developed reporting guidelines to support transparency, rigor and reproducibility of published research (e.g. https://doi.org/10.1073/pnas.2103238118.) Raising an expectation of this kind of level of transparency early in the research process is essential.
Reporting transparency and access to all outputs of research does not guarantee rigor and reproducibility but it facilitates examination of rigor and replication attempts. Recognizing and rewarding responsible, open science practices wherever researchers are evaluated will help foster a culture of transparency.
2) Support infrastructure that enable open science practices
The efforts required to effectively share various research outputs should not be an undue burden and researchers need access to well-maintained, user-friendly repositories, metadata standards, and other resources and support across the research lifecycle to support transparent and reproducible practices across the research lifecycle.
The development and maintenance of open infrastructure supporting these practices is essential to ensure the effectiveness of researchers' efforts. A robust, resilient, well-maintained infrastructure helps

ensure the value of these outputs.
3) Fund studies that probe additional parameters that can be optimized for reproducibility
Experimental design, discipline-specific factors and environmental factors also influence the rigor and replicability of findings. As an example, a report of the NIH Advisory Committee to the Director issued in June 2021 outlines many of these factors in the case of animal research (https://acd.od.nih.gov/working-groups/eprar.html). Many of these recommendations would apply to other types of experimental work. Discipline-specific studies (such as those performed in the social and behavioral sciences – https://doi.org/10.1038/s41586-025-09844-9) and experts committees (https://acd.od.nih.gov/working-groups/eprar.html) exploring the impact of specific factors will help provide better guidance for optimizing rigor and reproducibility by improving study design and reporting of key parameters.

2. Data, Software, and Model Sharing: Sharing data, software and models and other research outputs and practices can help enable reproducible research. Indicators of transparent research practices can provide useful information about whether the methods and other information needed to assess and reproduce research are available. How measures of rigor and reproducibility, and other new metrics, are used in practice is also important. Numerous studies have highlighted the challenges of independently reproducing much (published) research, which suggests that caution is needed in using indicators/metrics of reproducibility as compliance enforcement tools or as a basis for punitive action, not least because current technological approaches are not able to make these judgements at a meaningful scale. Rather, PLOS views new metrics and indicators as a means to understand researcher practices, how they differ in different contexts and why, and then use the insights they provide to create positive incentives to improve practices.

A key example of this approach is PLOS's Open Science Indicators (OSIs), which measure the prevalence of transparent and responsible research practices in articles. PLOS developed OSI according to six principles (https://doi.org/10.6084/m9.figshare.21640889), one of which is to use these metrics responsibly, such as not using these metrics to create rankings or league tables of researchers based on open science (or reproducibility metrics), but using this information to understand practices and monitor for improvement, rather than compliance.
PLOS publishes OSIs for all articles it publishes, as well as for a comparator group of non-PLOS articles available in PubMed Central. The indicators can be explored through the PLOS Open Science Indicators dashboard: https://explore.plos.org/open-science-indicators
For rigor and reproducibility specifically, the availability of complete and detailed research methods and protocols ("protocol sharing"), and the registration or preregistration of research ("study registration"), are particularly relevant.
Protocols can be shared publicly in several ways: through dedicated repositories and platforms such as protocols.io, as standalone methods and protocol articles, or as supplementary information. Research conducted by PLOS found that around one third of researchers share methods and protocols publicly (https://doi.org/10.7717/peerj.16731).
Other potential indicators of good methodological practice and research reporting include the use of community-endorsed reporting guidelines. PLOS supports the Transparency and Openness Promotion (TOP) Guidelines, which cover a range of research practices relevant to rigor, reproducibility and open sharing, and we recommend that NIH consider the TOP Guidelines when identifying potential indicators (updated in 2025: https://doi.org/10.1186/s41073-026-00223-0)
While transparency and availability of research methods are useful indicators, there are gaps in our

collective ability to assess credibility and quality of research methods at scale, and to develop new indicators that better meet the needs of research evaluators. Research by PLOS (https://doi.org/10.7717/peerj.20502) found that, when assessing research outputs as part of hiring, promotion and grant review, evaluators look for indications that:
the research is well designed;
the statistical analyses are valid;
the research was conducted ethically; and
there are no signs of fabrication, falsification or plagiarism.
But there are not yet convenient or widely accepted indicators for all these qualities. This contributes to the use of measures such as Journal Impact Factor and personal or institutional reputation as proxies for research rigor and quality, even though they were not designed for that purpose.
More work is needed to test how new indicators are used in practice, and whether they can provide better alternatives to the inappropriate proxies for research quality and impact that are often used in research assessment. To do this effectively, NIH will need indicators that can distinguish not only whether sharing takes place, but whether shared outputs are usable and contribute to further research. This can help ensure that recognition and incentives are directed towards practices that add value, as well as when sharing is primarily for transparency and accountability purposes.

Concerning data and software sharing, indicators can be considered in two areas: the prevalence of data and code / software sharing, and the quality and impact of the outputs that are shared. Indeed, PLOS's OSIs also include indicators for data and code or software sharing. Similar indicators are used in initiatives such as the French Open Science Monitor. For PLOS, these indicators have been useful in understanding differences in practice between research domains and regions, and in developing policies, tools, partnerships, incentives and training to improve those practices.

Measuring the prevalence of sharing is a useful and pragmatic starting point. More important, but also more difficult, is understanding the quality and impact of the data, software and code that are shared. A number of studies have linked the sharing of research data and code supporting publications with increased citations (academic impact) to the associated research, for example:
https://doi.org/10.1162/QSS.a.487
Reuse of data and code/ software in new research may provide a more direct indication of the impact of shared data and code than citations to the associated article. Traditional bibliometric approaches do not capture most instances of reuse, although new approaches are beginning to emerge. PLOS collaborated with DataSeer through the UK Reproducibility Network Open Research Indicator pilots to develop an experimental indicator for measuring data reuse using agentic artificial intelligence. This work suggests that data reuse in publications may be close to 40% (https://arxiv.org/abs/2604.28061) The work is still experimental, but it points to the potential for developing indicators that measure reuse more directly. Indicators of quality could include the presence of complete documentation and technical information, such as README files, which help researchers assess and reuse data and code. Other recent research by PLOS found that this kind of documentation is important to researchers when considering whether to read or potentially reuse research outputs (https://doi.org/10.6084/m9.figshare.32287383).

3. Training and Mentorship: N/A

4. Collaboration: Collaboration and team science rely on the ability of researchers to build on each other's expertise and outputs. It is essential therefore that different types of contributions corresponding to this expertise and outputs are recognized and that they are visible. Achieving this more broadly necessitates many stakeholders including funding agencies, research institutions and publishers acting at multiple levels: We would therefore like to bring three major, connected initiatives to NIH's attention:
Create a culture of inclusive credit that considers substantial contributions to team science as bona fide research contributions. Authorship of scientific articles remains a primary currency of credit and the culture of authorship needs to evolve to reflect the evolution of research conducted. A working group convened by the National Academies has recently published a set of recommendations to create a more inclusive, adaptable and responsible authorship culture (https://doi.org/10.1073/pnas.2531268123). PLOS is implementing these recommendations across our journal portfolio. The white paper also contains specific recommendations for research institutions and research funders that apply to the NIH.
Using standards and approaches that enable different contributions to be captured and monitored. We recommend wider use of Contributor Roles Taxonomy (CRediT) to capture the diverse contributions of researchers . The CRediT taxonomy provides a controlled list of contributor roles that provides greater nuance to researchers' contributions to a research study beyond their inclusion in an article's author list, and can also be applied to datasets and other research outputs where the supporting infrastructure allows. It provides a more detailed account of contributions such as data curation, software development, supervision, methodology and writing, and can help make visible the different ways individuals contribute to multidisciplinary and distributed research teams. A number of publishers, including PLOS, use CRediT across all articles they publish. Wider adoption could help NIH recognize a broader range of contributions to team science and understand more about the composition of collaborative research teams.
Rethink the future of scientific communication: PLOS is continuing to explore and develop ways of increasing the visibility of diverse contributions through the systems of scholarly communication, in addition to research articles – to provide a basis on which recognition mechanisms such as those sought by the NIH can be built. This is represented in our efforts to develop a new publishing model (a "knowledge stack") that connects articles and preprints with associated research outputs — data, code, methods, and materials — into a structured, open, machine-readable record that reflects the research process and credits everyone who contributed. The model is designed to work with the open science infrastructure and standards researchers already use, such as persistent identifiers, repositories, and the CRediT taxonomy. The knowledge stack concept is designed to provide the structured relationships, attributions and context that make the distributed outputs visible as a coherent whole to help credit, understand, verify and reuse the numerous different contributions to collaborative science.

5. Entrepreneurship and Translation: N/A

6. Foundational Scientific Exploration: In February 2025, PLOS convened predominantly US-based funders and institutional leaders in Washington, DC, to discuss researcher incentives and research assessment in the context of open science publishing. Greater recognition for measured risk-taking, and for research that does not produce the expected outcome, was an important theme (https://doi.org/10.6084/m9.figshare.32287383)
One potential indicator is whether methodologically sound research and research outputs are shared regardless of the outcome. Making negative, positive or no-difference results available can help reduce unnecessary duplication and address bias in a research literature that tends to favor positive findings.

This is particularly important in fields such as healthcare research, where an incomplete evidence base can have wider consequences.
Despite the range of venues now available (including but not limited to journals such as PLOS One) for sharing research outputs, negative or unsuccessful results remain much less visible. This suggests that infrastructure alone is not enough: incentives, resources and research culture also influence whether these findings are shared.
NIH could help address this by recognizing rigorous research regardless of outcome within its normal assessment and funding processes. This could include recognizing a wider range of outputs, such as preprints and shared data, and preregistered research articles alongside journal articles when assessing researchers and funded work.

7. Public Impact: PLOS supports NIH's interest in better understanding and recognizing the broader public impact of biomedical research. Some impacts, particularly economic and societal impacts, may take many years to emerge and can be difficult to attribute directly to an individual research output or project.
There is, however, evidence that open science practices can contribute to wider economic and societal value, particularly when research and research resources are made available for others to access and reuse.
PLOS recently commissioned an independent economic analysis of open science. The analysis found evidence that open science creates economic value, including through the reuse of research outputs and resources (https://zenodo.org/records/20669372).
This suggests there may be value in considering carefully selected leading indicators of longer-term public impact, including open access to research and the sharing and reuse of data and code.
Other recent research also found an association between open access and wider use of research in innovation, measured through citations to research in patents (https://link.springer.com/article/10.1007/s11192-026-05725-8).

8. Other Areas: PLOS strongly supports NIH's effort to develop a broader and more meaningful approach to measuring scientific impact, including research practices, contributions and outputs beyond the journal article.
We recommend that NIH take a values- and principles-led approach when deciding which indicators to develop and use. Established frameworks, including the INORMS SCOPE Framework (https://inorms.net/scope-framework-for-research-evaluation/) and the Principles of Open Science Monitoring (https://doi.org/10.5281/zenodo.15807480) provide useful guidance on how to approach metrics and indicator selection and development.
A central principle of these approaches is to start by identifying what is valuable and important to understand or assess, rather than beginning with the data or metrics that are already available. This helps avoid measurement being shaped by what is easiest to count, rather than what is most relevant in a specific context.
PLOS took a similar approach when developing its Open Science Indicators, beginning with a set of solution-agnostic principles (https://doi.org/10.6084/m9.figshare.21640889). Responsible use was an important part of that work. New indicators should provide additional information to support qualitative and contextual assessment, rather than be used to create uncontextualized comparisons, rankings or league tables.
PLOS research (https://doi.org/10.7717/peerj.20502) has also shown that, where better indicators are

not available, evaluators may rely on proxies such as Journal Impact Factor or personal and institutional reputation when assessing research quality and rigor.

For this reason, new indicators should be tested in the settings in which they are intended to be used, and developed with the researchers, funders, institutions and others who will rely on them. This will help establish whether they provide better information for assessment and identify unintended consequences before they become embedded in practice.

NIH may also wish to draw on the wider body of work already underway in research assessment and open science measurement, including CoARA, HELIOS, DORA, the Open Science Impact Indicators Handbook (https://handbook.pathos-project.eu/) the Open and Universal Science Project (https://opusproject.eu/) and the Science and Technology Innovation Indicators community. Indeed, while the focus of our responses have been on work PLOS has led, PLOS supports and has collaborated with numerous other initiatives to which are relevant to this RFI. These include but are not limited to: TIER2 (https://tier2-project.eu/), iRISE (https://irise-project.eu/), and OSIRIS (https://osiris4r.eu/) which have all produced outputs that will help multiple stakeholders further their thinking about measuring and improving reproducibility of published research.

193. Washington University in St. Louis

I am responding: On behalf of an organization

Name:

Name of Organization: Washington University in St. Louis

Type of Organization: Not Applicable

Role: Organizational Official

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: Recommendations:
• Recognize and reward independent external replication of findings across datasets, sites, scanners, and populations, not simply publication of novel findings.
• Create dedicated funding mechanisms for replication studies so they can be evaluated on their own terms rather than competing directly with novelty-driven research. NIH should also consider targeted mechanisms to support independent replication of contested findings or coordinated studies involving investigators with competing interpretations to rigorously test areas of scientific disagreement.
• Create durable publication and recognition pathways for rigorous replication studies, including studies that confirm, fail to confirm, or refine prior findings. Funding replication without ensuring that high-quality replication work can be disseminated and credited risks creating a second-tier research pathway that investigators, particularly early-career investigators, cannot afford to pursue.
• Promote publication of study protocols and registered reports.
• Invest in shared reproducibility infrastructure, including validated reference materials, benchmark datasets, standardized protocols, and training in rigorous study design, statistical methods, bias mitigation, and data stewardship. NIH should fund this infrastructure directly rather than shifting the cost of new reproducibility expectations to individual investigators or institutions.
• Refine the existing Contributions to Science section of the Biosketch: keep the cap of 4-5 “Contributions to Science” but explicitly allow and provide a clear rubric for narrative examples of open-source tool adoption, replication study leadership or protocol adoption, or start-up/tech transfer milestones.
• Suggested measurable indicators: % of studies with openly registered protocols; number of independent validation studies; number of studies adopting methodology established by NIH-funded investigators; compliance with ClinicalTrials.gov reporting deadlines. For measures such as adoption or reuse, NIH should first establish reliable methods for attribution and validation so that citations, downloads, or other easily captured activity are not automatically treated as evidence of meaningful scientific impact.

Potential unintended consequences:
• Replication studies require additional time, funding, and access to independent datasets, which may disadvantage early-career investigators or research areas where external validation cohorts are limited. For early-career investigators in particular, sustained investment in replication work may also create career risk under promotion and tenure systems that continue to emphasize novel findings and

traditional measures of productivity.
• Overemphasis on reproducibility metrics could discourage trainees and investigators from pursuing innovative, high-risk research in favor of safer projects that are more easily replicated.
• Journals are typically uninterested in a study that simply confirms a prior, well-conducted finding, so any incentive system NIH builds will need to address where this work gets published, not just how it gets funded.

Washington University has previously developed a more detailed set of recommendations for strengthening rigor and reproducibility in federally funded biomedical research. Our attached white paper, Reproducibility in Practice: Washington University's Perspective on Strengthening Federally Funded Biomedical Research, provides additional recommendations related to replication studies, reproducibility infrastructure, training, standardized research tools and resources, data sharing, and academic-industry collaboration.

2. Data, Software, and Model Sharing: Recommendations:
• Formally credit non-traditional research products such as datasets, software, standard operating procedures so that they are citable scholarly outputs.
• Reward open-source hardware/software, custom instrumentation, protocols, and curated baseline datasets that enable other labs' discoveries.
• Integration with Existing Data Repositories (ORCID & Crossref): expand the capability of SciENcv and the eRA Commons to pull verified digital object identifiers (DOIs) for non-traditional outputs automatically. If an investigator uploads a validated baseline dataset to a public repository, open sources a software package on GitHub, or registers a patent, these repositories issue distinct DOIs. Allowing these verified DOIs to auto-populate into standard NIH biosketches and progress reports (RPPRs) treats open assets with the exact same administrative simplicity as a traditional PubMed ID.
• Suggested indicators of sharing and reuse: repository downloads, material transfer requests, documented reuse of data or methods by independent labs, adoption of a tool or protocol by other institutions or journals. This is one area that is best suited to a fully automated measurement using repository/registry analytics or expanding iCite-type analytics rather than requiring new ones. Where feasible, NIH should favor verifiable indicators of sharing, such as deposition, functional availability, and documented reuse, rather than attempting to assign a subjective quality score to shared products.
• BioLINCC at NHLBI already shows what this can look like: a shared, freely accessible repository that lowers the barrier to depositing and reusing data. Building out more infrastructure like this, rather than adding new reporting requirements, would likely do more to encourage sharing.

Potential unintended consequences:
• Measures such as downloads, citations, or repository activity can be easy to capture but may not reliably reflect meaningful scientific reuse or impact and could be susceptible to gaming.
• Expectations for open sharing must account for legitimate limitations involving privacy, consent, intellectual property, proprietary information, data-use agreements, and the costs of long-term data or software maintenance.
• NIH should avoid creating incentives that disproportionately favor fields where digital outputs are easier to share and quantify.

3. Training and Mentorship: Recommendations:
· Track trainee career trajectories across sectors (academia, industry, government) as one contextual indicator of mentoring impact, rather than relying on co-authored paper counts. Career placement or advancement should not be used as a standalone measure of mentorship quality.
· Multi-year tracking of mentee career outcomes, not just a single snapshot at first job placement, built by reusing existing NIH data systems rather than creating new survey burden for training grant administrators.
· Fund mechanisms that encourage and support co-mentorship across disciplines or with non-academic partners to enhance innovation and translation.
· Consider structured, confidential trainee feedback as one qualitative input to mentorship assessment. Such feedback may provide a more direct measure of mentoring quality than downstream career outcomes alone.
· Track mentorship as a protected, distinct effort line, credited separately from research percent-effort, so faculty who invest heavily in mentoring aren't penalized against peers who don't in productivity-based comparisons. Allow mentees to identify who actually mentored them rather than assuming the PI-of-record captures it. Outside lab-based fields especially, people are often mentored by several individuals or informal networks, and any tracking system should be built to reflect that.

Potential unintended consequences:
• Mentorship outcomes often emerge over many years and are influenced by factors beyond an individual mentor's control. Career placement or advancement should therefore not be treated as a simple measure of mentorship quality. Outcome-based measures could also create disincentives to mentor trainees whose career paths are less predictable or less readily captured by conventional placement metrics.
• Any mentorship metric should recognize team and informal mentoring relationships and avoid rewarding nominal mentorship arrangements over substantive contributions.
• New mentorship reporting requirements should rely on existing or automated data wherever possible rather than creating additional tracking responsibilities for investigators, trainees, or institutions.

4. Collaboration: Recommendations:
· Early career scientists can benefit greatly from being on interdisciplinary teams to kick start their NIH careers. But, they are discouraged from being MPIs and gaining credit on these teams because they lose their ESI status. A new category for recognizing team members without losing ESI status would encourage more leadership from early career scientists in team proposals.
· Recognize a role and give credit for people whose technical or methodological expertise makes a project possible, but who are neither PI nor first author.
· Suggested indicators: Use contributor-role data to identify "hub" team members whose expertise is broadly relied upon and formally recognize this role in review and award criteria. Contributor-role statements can provide useful context for expert review, but NIH should avoid converting individual contribution categories into a rigid point system. For multi-site trials, use site-level trial performance metrics.
· The state of the art for identifying who actually contributed to a team, and how much, is still weak. NIH should fund research into team science measurement itself, especially for large, multidisciplinary teams outside basic science, rather than assuming existing tools transfer cleanly. NIH should also add a section in NOFO that requires the role for each contributor to be defined.

· Team science should be measured at more than one level. A team's output is more than the sum of individual contributors and must be measured at multiple nested levels (individual, team, institution) simultaneously.
· New measures should also distinguish individual contribution from team-, institutional-, and infrastructure-level impact. NIH should avoid assigning outcomes generated collectively by teams, cores, networks, or institutions to a single investigator simply because that individual is the PI of record.

Potential unintended consequences:
• Rewarding "hub" status also creates a gaming risk: contributor lists could become inflated, with credit flowing to well-known names rather than the people who actually did the work. Any new collaboration metric needs a safeguard against this before it's tied to review or funding decisions.
• Contributor roles may change over the life of a project, and formal titles may not capture the relative significance of individual contributions. Any system used to assess team-science contributions should allow roles to evolve and should avoid creating rigid hierarchies among different types of scientific contribution.
• New approaches to recognizing team science should not inadvertently disadvantage investigators who work in fields or research settings where smaller teams or individual-led research remain appropriate. Collaboration should be recognized when it adds scientific value, but should not become an expectation or proxy for impact in every field.

5. Entrepreneurship and Translation: Recommendations:
· Early-stage translational work (patents, licensing, regulatory-compliant SOPs, startup formation) is under-recognized because investigators can appear unproductive by traditional metrics during these long, high-effort phases.
· Recognize early-stage tech transfer milestones such as invention disclosures, licensing agreements, SBIR/STTR transitions.
· Track implementation/scale-up work and community partnerships as translational impact in public-health and clinical settings.
· Support more funding mechanisms that bridge basic discovery to clinical trial in one program.

Potential unintended consequences:
• For basic biomedical research, entrepreneurship and commercialization should be recognized when relevant but should not become a required dimension of individual scientific impact. Making patents, licensing, startup formation, or other commercial outcomes an expected marker of success could redirect investigators toward patentable outputs rather than the most important scientific questions.
• Entrepreneurship and commercialization opportunities vary substantially across disciplines and types of research. Metrics such as patents, licenses, startup formation, or industry partnerships should therefore supplement rather than replace other measures of scientific contribution.
• Overweighting commercial outcomes could disadvantage foundational, population-based, implementation, or other research whose primary value is scientific or public rather than commercial.
• Translation often occurs over long-time horizons and involves contributions from multiple investigators and organizations, making attribution to an individual investigator difficult.

6. Foundational Scientific Exploration: Recommendations:
· Recognize the development of new methods and research tools, and the adaptation of concepts from

other fields (e.g., applying physics, mathematics, or engineering approaches to new biomedical problems), as foundational contributions. These tools and approaches often enable many downstream discoveries but are rarely rewarded as heavily as the discoveries they make possible.
· Explicitly define “success” to include informative negative or null results, since the value of high-risk work lies partly in ruling out unproductive directions.
· Expand R21-type funding for high-risk ideas ahead of R01 submission and consider renewal pathways for demonstrated foundational progress even without traditional productivity metrics, creating an R21-to-R01 pipeline.
· Consider longer-duration, flexible funding mechanisms for foundational and high-risk research that allow investigators to change direction as evidence evolves. Renewal evaluation should emphasize the significance of the scientific question and the rigor with which it was pursued rather than milestone completion alone.
· Support more R35 and DP2 activity code funding within each institute to promote creative thinking and exploration.

Potential unintended consequences:
• Any new reward system should be explicitly evaluated for whether it disincentivizes foundational, high-risk research. It is critical that NIH not overweight near-term or traditionally measured impact, as this could starve the unglamorous validation, optimization, and replication work needed to refine foundational advances into reproducible tools and protocols.
• If “high-risk” or “paradigm-shifting” becomes a checkbox metric, investigators may manufacture synthetic risk or overhype standard, incremental work to satisfy the criteria.
• Well-funded, established labs can absorb the failure of a high-risk project through a portfolio of safer grants, but for an early-stage investigator a project that yields no publishable data over three to five years can be career-ending under current tenure and promotion frameworks.

7. Public Impact: Recommendations:
• Automated Cross-Disciplinary Citation and Funding Analytics: Instead of requiring investigators to manually track and justify their reach, the NIH should utilize automated bibliographic tools (akin to the existing NIH iCite platform) to provide contextual indicators of a grant’s reach and downstream influence. The platform could automatically flag cross-disciplinary breadth (e.g., the diversity of journal subject categories citing the work) and downstream proposal catalysis (e.g., tracking when an NIH grant number or its resulting publication is cited within the Significance or Innovation sections of subsequent, independent applications).
• Recognize completion of clinical trials and downstream use of results to inform clinical practice, including incorporation into clinical guidelines, as a core public-impact outcome. Reward site-level contributions in multicenter trials. Site PIs provide essential local leadership but are rarely top-listed authors and go unrecognized. NIH should reward participating sites and investigators commensurate with their contributions and track site-level performance (accrual and data-submission commitments) across studies.
• Washington University can point to an existing example of this kind of framework in the Translational Science Benefits Model (https://www.translationalsciencebenefits.wustl.edu/), which already assesses public impact across a research portfolio.

Potential unintended consequences:

• “Public impact” is ill-defined. Important research may never directly change clinical practice, and null findings can themselves represent meaningful scientific contributions. Public impact also differs substantially across basic science, clinical research, and public health and may emerge years or even decades after the original discovery. NIH should therefore avoid measurement approaches that systematically favor outcomes that are visible within a single grant cycle or that privilege near-term translational impact over foundational research.
• Attribution of public impact is inherently difficult because changes in clinical practice, health outcomes, policy, or economic activity typically result from cumulative contributions across many studies, investigators, institutions, and sectors. NIH should be cautious about assigning downstream societal outcomes to individual investigators or awards.
• Measures of public impact should not depend primarily on visibility, media attention, public engagement, or other indicators that may favor certain topics or investigators without demonstrating greater scientific or health impact. Measures should emphasize demonstrable contribution rather than prominence or reach alone.

8. Other Areas: · Washington University supports broadening the ways NIH recognizes scientific contribution but strongly cautions against replacing imperfect traditional metrics with a new layer of unvalidated metrics. No single score, automated index, or checklist can capture scientific impact across disciplines, career stages, research types, and time horizons. New indicators should supplement, not substitute for, expert scientific judgment and should be used only for purposes for which they have been validated.
· Substitution instead of addition: replacing traditional metrics rather than supplementing them would penalize excellent small, focused labs that do not do team science or that lack the capacity to pursue innovative discovery research and replication activities simultaneously. New measures should broaden the ways scientific contribution can be recognized without creating an expectation that every investigator demonstrates impact across every dimension.
· Avoid a single composite measure of scientific impact: NIH should resist collapsing diverse dimensions of scientific impact into a single score or ranking. Different forms of impact are appropriate to different disciplines, career stages, research objectives, and time horizons. A multidimensional framework would preserve this context and reduce incentives for investigators to optimize research activity toward a narrow set of measurable outcomes.
· Prioritize scientific quality over publication quantity or venue prestige: NIH should avoid relying on publication counts, journal prestige, or raw citation measures as proxies for scientific impact. Assessment should place greater emphasis on the rigor and reproducibility of the work, methodological contributions, the significance of the scientific questions addressed, and the extent to which the work advances the field.
· Distinguish measurement from decision-making: NIH should distinguish between indicators used for portfolio-level evaluation, information provided as context during peer review, and measures used directly in funding decisions. Evidence that an indicator is informative for understanding NIH’s overall research portfolio does not establish that it is valid or appropriate for evaluating an individual investigator or application.
· Recognize meaningful scientific peer review: Sustained, rigorous peer review is an important contribution to the quality and integrity of the scientific enterprise. NIH should consider approaches for recognizing substantive peer-review service without incentivizing review volume over review quality.
· Protect expert review and reviewer capacity: Broader measures of scientific impact should not simply

add new scoring categories to an already complex peer-review process. Meaningful qualitative assessment requires reviewers with appropriate expertise and sufficient time to engage deeply with an investigator's contributions. NIH should consider the effect of any new assessment framework on reviewer workload and the quality of peer review.
· Validate before implementation: Before incorporating new impact measures into peer review or funding decisions, NIH should first determine that new tracking is necessary and pilot proposed measures. The ability to automate a measure does not establish its validity or usefulness. New measures should be evaluated for reliability, validity, administrative burden, and differential effects across disciplines, career stages, institution types, and research approaches. Measures that do not provide meaningful information beyond existing indicators should be revised or abandoned.
· Impact on junior investigators: New approaches may unfairly affect junior researchers given that they have less time to demonstrate their impact. They may also alter their research to over-conform or anticipate the new approaches since they have more concern regarding job stability. University promotion and tenure rubrics lag NIH incentives, and NIH should coordinate with institutions on this.
· Chilling effect on high-risk work: putting too much weight on reproducibility or near-term translation could push researchers toward safer, more easily replicated projects.
· Adopting impact measures that are difficult to document in a consistent and verifiable manner could lead to "storytelling" and inflated narratives. Broadening impact measures must not result in "metric inflation" that forces investigators and staff to act as public relations agents or administrative data entry clerks.
· Adding administrative burden: new categories of impact could add significant administrative burden and detract investigators from time conducting research. New measures must be automated as opposed to self-reported.
· Consider institutional resource differences: New reporting or infrastructure requirements that are not accompanied by NIH-supported resources may disproportionately burden smaller and less-resourced institutions. NIH should provide shared infrastructure and, where appropriate, financial support for new requirements so that changes intended to broaden the recognition of scientific impact do not instead widen disparities among research institutions.
· Move deliberately: Consult experts across disciplines and research settings, assess unintended consequences, and phase in any new approaches only after testing and evaluation.
· Normalize metrics across disciplines and subfields. Publication and citation rates vary widely (e.g., hardware-intensive versus computational fields), and only the "hottest" subfields attract high citations. NIH should normalize to granular subfields (e.g., by expanding Relative Citation Ratio) and exclude review and survey articles from citation counts, recognizing them separately as community service.
· Preserve scientific and apolitical review. Impact must be assessed impartially using scientifically grounded criteria, appropriate evidence, and expert judgment, free of political agendas. Scientific review should be conducted by scientists rather than driven by political appointees.

Description: Washington University has previously developed a more detailed set of recommendations for strengthening rigor and reproducibility in federally funded biomedical research. Our attached white paper, Reproducibility in Practice: Washington University's Perspective on Strengthening Federally Funded Biomedical Research, provides additional recommendations related to replication studies,

reproducibility infrastructure, training, standardized research tools and resources, data sharing, and academic-industry collaboration.

Title:
"Reproducibility in Practice: Washington University's Perspective on Strengthening Federally Funded Biomedical Research"

Prepared by: Mark Lowe, Bill Powderly, Sandro Galea, Charles Goss, Nichole Moore, and Doug E. Frantz
Washington University in St. Louis
June 2025

Executive Summary

Reproducibility is a foundational principle of scientific integrity, yet it remains a persistent challenge across all scientific disciplines. Despite major advances in technology and discovery, studies estimate that a significant portion of federally funded biomedical research is difficult or impossible to replicate—undermining public trust and slowing the translation of findings into clinical impact.

Washington University in St. Louis (WashU) has a strong track-record and national reputation of conducting NIH-funded research that meets the highest standards of rigor and reproducibility. This white paper outlines our perspective of the top contributors to irreproducibility and presents actionable recommendations for how federal funding agencies—especially the NIH—can strengthen the reproducibility of U.S. biomedical research through targeted investments, cross-agency collaboration, and engagement with industry partners.

Key Challenges to Reproducibility of Scientific Findings

1. Systemic Challenges in the Scientific Ecosystem

Reproducibility in science, as emphasized by the Office of Science and Technology Policy (OSTP), reflects the ability of independent researchers to test a hypothesis using diverse methods and consistently reach results that validate or challenge the original findings—ensuring scientific conclusions are transparent, trustworthy, and broadly generalizable. However, incentive structures across academia and funding agencies often prioritize novelty over validation, speed over rigor, and novel approaches over reproducible methods. These pressures discourage replication studies and shortchange robust experimental design, statistical power, and transparent reporting. Further, tight timelines and limited budgets for early-stage research often lead to underpowered studies and insufficient preclinical validation. Additionally, there may be substantial cognitive bias where certain hypotheses become accepted wisdom and studies challenging these 'agreed' conclusions are less likely to be supported.

2. Lack of Formal Training in Rigor and Reproducibility

Despite widespread acknowledgment of these challenges, structured training in scientific rigor and reproducibility remains inconsistent across institutions. Many trainees—and even faculty—lack foundational instruction in areas such as experimental design, bias mitigation, data stewardship, and statistical reproducibility. This educational gap perpetuates poor practices and limits the adoption of emerging standards.

3. Limited Access to Standards, Tools, and Sharable Resources

Many investigators lack access to well-characterized research tools, standardized protocols, and high-quality reagents. The absence of universally accepted benchmarks for materials (e.g., cell lines,

chemical probes), analytical methods, and computational workflows increases variability and undermines reproducibility. Similarly, the absence of standardization of datasets that can be used to replicate results hampers reproducibility. Legal, logistical, and cultural barriers often prevent the timely sharing of raw data, code, and research samples—especially across institutional or national boundaries.

Recommendations for Federal Action

To meaningfully address the reproducibility crisis, federal agencies should invest in a coordinated, multi-faceted response. Washington University recommends the following actions aligned with the three challenges noted above:

1. Overcoming challenges in the scientific ecosystem:

- **Create reproducibility pilot programs** within NIH translational initiatives (e.g., NCATS, RADx, BRAIN Initiative, HEAL Initiative, NSF-GOALI program) to support independent replication studies and develop standard operating procedures (SOPs) before downstream translation and commercialization.
- **Align grant review criteria and funding decisions more closely with translational readiness**, requiring detailed reproducibility plans and encouraging applicants to integrate cross-sector collaborators early in the research lifecycle to validate data generated.
- Develop mechanisms to allow investigators to propose novel hypotheses that run counter to accepted thought.
- **Fund infrastructure for standardization and benchmarking**, including common reagents, reference and tool compounds, extrinsic factors and uncertainty quantification studies for biomedical research (similar to PAR-24-167: Utilizing Equipment to Study Environmental Extrinsic Factors and Enhance Rigor and Reproducibility of Animal Research (R24, Clinical Trials Not-Allowed) FAIR-compliant data repositories, and instruments to facilitate data sharing, that serve both academic and private-sector users.
- **Establish institutional GLP laboratories/core facilities through strategic investments** to lower the barrier for academic labs to facilitate the reliability, reproducibility, and traceability of biomedical research under GLP-compliant protocols.
- **Seed industry-academic partnerships**, possibly through new RFAs. cost-share mechanisms, and faculty sabbatical programs where academic findings are validated in industrial settings under GLP/GMP-like rigor especially those involving assay development, biomarker validation, or therapeutic discovery.

2. Training in rigor and reproducibility

- **Develop training resources through** NIH, NIST, FDA, DOE, and other agencies that can create opportunities for training programs at graduate and post-graduate level that change the scientific culture and convey the nine core tenets of Gold Standard Science as outlined by the OSTP. Resources should include training in statistical methods, study design, and the importance of casual inference frameworks in the analysis of biomedical datasets.
- **Establish and expand reproducibility-focused consortia** that unite federally funded researchers with industry scientists to cocreate educational and developmental opportunities centered around shared protocols, reference standards, and validation datasets.

3. Robust sharing of data, materials, software and other research tools

- **Advance Interagency Collaboration through the co-development and dissemination of standardized reference materials** and protocols (e.g., authenticated cell lines, benchmark datasets, small molecule probe compounds) through centralized national repositories that undergo routine QA/QC validation throughout their lifecycle.
- **Invest in FAIR-compliant data repositories, sample-sharing platforms, and adoption of electronic notebook documentation** that incentivize and lower the barrier to open access to raw data, code, thorough descriptions of methods or protocols, and research samples.
- **Encourage the development of application protocol interfaces (APIs)** and cloud-based tools that allow for real-time reproducibility checks, automated protocol validation, and collaborative data analysis.

Conclusion: A Call to Action

Ensuring the reproducibility of biomedical research is essential to maintaining the integrity of the scientific enterprise and the impact of federal investment. Addressing this issue requires not only institutional reforms, but bold, coordinated action by federal agencies and their partners. Washington University in St. Louis stands ready to work with OSTP, OMB, the NIH and other federal stakeholders, as well as private-sector collaborators, to lead this cultural and structural transformation.

194. Society for Academic Emergency Medicine (SAEM)

I am responding: On behalf of an organization

Name: Melissa McMillian

Name of Organization: Society for Academic Emergency Medicine (SAEM)

Type of Organization: Professional Organization/Association

Role: Other

Role - Other: Senior Director

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: Emergency medicine research operates in a uniquely challenging environment for reproducibility. Our studies are conducted in high-acuity, time-constrained settings with heterogeneous patient populations, variable institutional protocols, and outcomes that are inherently difficult to standardize across sites. NIH should recognize that reproducibility in emergency medicine often requires multi-site pragmatic trials rather than single-site replication studies, and that these studies require dedicated multicenter infrastructure that conventional measures of scientific productivity may not capture.. Incentives for reproducibility should specifically support emergency care networks and collaborative research consortia such as PECARN and SIREN, which are specifically designed to enable reproducible multi-site emergency medicine research at scale. Metrics of rigor should reward pre-registration of clinical trials, prospective data collection, and transparent reporting of null results. These are practices that emergency medicine investigators already value, although they are not currently recognized in grant scoring or career advancement decisions.

2. Data, Software, and Model Sharing: Emergency department data, including electronic health records, triage timestamps, medication administration records, and disposition data, represents an underutilized national resource for health services research, comparative effectiveness research, and health equity science. NIH should develop incentive structures that reward emergency medicine investigators for sharing de-identified ED data, developing and releasing open-source clinical decision support tools, and contributing to national registries. Currently, the administrative and legal burden of data sharing falls disproportionately on individual investigators at community-based academic medical centers who lack the dedicated informatics and legal infrastructure of large research universities. This barrier disproportionately disadvantages early-career EM investigators and those at smaller or community institutions. These smaller and community institutions represent the majority of emergency care that is delivered in the US. Ideally, the NIH should fund the infrastructure necessary to make data sharing feasible, not merely require it as a policy mandate without allocating resource support.

3. Training and Mentorship: Emergency medicine research training operates through a narrow and fragile pipeline. While the specialty has produced a generation of physician-scientists through SAEM Foundation grants, emergency care K to R award pathways, and ACEP research funding mechanisms, these are limited relative to the clinical and public-health needs that emergency medicine research is positioned to address. The NIH should develop metrics that explicitly reward the mentorship of

emergency medicine trainees into research careers, including recognition of successful K award sponsorship, research fellowship direction, and the production of independently funded physician-scientists in clinical departments. Currently, faculty who invest substantial effort in research mentorship at community-based academic hospitals receive no credit in grant scoring, promotion criteria, or NIH impact metrics, contributing to a structural disincentive that undermines the long-term sustainability of the emergency medicine research workforce.

4. Collaboration: Emergency medicine is fundamentally an interprofessional and collaborative specialty. Without an Institute of our own, emergency medicine research increasingly spans multiple NIH Institutes and disciplines like pharmacology, toxicology, simulation science, health systems, global health, multiple body systems, and implementation science. Nonetheless, current NIH metrics heavily reward the single-PI model and do not adequately recognize contributions to multi-PI and team-based science. For example, an emergency medicine investigator who serves as site PI for a 40-site national trial, leads patient enrollment, and generates a substantial proportion of the study's data may receive limited recognition because conventional metrics emphasize lead authorship and overall PI status rather than the scientific and operational contributions required to execute a rigorous multisite study. The NIH should develop metrics that recognize the value of clinical trial execution, site PI leadership, and collaborative contributions to large-scale team science. These are the contributions that emergency medicine investigators make routinely and that are essential to the field's evidence base.

5. Entrepreneurship and Translation: Emergency medicine is uniquely positioned to translate scientific discovery into practical innovations because investigators work at the interface of acute clinical need, health systems, technology, and implementation. Emergency physicians routinely identify unmet needs that lead to new clinical decision-support tools, diagnostic technologies, medical devices, digital health platforms, and novel models of care. However, traditional measures of scientific impact often undervalue contributions across the translational lifecycle, including validation, regulatory development, commercialization, workflow integration, and implementation widely across health systems. The NIH should recognize entrepreneurship and successful translation as legitimate forms of scientific impact and apply stage-appropriate measures, including technical validation, regulatory and clinical milestones, adoption, reach, affordability, sustainability, and patient outcomes. Patents, licenses, startups, and private investment can be useful indicators but should not be treated as ends in themselves. The NIH should also recognize translation through clinical protocols, open tools, nonproprietary interventions, and implementation in community, rural, and resource-constrained settings. Such metrics would encourage investigators not only to produce new knowledge, but also to ensure that discoveries are successfully translated into scalable solutions with meaningful public health impact.

6. Foundational Scientific Exploration: Emergency medicine plays a critical role in identifying clinical phenomena that generate basic science hypotheses, ranging from the pathophysiology of sepsis-induced immunosuppression to the cardiovascular toxicology of emerging drug adulterants. The NIH should preserve robust support for foundational discovery while also recognizing the role of hypothesis-generating observational research and pilot investigations in inspiring questions for subsequent basic, translational, and clinical investigation. Stage-appropriate metrics should recognize bedside observation and characterization as early contributions within this continuum, while evaluating later foundational and translational work according to the knowledge, mechanisms, and capabilities it creates.

7. Public Impact: Emergency medicine generates scientific value that is immediate, population-level, and directly translatable to patient care, but this value is poorly captured by citation metrics and journal impact factors. A clinical decision rule that reduces unnecessary CT scanning in children presenting with head trauma, a protocol that improves sepsis recognition in triage nurses, or a simulation curriculum that reduces procedural complications in residents represents enormous public health impact that may not generate correlative high citation counts. To best improve the health of the entire population, NIH should develop metrics that explicitly value clinical practice change, guideline adoption, reduction in healthcare utilization, patient safety improvement, and health equity outcomes as measures of scientific impact.

Recognizing these outcomes should complement, not displace, support for foundational research whose eventual applications may be uncertain or decades away. NIH needs both sustained discovery and effective pathways for mature evidence to reach patients.

8. Other Areas: Recommendations:

NIH should sustain a balanced portfolio encompassing foundational, translational, clinical, and implementation research. The goal is not to privilege one stage over another, but to apply stage-appropriate measures that recognize the distinct contributions each makes to scientific progress and public health.
NIH should develop a diversified portfolio of impact metrics that includes: clinical practice change and guideline adoption; patient-centered outcomes beyond mortality; contributions to open-access data and tools; mentorship productivity measured by trainee career outcomes; and equitable recognition of collaborative and site-level scientific contributions. These metrics should be applied with sensitivity to career stage, institution type, specialty and research stage, without misattributing institutional resources or a particular type of scientific output for investigator impact.
Emergency medicine's contribution to the NIH mission is substantial, immediate, and population-level. The metrics that NIH adopts to measure and reward scientific impact will ultimately determine whether the next generation of emergency medicine investigators can build sustainable research careers. We hope that the NIH will use this opportunity to design impact metrics that finally recognize the full breadth of scientific value that clinical investigators in underrepresented specialties generate.

195. Washington State University

I am responding: On behalf of an organization

Name: Kim Christen, PhD

Name of Organization: Washington State University

Type of Organization: Not Applicable

Role: Organizational Official

Date Submitted: 8/18/2026

1. Rigor and Reproducibility: Washington State University believes rigor and reproducibility should be recognized as fundamental scientific contributions rather than solely as compliance requirements. For biomedical research assessments, NIH could consider adapting industry principles such as the methodologies of Gage Repeatability and Reproducibility, which evaluate measurement consistency and identify sources of variation. Potential biomedical science indicators could include the percentage of publications with publicly available protocols, analysis plans, data, and code; use of preregistration, blinded analyses, validation cohorts, and replication studies; documentation of assay performance and measurement variation; and dissemination of well-designed studies that yield positive, negative, or null findings. Importantly, null findings are a valuable scientific outcome that can refine hypotheses, prevent duplication of effort, and strengthen the overall evidence base and should therefore be recognized as meaningful contributions to scientific progress.

NIH should also recognize contributions to causal research, defined as research that improves understanding of whether and how specific mechanisms, interventions, exposures, programs, practices, or policies influence health-related outcomes. Because causal questions arise across the biomedical research continuum, measures of causal research should be appropriate to disciplinary context and study design. Indicators could include the use of rigorous causal inference approaches, such as randomized controlled trials, natural experiments, quasi-experimental designs, instrumental variable analyses, difference-in-differences methods, regression discontinuity designs, propensity score methods, mediation analyses, longitudinal studies, mechanistic investigations, and the use of causal frameworks. Additional measures could include replication of causal findings across populations or settings and demonstrated influence on clinical practice, public health interventions, or policy decisions.

NIH could support dedicated replication funding opportunities, establish reproducibility networks, and incorporate rigor, transparency, and causal inference considerations into progress reporting and review criteria. While quantitative indicators can provide useful evidence of rigor and impact, excessive reliance on metrics may increase administrative burden for investigators and institutions, incentivize reporting activities over scientific quality, and may overlook meaningful scientific contributions that are not easily quantified. To minimize burden, NIH should prioritize measures that can be derived from existing grant reports, publications, and public data repositories rather than creating new reporting requirements. Quantitative indicators should be complemented by qualitative assessments, including investigator narratives describing methodological innovations, contributions to community standards, advances in

causal understanding, efforts to improve research transparency, and the translation of research findings into practice. Such an approach would better capture meaningful scientific advances while preserving flexibility across disciplines. Potential benefits include greater confidence in scientific findings, stronger evidence for decision-making, more efficient use of research resources, and enhanced public trust. However, excessive emphasis on replication, causal attribution, or resource-intensive validation requirements could discourage innovative or exploratory work and disproportionately burden early-career investigators and smaller institutions with limited administrative personnel and support infrastructure. Expectations should therefore be adapted to disciplinary norms and emphasize transparency, methodological rigor, sound causal reasoning, and meaningful scientific contribution rather than uniform replication requirements or metric-driven evaluation.

2. Data, Software, and Model Sharing: Washington State University supports expanded recognition of data, software, and model sharing as valuable scientific outputs that accelerate discovery, enhance transparency, improve reproducibility, and increase the return on public research investments. Broad access to high-quality datasets, software tools, and computational models enables researchers to validate findings, conduct secondary analyses, develop new hypotheses, leverage existing data for novel applications, and avoid unnecessary duplication of effort. Data sharing can also facilitate interdisciplinary collaboration, support workforce development, improve research efficiency, and accelerate the translation of scientific discoveries into clinical, public health, and community benefits. To realize these outcomes, NIH should continue investing in infrastructure and tools that make data collection, curation, storage, preservation, and sharing easier for researchers. Effective data-sharing policies depend on systems that reduce administrative burden while ensuring research outputs remain accessible, reusable, interoperable, and discoverable by the broader scientific community. Researchers are more likely to participate in data-sharing efforts when repositories, standards, and submission processes are user-friendly, sustainable, and supported through appropriate training, technical assistance, and dedicated funding for data stewardship activities.

The value of data sharing, however, depends not simply on whether data are deposited in a repository, but on the quality, usability, and reusability of the shared resources. Ensuring data quality is therefore essential to realizing the full benefits of data sharing. NIH should encourage the adoption of FAIR (Findable, Accessible, Interoperable, and Reusable) data principles, community-developed data and metadata standards, comprehensive data dictionaries, and clear documentation that enable other researchers to understand and reuse shared datasets. Quality assurance could be further supported through repository-based validation checks, quality control procedures, version control systems, provenance tracking, and the use of certified repositories that provide quality review and long-term preservation. NIH could also encourage independent review of datasets during peer review or repository submission processes to ensure completeness, accuracy, and usability. Because high-quality data sharing requires specialized expertise, continued investment in professional data managers, curators, informatics support, and researcher training in data management and quality assurance practices is essential.

Measurable indicators could include deposition of FAIR-compliant datasets, compliance with NIH Data Management and Sharing requirements, use of persistent identifiers and interoperable metadata, dataset citations and downloads, software adoption metrics, evidence of successful dataset reuse, and demonstrations that shared resources have enabled new collaborations, publications, discoveries, or applications. Assessments should also consider indicators of data completeness, documentation quality,

adherence to community standards, reproducibility, and successful reuse by other researchers, rather than relying solely on measures of dataset volume or repository deposits. NIH could further encourage these activities by recognizing datasets, software tools, workflows, computational models, and curated data resources as distinct research products in grant applications, progress reports, and promotion processes; providing supplemental funding for data curation, maintenance, and stewardship; and recognizing investigators who develop widely used community resources. Community-governed data-sharing trust models may provide additional mechanisms for balancing collaboration, stewardship, accountability, and appropriate protections for sensitive data.

The benefits of these approaches include increased data reuse, accelerated validation of findings, more efficient use of research resources, stronger collaboration across institutions, improved reproducibility, and broader dissemination of scientific knowledge. Potential unintended consequences include incentives for quantity over quality, increased burdens associated with maintaining shared resources, and challenges related to privacy, consent, and the sharing of sensitive human participant data. Flexibility will be required to accommodate disciplinary differences and ensure that early-career researchers receive meaningful credit for creating and maintaining high-quality shared resources regardless of traditional publication volume. By emphasizing data quality, stewardship, and meaningful reuse alongside accessibility, NIH can encourage the sharing of well-curated, reusable datasets while minimizing incentives that prioritize quantity over scientific value.

3. Training and Mentorship: Washington State University recommends that training and mentorship be recognized as critical scientific contributions that support the long-term strength, sustainability, and diversity of the biomedical research workforce. Effective evaluation should include both leading indicators, such as mentoring engagement, completion of individual development plans, participation in professional development activities, and mentor training, and lagging indicators, including trainee retention, graduation rates, career advancement, workforce placement, research productivity, success in obtaining independent funding, contributions to publications and shared research resources, development of interdisciplinary collaborations, participation in team science, and translation of research into clinical, public health, community, or policy outcomes. Because many important outcomes of training and mentorship are not readily captured through quantitative metrics alone, NIH should also incorporate qualitative assessments. Particularly valuable measures could include confidential trainee and alumni feedback, mentoring effectiveness assessments, evidence of leadership development, case studies demonstrating career progression, examples of successful sponsorship and networking, contributions to creating inclusive and supportive research environments, and narratives describing how mentoring has influenced scientific development, career decisions, collaboration, and professional growth. Standardized and confidential mentoring assessments, including exit surveys, could provide additional evidence of mentoring quality while minimizing reporting burden. Benefits of recognizing training and mentorship contributions include stronger workforce development, improved trainee retention, enhanced research culture, and more sustainable scientific careers. However, overreliance on quantitative outcomes may disadvantage mentors working with populations facing structural barriers or in disciplines with longer training and career timelines. NIH should therefore account for career stage, institutional context, and disciplinary variation when evaluating mentoring impact and adopt a balanced approach that integrates both quantitative and qualitative evidence.

4. Collaboration: Washington State University encourages NIH to develop mechanisms that recognize meaningful contributions to collaborative, team-based, interdisciplinary, and community-engaged biomedical research rather than relying primarily on conventional authorship metrics. As many of today's complex biomedical challenges require expertise spanning multiple disciplines, sectors, and stakeholder groups, assessment frameworks should reflect the increasingly collaborative nature of scientific discovery. At the same time, the quality, depth, and integration of collaboration should be more highly valued than the number of collaborators involved, because increased team size does not necessarily equate to increased scientific impact.

Potential quantitative indicators include documented individual contributions through standardized contributor role reporting systems; participation in multi-investigator, multi-institutional, and cross-sector collaborations; the number and diversity of disciplines represented on research teams; cross-disciplinary publications; sustained partnerships; development of shared datasets, tools, methods, software, and research infrastructure; and evidence that interdisciplinary approaches have generated novel research directions, discoveries, or applications. Additional indicators could include achievement of team-specific project goals, establishment of new collaborations, and community participation in research activities.

Because the value of collaborative and interdisciplinary research is not fully captured by quantitative measures alone, NIH should also incorporate qualitative assessments. Useful indicators could include investigator and partner narratives describing how diverse expertise contributed to scientific advances, examples of successful integration of different methodologies or perspectives, evidence of collaboration across traditionally separate disciplines, stakeholder and community feedback, and case studies demonstrating how interdisciplinary approaches improved research relevance, quality, translation, or societal benefit. NIH should also recognize contributions that may not be adequately reflected through authorship or publication metrics, including the development of community partnerships, stakeholder engagement activities, clinical trial recruitment and retention efforts, shared research infrastructure, and other activities that enable successful team science. NIH could support these efforts by incorporating contributor statements into reporting processes and encouraging the use of collaborative impact portfolios that capture diverse forms of participation and scientific contribution.

Such approaches would better reflect the realities of modern biomedical research, promote interdisciplinary problem solving, strengthen community engagement, and recognize expertise that may otherwise be overlooked in traditional assessment systems. Potential benefits include increased innovation, stronger scientific rigor, accelerated translation of discoveries, and improved capacity to address complex biomedical and public health challenges. To minimize administrative burden, NIH should rely whenever possible on information already available through grant applications, publications, progress reports, and publicly available research outputs rather than creating new reporting requirements. Evaluation frameworks should also provide sufficient flexibility to account for disciplinary and institutional differences while maintaining transparency and accountability in the assessment of individual and team contributions.

5. Entrepreneurship and Translation: Washington State University encourages NIH to recognize innovation and entrepreneurship as important pathways through which biomedical research generates public benefit and advances the agency's mission of improving health. While publications and citations

remain important indicators of scholarly activity, they do not fully capture the translational, clinical, economic, and societal impacts of scientific discovery. NIH should therefore recognize a broad range of innovation-related outputs, including patents, licenses, startup companies, software tools, diagnostics, therapeutics, medical devices, implementation strategies, and other technologies that advance research or improve health outcomes. Potential indicators could include invention disclosures, patent and licensing activity, startup formation, participation in and outcomes from Small Business Innovation Research and Small Business Technology Transfer programs, follow-on investment, public-private partnerships, technology adoption, and demonstrated impacts on healthcare practice, public health, or economic development.

Assessment frameworks should also recognize key translational and regulatory milestones that mark progress along the pathway from discovery to application, including Investigational New Drug applications, Investigational Device Exemption filings, Federal Drug Administration submissions and approvals, advancement through clinical trial phases, development of clinical guidelines, and implementation of evidence-based interventions. Because innovation often follows a lengthy and non-linear trajectory, NIH should consider measures of long-term impact, such as sustained adoption of technologies or interventions, downstream improvements in health outcomes, continued commercial development, market penetration, follow-on scientific advances enabled by the innovation, and enduring contributions to research infrastructure, public health practice, and economic growth.

Economic indicators can provide valuable evidence of the broader return on public research investments and may include follow-on federal, nonprofit, or private-sector funding; licensing activity and revenue; startup company sustainability; job creation and workforce development; healthcare cost savings or efficiency gains; technology adoption; manufacturing activity; and economic activity generated within local or regional innovation ecosystems. However, economic measures should complement, rather than replace, assessments of scientific quality, innovation, and public health benefits.

To ensure fairness, NIH should evaluate innovation and entrepreneurial impact within the context of institutional resources, disciplinary norms, and career stage rather than applying uniform expectations across the biomedical research enterprise. Smaller and rural institutions may have more limited access to technology transfer infrastructure, commercialization support, industry partnerships, venture capital networks, and regulatory expertise, which can affect their ability to translate discoveries into traditional entrepreneurial outcomes despite producing highly impactful research. Similarly, pathways to innovation vary substantially across disciplines, with some fields generating patents, licenses, and commercial products, while others create impact through advances in scientific knowledge, clinical practice, public health, policy, or community outcomes. Early-career investigators may also have fewer opportunities to demonstrate long-term innovation impacts because translational and commercialization outcomes often require many years to mature. NIH should therefore assess innovation relative to opportunity and stage of development and recognize a broad range of translational, scientific, societal, and economic contributions. Such an approach would preserve incentives for innovation across diverse institutional settings, disciplines, and career stages.

Given the diverse pathways through which innovation creates value, quantitative indicators should be complemented by qualitative assessments, including case studies, investigator narratives, peer review,

and evidence of contributions to innovation ecosystems, entrepreneurial mentorship, workforce development, and cross-sector partnerships. A balanced approach would encourage translation and entrepreneurship while recognizing the many ways federally funded research produces lasting scientific, health, societal, and economic benefits.

6. Foundational Scientific Exploration: Washington State University strongly supports NIH's continued investment in foundational scientific exploration, including high-risk, high-reward research that may not generate immediate results but has the potential to produce transformative advances. NIH has long demonstrated its commitment to this area through programs such as the High-Risk, High-Reward Research Program, Pioneer Awards, New Innovator Awards, Transformative Research Awards, and other funding mechanisms designed to support bold, creative, and unconventional ideas. Because paradigm-shifting discoveries often emerge from ambitious scientific questions, novel approaches, and investigations whose outcomes are inherently uncertain, NIH should ensure that foundational and exploratory research remains a visible and valued component of the broader biomedical research enterprise.

Indicators of impact should extend beyond traditional measures of productivity and continue to emphasize novelty, originality, and scientific creativity. Additional indicators could include the development of new theories, methodologies, or enabling technologies; the establishment of entirely new areas of inquiry; follow-on research stimulated by exploratory projects; and expert assessments of scientific risk, innovation potential, and intellectual contribution. NIH should continue to employ review criteria specifically designed for exploratory research and maintain funding mechanisms that provide investigators with the flexibility to pursue ambitious and unconventional ideas, including milestone-based awards, pilot and proof-of-concept programs, and longer-term funding opportunities that recognize the extended timelines often required for transformative discoveries.

Because the impacts of foundational research frequently emerge over years or decades, evaluation frameworks should emphasize long-term influence rather than short-term productivity alone. Quantitative and qualitative measures could include the development of new scientific fields, theories, methods, datasets, software tools, or research platforms; follow-on funding and research activity enabled by an initial discovery; downstream clinical, public health, or technological applications; and expert assessments or case studies documenting how exploratory research influenced subsequent advances. NIH could further embed and sustain high-risk, high-reward research within the academic enterprise by encouraging institutional recognition of such contributions in promotion, tenure, and annual evaluation processes; supporting interdisciplinary collaborations that foster innovative thinking; and providing career-stage protections that allow investigators, particularly early-career researchers, to pursue ambitious research directions without undue concern over short-term publication or funding outcomes. NIH should also promote a research culture that recognizes well-executed studies with negative or inconclusive results as valuable scientific contributions when they advance understanding, refine hypotheses, or open new avenues for investigation.

The principal benefit of this approach is the promotion of creativity, innovation, and breakthrough discoveries that expand the boundaries of knowledge and create opportunities for future scientific, clinical, and societal advances. Potential challenges include the difficulty of measuring impact over shorter timescales and distinguishing thoughtful scientific risk-taking from poorly conceived projects.

Evaluation frameworks should therefore account for the extended timeline often associated with foundational discovery and ensure that investigators and institutions are appropriately recognized and rewarded for pursuing innovative research with the potential to generate substantial long-term scientific and public benefit.

7. Public Impact: Washington State University believes assessments of the public impact of biomedical research should focus on demonstrable contributions to health, society, and public well-being. While publications and citations provide evidence of scholarly productivity, they do not fully capture the many ways research benefits society. Biomedical research creates public value through improvements in health outcomes, clinical practice, healthcare delivery, economic growth, workforce development, public trust in science, accessibility of healthcare and scientific knowledge, and other societal benefits. Researchers also make important contributions through community-engaged research, clinical trial recruitment and retention, stakeholder engagement, mentorship, development of shared research resources, and dissemination of evidence to practitioners, policymakers, patients, and the public.

Evaluation frameworks should therefore incorporate a broad portfolio of indicators that reflect these diverse pathways to impact. Potential measures include contributions to clinical practice guidelines, public health recommendations, healthcare quality improvements, disease prevention efforts, policy development, patient and community engagement, adoption of research-informed practices, workforce development, economic impacts, and evidence of increased public trust and confidence in science. Assessments may also consider longer-term outcomes such as improvements in population health, reductions in disease burden, healthcare cost savings, job creation, technology adoption, and economic activity resulting from research translation and innovation.

Because many public benefits emerge over extended timeframes and cannot easily be attributed to a single project, NIH should employ mixed-method assessment approaches that combine quantitative indicators with qualitative evidence. Implementation could include standardized impact narratives within existing reporting processes, periodic case studies documenting pathways from discovery to application, stakeholder and community feedback, expert review, and the use of evidence already captured through publications, clinical guidelines, policy documents, and public data sources. NIH may also consider periodic retrospective assessments to evaluate the long-term influence of research investments and document how discoveries contribute to health, policy, economic, and societal outcomes over time.

Because no single metric can adequately capture the full public impact of biomedical research, NIH should adopt assessment approaches that integrate multiple forms of evidence. A mixed-method approach offers several benefits, including a more comprehensive assessment of research value, recognition of multiple pathways to impact, reduced reliance on any single metric, and stronger alignment with NIH's mission to improve health and reduce disease burden. However, NIH should also consider potential unintended consequences. Excessive reporting requirements could increase administrative burden, while overly prescriptive impact frameworks could disadvantage foundational research, early-career investigators, and projects whose benefits emerge only over longer time horizons. Attribution may also be challenging when societal outcomes result from the cumulative contributions of multiple investigators, institutions, and funding sources. Flexible impact assessment frameworks that rely primarily on existing data sources can help balance accountability, feasibility, and fairness across disciplines, institutions, and career stages.

8. Other Areas: Finally, as NIH considers new approaches for assessing and incentivizing scientific impact, it is essential that evaluation frameworks reflect the full breadth of contributions that advance biomedical research and improve human health. The considerations outlined above underscore the need for a balanced, flexible, and context-sensitive approach to impact assessment that recognizes the diverse pathways through which research generates scientific, clinical, economic, and societal value. Washington State University (WSU) further emphasizes that expert peer review should remain a central component of any assessment framework and should be integrated with both quantitative and qualitative indicators. Reviewers should possess the scientific expertise and contextual understanding necessary to evaluate the significance of research contributions, including their methodologies, hypotheses, and intended outcomes. This is particularly important for interdisciplinary, foundational, community-engaged, and emerging areas of research, where conventional metrics may not adequately capture scientific significance, long-term influence, or future potential. No single metric can fully reflect the value of scientific contributions, and excessive reliance on any one measure risks creating unintended incentives, narrowing research priorities, and overlooking important dimensions of research excellence.

Accordingly, Washington State University recommends that NIH adopt a comprehensive, multi-indicator framework for assessing scientific impact that recognizes contributions across multiple dimensions, including rigor and reproducibility, data and software sharing, mentorship and workforce development, collaboration and team science, entrepreneurship and translation, foundational scientific exploration, and broader public impact. Metrics should inform, rather than replace, expert judgment and should recognize the many ways biomedical research advances knowledge and benefits society. Evaluation systems should remain adaptable to differences in discipline, institution type, career stage, and research context, while avoiding overly prescriptive measures that may discourage innovative, high-risk, exploratory, or community-focused research. NIH should also carefully monitor implementation to identify and mitigate unintended consequences, including increased administrative burden, incentives that favor easily measurable activities over meaningful scientific contributions, disadvantages for certain disciplines or institution types, and disincentives for high-risk or long-term research. A balanced framework that integrates multiple forms of evidence, relies on existing data sources whenever possible, and incorporates ongoing evaluation and refinement would provide a more comprehensive and fair assessment of scientific impact, encourage diverse pathways to success, and better align researcher incentives with NIH's mission to advance rigorous, collaborative, transparent, innovative, and publicly beneficial biomedical research.

Thank you for the opportunity to provide these comments. Washington State University appreciates NIH's leadership in developing a more comprehensive approach to measuring and rewarding scientific impact and looks forward to continued engagement on these important issues.

Office of Science Policy
National Institutes of Health
6705 Rockledge Drive, Suite 630
Bethesda, Maryland 20892

Re: Request for Information on Measuring and Rewarding Scientific Impact (NOT-OD-26-087)

Submitted online at https://osp.od.nih.gov/comment-form-measuring-and-rewarding-scientific-impact/.

On behalf of Washington State University (WSU), I appreciate the opportunity to provide the following comments to the NIH Request for Information (RFI) on measuring and rewarding scientific impact (NOT-OD-26-087).

WSU acknowledges NIH's efforts to identify and incentivize measurable indicators of scientific impact that more accurately reflect the collaborative, rigorous, innovative, and mission-driven nature of modern biomedical research. NIH should adopt a balanced and flexible framework that recognizes the full range of scientific contributions while remaining feasible across career stages, disciplines, and institution types. Because biomedical research encompasses a broad spectrum of activities, including foundational discovery science, translational research, clinical research, implementation science, and community-engaged scholarship, definitions of scientific impact should remain adaptable.

As a land-grant institution, WSU recognizes that impactful research often extends beyond traditional academic outputs to include meaningful contributions to communities, industries, healthcare systems, and public well-being. Evaluation frameworks should also acknowledge that scientifically rigorous research can be impactful regardless of whether findings are positive, negative, or null, as null results play a critical role in refining hypotheses, reducing duplication of effort, and strengthening the overall evidence base. While quantitative indicators can provide useful and comparable measures of impact, overreliance on metrics may create unintended administrative burdens for researchers and institutions and may incentivize behaviors that prioritize measurable outputs over meaningful scientific contributions. NIH should therefore incorporate qualitative measures alongside quantitative indicators, allowing investigators to demonstrate impact through narratives, case studies, mentorship, team science, community engagement, policy influence, and other contributions that may not be fully captured through numerical metrics alone. A balanced framework that integrates quantitative and qualitative evidence will better reflect the diverse pathways through which biomedical research advances science and benefits society.

NIH has specifically requested input on measurable indicators, implementation approaches, benefits, unintended consequences, and feasibility considerations, and our comments below are offered within that context.

Rigor and Reproducibility

Washington State University believes rigor and reproducibility should be recognized as fundamental scientific contributions rather than solely as compliance requirements. For biomedical research assessments, NIH could consider adapting industry principles such as the methodologies of Gage Repeatability and Reproducibility, which evaluate measurement consistency and identify sources of variation. Potential biomedical science indicators could include the percentage of publications with publicly available protocols, analysis plans, data, and code; use of preregistration, blinded analyses, validation cohorts, and replication studies; documentation of assay performance and measurement variation; and dissemination of well-designed studies that yield positive, negative, or null findings. Importantly, null findings are a valuable scientific outcome that can refine hypotheses, prevent duplication of effort, and strengthen the overall evidence base and should therefore be recognized as meaningful contributions to scientific progress.

NIH should also recognize contributions to causal research, defined as research that improves understanding of whether and how specific mechanisms, interventions, exposures, programs, practices, or policies influence health-related outcomes. Because causal questions arise across the biomedical research continuum, measures of causal research should be appropriate to disciplinary context and study design. Indicators could include the use of rigorous causal inference approaches, such as randomized controlled trials, natural experiments, quasi-experimental designs, instrumental variable analyses, difference-in-differences methods, regression discontinuity designs, propensity score methods, mediation analyses, longitudinal studies, mechanistic investigations, and the use of causal frameworks. Additional measures could include replication of causal findings across populations or settings and demonstrated influence on clinical practice, public health interventions, or policy decisions.

NIH could support dedicated replication funding opportunities, establish reproducibility networks, and incorporate rigor, transparency, and causal inference considerations into progress reporting and review criteria. While quantitative indicators can provide useful evidence of rigor and impact, excessive reliance on metrics may increase administrative burden for investigators and institutions, incentivize reporting activities over scientific quality, and may overlook meaningful scientific contributions that are not easily quantified. To minimize burden, NIH should prioritize measures that can be derived from existing grant reports, publications, and public data repositories rather than creating new reporting requirements. Quantitative indicators should be complemented by qualitative assessments, including investigator narratives describing methodological innovations, contributions to community standards, advances in causal understanding, efforts to improve research transparency, and the translation of research findings into practice. Such an approach would better capture meaningful scientific advances while preserving flexibility across disciplines. Potential benefits include greater confidence in scientific findings, stronger evidence for decision-making, more efficient use of research resources, and enhanced public trust. However, excessive emphasis on replication, causal attribution, or resource-intensive validation requirements could discourage innovative or exploratory work and disproportionately burden early-career investigators and smaller institutions with limited administrative personnel and support infrastructure. Expectations should therefore be adapted to disciplinary norms and emphasize transparency, methodological rigor, sound causal reasoning, and meaningful scientific contribution rather than uniform replication requirements or metric-driven evaluation.

Data, Software, and Model Sharing

Washington State University supports expanded recognition of data, software, and model sharing as valuable scientific outputs that accelerate discovery, enhance transparency, improve reproducibility, and increase the return on public research investments. Broad access to high-quality datasets, software tools, and computational models enables researchers to validate findings, conduct secondary analyses, develop new hypotheses, leverage existing data for novel applications, and avoid unnecessary duplication of effort. Data sharing can also facilitate interdisciplinary collaboration, support workforce development, improve research efficiency, and accelerate the translation of scientific discoveries into clinical, public health, and community benefits. To realize these outcomes, NIH should continue investing in infrastructure and tools that make data collection, curation, storage, preservation, and sharing easier for researchers. Effective data-sharing policies depend on systems that reduce administrative burden while ensuring research outputs remain accessible, reusable, interoperable, and discoverable by the broader scientific community. Researchers are more likely to participate in data-sharing efforts when repositories, standards, and submission processes are user-friendly, sustainable, and supported through appropriate training, technical assistance, and dedicated funding for data stewardship activities.

The value of data sharing, however, depends not simply on whether data are deposited in a repository, but on the quality, usability, and reusability of the shared resources. Ensuring data quality is therefore essential to realizing the full benefits of data sharing. NIH should encourage the adoption of FAIR (Findable, Accessible, Interoperable, and Reusable) data principles, community-developed data and metadata standards, comprehensive data dictionaries, and clear documentation that enable other researchers to understand and reuse shared datasets. Quality assurance could be further supported through repository-based validation checks, quality control procedures, version control systems, provenance tracking, and the use of certified repositories that provide quality review and long-term preservation. NIH could also encourage independent review of datasets during peer review or repository submission processes to ensure completeness, accuracy, and usability. Because high-quality data sharing requires specialized expertise, continued investment in professional data managers, curators, informatics support, and researcher training in data management and quality assurance practices is essential.

Measurable indicators could include deposition of FAIR-compliant datasets, compliance with NIH Data Management and Sharing requirements, use of persistent identifiers and interoperable metadata, dataset citations and downloads, software adoption metrics, evidence of successful dataset reuse, and demonstrations that shared resources have enabled new collaborations, publications, discoveries, or applications. Assessments should also consider indicators of data completeness, documentation quality, adherence to community standards, reproducibility, and successful reuse by other researchers, rather than relying solely on measures of dataset volume or repository deposits. NIH could further encourage these activities by recognizing datasets, software tools, workflows, computational models, and curated data resources as distinct research products in grant applications, progress reports, and promotion processes; providing supplemental funding for data curation, maintenance, and stewardship; and recognizing investigators who develop widely used community resources. Community-governed data-sharing trust models may provide additional mechanisms for balancing collaboration, stewardship, accountability, and appropriate protections for sensitive data.

The benefits of these approaches include increased data reuse, accelerated validation of findings, more efficient use of research resources, stronger collaboration across institutions, improved reproducibility, and broader dissemination of scientific knowledge. Potential unintended

consequences include incentives for quantity over quality, increased burdens associated with maintaining shared resources, and challenges related to privacy, consent, and the sharing of sensitive human participant data. Flexibility will be required to accommodate disciplinary differences and ensure that early-career researchers receive meaningful credit for creating and maintaining high-quality shared resources regardless of traditional publication volume. By emphasizing data quality, stewardship, and meaningful reuse alongside accessibility, NIH can encourage the sharing of well-curated, reusable datasets while minimizing incentives that prioritize quantity over scientific value.

Training and Mentorship

Washington State University recommends that training and mentorship be recognized as critical scientific contributions that support the long-term strength, sustainability, and diversity of the biomedical research workforce. Effective evaluation should include both leading indicators, such as mentoring engagement, completion of individual development plans, participation in professional development activities, and mentor training, and lagging indicators, including trainee retention, graduation rates, career advancement, workforce placement, research productivity, success in obtaining independent funding, contributions to publications and shared research resources, development of interdisciplinary collaborations, participation in team science, and translation of research into clinical, public health, community, or policy outcomes. Because many important outcomes of training and mentorship are not readily captured through quantitative metrics alone, NIH should also incorporate qualitative assessments. Particularly valuable measures could include confidential trainee and alumni feedback, mentoring effectiveness assessments, evidence of leadership development, case studies demonstrating career progression, examples of successful sponsorship and networking, contributions to creating inclusive and supportive research environments, and narratives describing how mentoring has influenced scientific development, career decisions, collaboration, and professional growth. Standardized and confidential mentoring assessments, including exit surveys, could provide additional evidence of mentoring quality while minimizing reporting burden. Benefits of recognizing training and mentorship contributions include stronger workforce development, improved trainee retention, enhanced research culture, and more sustainable scientific careers. However, overreliance on quantitative outcomes may disadvantage mentors working with populations facing structural barriers or in disciplines with longer training and career timelines. NIH should therefore account for career stage, institutional context, and disciplinary variation when evaluating mentoring impact and adopt a balanced approach that integrates both quantitative and qualitative evidence.

Collaboration

Washington State University encourages NIH to develop mechanisms that recognize meaningful contributions to collaborative, team-based, interdisciplinary, and community-engaged biomedical research rather than relying primarily on conventional authorship metrics. As many of today's complex biomedical challenges require expertise spanning multiple disciplines, sectors, and stakeholder groups, assessment frameworks should reflect the increasingly collaborative nature of scientific discovery. At the same time, the quality, depth, and integration of collaboration should be more highly valued than the number of collaborators involved, because increased team size does not necessarily equate to increased scientific impact.

Potential quantitative indicators include documented individual contributions through standardized contributor role reporting systems; participation in multi-investigator, multi-institutional, and cross-sector collaborations; the number and diversity of disciplines represented on research teams; cross-disciplinary publications; sustained partnerships; development of shared datasets, tools, methods,

software, and research infrastructure; and evidence that interdisciplinary approaches have generated novel research directions, discoveries, or applications. Additional indicators could include achievement of team-specific project goals, establishment of new collaborations, and community participation in research activities.

Because the value of collaborative and interdisciplinary research is not fully captured by quantitative measures alone, NIH should also incorporate qualitative assessments. Useful indicators could include investigator and partner narratives describing how diverse expertise contributed to scientific advances, examples of successful integration of different methodologies or perspectives, evidence of collaboration across traditionally separate disciplines, stakeholder and community feedback, and case studies demonstrating how interdisciplinary approaches improved research relevance, quality, translation, or societal benefit. NIH should also recognize contributions that may not be adequately reflected through authorship or publication metrics, including the development of community partnerships, stakeholder engagement activities, clinical trial recruitment and retention efforts, shared research infrastructure, and other activities that enable successful team science. NIH could support these efforts by incorporating contributor statements into reporting processes and encouraging the use of collaborative impact portfolios that capture diverse forms of participation and scientific contribution.

Such approaches would better reflect the realities of modern biomedical research, promote interdisciplinary problem solving, strengthen community engagement, and recognize expertise that may otherwise be overlooked in traditional assessment systems. Potential benefits include increased innovation, stronger scientific rigor, accelerated translation of discoveries, and improved capacity to address complex biomedical and public health challenges. To minimize administrative burden, NIH should rely whenever possible on information already available through grant applications, publications, progress reports, and publicly available research outputs rather than creating new reporting requirements. Evaluation frameworks should also provide sufficient flexibility to account for disciplinary and institutional differences while maintaining transparency and accountability in the assessment of individual and team contributions.

Entrepreneurship and Translation

Washington State University encourages NIH to recognize innovation and entrepreneurship as important pathways through which biomedical research generates public benefit and advances the agency's mission of improving health. While publications and citations remain important indicators of scholarly activity, they do not fully capture the translational, clinical, economic, and societal impacts of scientific discovery. NIH should therefore recognize a broad range of innovation-related outputs, including patents, licenses, startup companies, software tools, diagnostics, therapeutics, medical devices, implementation strategies, and other technologies that advance research or improve health outcomes. Potential indicators could include invention disclosures, patent and licensing activity, startup formation, participation in and outcomes from Small Business Innovation Research and Small Business Technology Transfer programs, follow-on investment, public-private partnerships, technology adoption, and demonstrated impacts on healthcare practice, public health, or economic development.

Assessment frameworks should also recognize key translational and regulatory milestones that mark progress along the pathway from discovery to application, including Investigational New Drug applications, Investigational Device Exemption filings, Federal Drug Administration submissions and approvals, advancement through clinical trial phases, development of clinical guidelines, and implementation of evidence-based interventions. Because innovation often follows a lengthy and

non-linear trajectory, NIH should consider measures of long-term impact, such as sustained adoption of technologies or interventions, downstream improvements in health outcomes, continued commercial development, market penetration, follow-on scientific advances enabled by the innovation, and enduring contributions to research infrastructure, public health practice, and economic growth.

Economic indicators can provide valuable evidence of the broader return on public research investments and may include follow-on federal, nonprofit, or private-sector funding; licensing activity and revenue; startup company sustainability; job creation and workforce development; healthcare cost savings or efficiency gains; technology adoption; manufacturing activity; and economic activity generated within local or regional innovation ecosystems. However, economic measures should complement, rather than replace, assessments of scientific quality, innovation, and public health benefits.

To ensure fairness, NIH should evaluate innovation and entrepreneurial impact within the context of institutional resources, disciplinary norms, and career stage rather than applying uniform expectations across the biomedical research enterprise. Smaller and rural institutions may have more limited access to technology transfer infrastructure, commercialization support, industry partnerships, venture capital networks, and regulatory expertise, which can affect their ability to translate discoveries into traditional entrepreneurial outcomes despite producing highly impactful research. Similarly, pathways to innovation vary substantially across disciplines, with some fields generating patents, licenses, and commercial products, while others create impact through advances in scientific knowledge, clinical practice, public health, policy, or community outcomes. Early-career investigators may also have fewer opportunities to demonstrate long-term innovation impacts because translational and commercialization outcomes often require many years to mature. NIH should therefore assess innovation relative to opportunity and stage of development and recognize a broad range of translational, scientific, societal, and economic contributions. Such an approach would preserve incentives for innovation across diverse institutional settings, disciplines, and career stages.

Given the diverse pathways through which innovation creates value, quantitative indicators should be complemented by qualitative assessments, including case studies, investigator narratives, peer review, and evidence of contributions to innovation ecosystems, entrepreneurial mentorship, workforce development, and cross-sector partnerships. A balanced approach would encourage translation and entrepreneurship while recognizing the many ways federally funded research produces lasting scientific, health, societal, and economic benefits.

Foundational Scientific Exploration

Washington State University strongly supports NIH's continued investment in foundational scientific exploration, including high-risk, high-reward research that may not generate immediate results but has the potential to produce transformative advances. NIH has long demonstrated its commitment to this area through programs such as the High-Risk, High-Reward Research Program, Pioneer Awards, New Innovator Awards, Transformative Research Awards, and other funding mechanisms designed to support bold, creative, and unconventional ideas. Because paradigm-shifting discoveries often emerge from ambitious scientific questions, novel approaches, and investigations whose outcomes are inherently uncertain, NIH should ensure that foundational and exploratory research remains a visible and valued component of the broader biomedical research enterprise.

Indicators of impact should extend beyond traditional measures of productivity and continue to emphasize novelty, originality, and scientific creativity. Additional indicators could include the development of new theories, methodologies, or enabling technologies; the establishment of entirely new areas of inquiry; follow-on research stimulated by exploratory projects; and expert assessments of scientific risk, innovation potential, and intellectual contribution. NIH should continue to employ review criteria specifically designed for exploratory research and maintain funding mechanisms that provide investigators with the flexibility to pursue ambitious and unconventional ideas, including milestone-based awards, pilot and proof-of-concept programs, and longer-term funding opportunities that recognize the extended timelines often required for transformative discoveries.

Because the impacts of foundational research frequently emerge over years or decades, evaluation frameworks should emphasize long-term influence rather than short-term productivity alone. Quantitative and qualitative measures could include the development of new scientific fields, theories, methods, datasets, software tools, or research platforms; follow-on funding and research activity enabled by an initial discovery; downstream clinical, public health, or technological applications; and expert assessments or case studies documenting how exploratory research influenced subsequent advances. NIH could further embed and sustain high-risk, high-reward research within the academic enterprise by encouraging institutional recognition of such contributions in promotion, tenure, and annual evaluation processes; supporting interdisciplinary collaborations that foster innovative thinking; and providing career-stage protections that allow investigators, particularly early-career researchers, to pursue ambitious research directions without undue concern over short-term publication or funding outcomes. NIH should also promote a research culture that recognizes well-executed studies with negative or inconclusive results as valuable scientific contributions when they advance understanding, refine hypotheses, or open new avenues for investigation.

The principal benefit of this approach is the promotion of creativity, innovation, and breakthrough discoveries that expand the boundaries of knowledge and create opportunities for future scientific, clinical, and societal advances. Potential challenges include the difficulty of measuring impact over shorter timescales and distinguishing thoughtful scientific risk-taking from poorly conceived projects. Evaluation frameworks should therefore account for the extended timeline often associated with foundational discovery and ensure that investigators and institutions are appropriately recognized and rewarded for pursuing innovative research with the potential to generate substantial long-term scientific and public benefit.

Public Impact

Washington State University believes assessments of the public impact of biomedical research should focus on demonstrable contributions to health, society, and public well-being. While publications and citations provide evidence of scholarly productivity, they do not fully capture the many ways research benefits society. Biomedical research creates public value through improvements in health outcomes, clinical practice, healthcare delivery, economic growth, workforce development, public trust in science, accessibility of healthcare and scientific knowledge, and other societal benefits. Researchers also make important contributions through community-engaged research, clinical trial recruitment and retention, stakeholder engagement, mentorship, development of shared research resources, and dissemination of evidence to practitioners, policymakers, patients, and the public.

Evaluation frameworks should therefore incorporate a broad portfolio of indicators that reflect these diverse pathways to impact. Potential measures include contributions to clinical practice guidelines, public health recommendations, healthcare quality improvements, disease prevention efforts, policy development, patient and community engagement, adoption of research-informed practices, workforce development, economic impacts, and evidence of increased public trust and confidence in science. Assessments may also consider longer-term outcomes such as improvements in population health, reductions in disease burden, healthcare cost savings, job creation, technology adoption, and economic activity resulting from research translation and innovation.

Because many public benefits emerge over extended timeframes and cannot easily be attributed to a single project, NIH should employ mixed-method assessment approaches that combine quantitative indicators with qualitative evidence. Implementation could include standardized impact narratives within existing reporting processes, periodic case studies documenting pathways from discovery to application, stakeholder and community feedback, expert review, and the use of evidence already captured through publications, clinical guidelines, policy documents, and public data sources. NIH may also consider periodic retrospective assessments to evaluate the long-term influence of research investments and document how discoveries contribute to health, policy, economic, and societal outcomes over time.

Because no single metric can adequately capture the full public impact of biomedical research, NIH should adopt assessment approaches that integrate multiple forms of evidence. A mixed-method approach offers several benefits, including a more comprehensive assessment of research value, recognition of multiple pathways to impact, reduced reliance on any single metric, and stronger alignment with NIH's mission to improve health and reduce disease burden. However, NIH should also consider potential unintended consequences. Excessive reporting requirements could increase administrative burden, while overly prescriptive impact frameworks could disadvantage foundational research, early-career investigators, and projects whose benefits emerge only over longer time horizons. Attribution may also be challenging when societal outcomes result from the cumulative contributions of multiple investigators, institutions, and funding sources. Flexible impact assessment frameworks that rely primarily on existing data sources can help balance accountability, feasibility, and fairness across disciplines, institutions, and career stages.
